The tapeworms of the dog and cœnurus of sheep, E. THIERRY (*Jour. Agr. Prat., n. ser., 6 (1903), No. 39, pp. 418, 419*).—A list is presented of tapeworms which infest the dog and notes are given on the life history and other hosts of these species.

Studies on so-called crude carbolic acid with special reference to its use in disinfecting cattle cars, C. FISCHER and F. KOSKE (*Arb. K. Gesundheitsamte, 19 (1903), No. 3, pp. 577–671, figs. 2*).—Experiments in disinfecting cattle cars, especially in destroying bacteria commonly found in such cars, were made with crude carbolic acid of 3 strengths, 25 to 30 per cent, 50 to 60 per cent, and 95 to 100 per cent. The latter form is also known as crude cresol. The experiments also included tests with commercial carbolic acid imported from England, and various mixtures of cresol with sulphuric acid, etc., as well as with Sanatol, Bacillol, Cresolin, Cresapolin, etc.

During these investigations it was found that the ordinary commercial preparations of crude cresol vary considerably in chemical composition, and that the disinfectant action of these preparations is therefore not uniform. Standard cresol only should

be used in the preparation of cresol mixtures and cresol solutions. In gross disinfection of cattle cars it was found that, as a substitute for the prescribed use of a 5 per cent solution of crude carbolic acid, good results were obtained from the use of a 3 per cent aqueous solution of crude cresol and crude sulphuric acid combined in the proportion of 2:1. This solution is easily soluble in water and exercises a pronounced disinfectant action.

A $2\frac{1}{2}$ per cent mixture of crude cresol and sulphuric acid destroyed glanders bacilli within 1 to $1\frac{1}{2}$ minutes, hog cholera bacilli within from 1 to 2 minutes, and *Staphylococcus pyogenes aureus* in from 2 to 3 minutes. The disinfectant power of the other substances mentioned above, all of which were used in a 5 per cent solution, stood in the following order of effectiveness: Crude carbolic acid, Sanatol, Bacillol, Cresolin, and Cresapolin.

The quarantine station at Athenia (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 293-296, pls. 6*).—A general description of the buildings, grounds, and capacity of the quarantine station of the Bureau of Animal Industry at Athenia, N. J.

AGRICULTURAL ENGINEERING.

Report of irrigation investigations for 1902, E. MEAD ET AL. (*U. S. Dept. Agr., Office of Experiment Stations Bul. 133, pp. 266, pls. 12, figs. 16*).—Investigations during 1902 similar to those of previous years (E. S. R., 14, p. 713) are here reported in part. The bulletin contains reports of special agents and observers as follows:

Irrigation in Mountain Water District, Salt Lake County, Utah, by E. R. Morgan; The Use of Water from the Wood Rivers, Idaho, by J. D. Stannard; Irrigation Investigations on Sand Creek, Albany County, Wyo., by B. P. Fleming; Irrigation in Washington, by O. L. Waller; Irrigation Investigations in Montana, 1902, by S. Fortier; Irrigation Systems on Stony Creek, Cal., by W. T. Clarke and C. W. Landis; Irrigation in the Black Hills, S. Dak., by A. B. Crane; Rice Irrigation in Louisiana and Texas, by F. Bond; Third Progress Report on Silt Measurements, by J. C. Nagle; Irrigation Experiments at the Missouri Experiment Station, by H. J. Waters; Irrigation in Wisconsin in 1902, by A. R. Whitson; Irrigation Investigations in New Jersey, 1902, by E. B. Voorhees; and The Use of Pumps for Irrigation in Hawaii, by J. G. Smith.

These reports deal primarily with duty of water in irrigation. That of Mr. Morgan on Jordan River and its tributaries shows the large losses from these streams and discusses means of saving the water now lost, among which is the running of the spring floods onto the lands along the upper reaches of the streams, thus storing the water in the soil. Mr. Stannard's report shows the large losses of water occurring on the Wood Rivers and discusses the advisability of using special structures to prevent these losses. Mr. Fleming's report deals with the use of the water of Sand Creek for the production of forage, and with the effect of the diversion of the water of the stream in Colorado on the supply to Wyoming users. The latter is of special importance because of its bearing on the use of other interstate streams.

Professor Waller's report calls attention especially to the damage being done by excessive irrigation in parts of Washington.

Professor Fortier's report gives a large number of measurements of the duty of water on special crops.

The report on irrigation systems of Stony Creek, Cal., shows especially the profit resulting from irrigation and diversification of crops as opposed to exclusive wheat growing without irrigation, and calls attention to what is being done by farmers in that region in storing storm water. Mr. Crane's report on irrigation in the Black Hills shows that storing storm water is profitable in that region also.

Mr. Bond's second report on irrigation of rice in Louisiana and Texas shows that the demand for water for rice-growing is in many cases outrunning the supply both from streams and from wells.

Professor Nagle reports as a general average of all of his measurements that the Brazos River carries "1.2 per cent of silt by volume at the end of one week's settlement and 0.9 per cent at the end of one year's settlement. He thinks the Brazos fairly represents the streams of the State of Texas."

Professor Waters reports a decided residual benefit to strawberries and asparagus at the Missouri Station from water applied the previous year. Observations at the Wisconsin Station on the residual effect of irrigation in the previous year show that irrigation may result in a decrease in yield the second year if the soil is not manured.

Professor Voorhees' report for 1902 is a study of methods of distributing and applying water. He found that open ditches lost large percentages of the water turned into them. Tarred canvas used as a ditch lining proved very effective and not expensive. Clay thrown in the water and puddled did not do so well. Professor Voorhees also gives the records of wells in several sections of New Jersey, in order to show the possibilities of this source of water supply.

Mr. Smith's report on pumping water in the Hawaiian Islands gives valuable data on the efficiency and cost of operation of various kinds of pumps.

Plans of structures in use on irrigation canals in the United States (*U. S. Dept. Agr., Office of Experiment Stations Bul. 131, pp. 51, pls. 22*).—This is an album of 22 plans of irrigation structures designed by leading irrigation engineers of the United States. The plates were made from drawings exhibited at the Paris Exposition in 1900 and the Buffalo Exposition in 1901.

Storage of water on Cache la Poudre and Big Thompson rivers, C. E. TAIT (*U. S. Dept. Agr., Office of Experiment Stations Bul. 134, pp. 100, pls. 5, figs. 10*).—This bulletin gives details of areas, capacities, and construction of reservoirs in northern Colorado, in the watersheds of the Cache la Poudre and Big Thompson rivers, and the profits from their use.

Storage reservoirs on Stony Creek, California, B. COLE (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 86, pp. 62, pls. 16, figs. 38*).—"The paper treats of the possibilities of reclaiming by irrigation large areas of land in the valley of Stony Creek, a tributary of the Sacramento River, and on the west side of the Sacramento Valley, which have been cultivated by dry farming, but on which irrigation may apparently be introduced with much advantage."

From the investigations reported the conclusion is drawn that "several commercially valuable reservoir sites exist in the water shed of Stony Creek and its tributaries. The annual run-off is sufficient to fill these reservoirs in years of average rainfall. In the case of the Mill Site reservoir the supply is many times greater than the capacity of the reservoir. There would probably not be sufficient run-off to fill the Briscoe Creek and Little Stony Creek reservoirs in years of very low rainfall. . . . The conditions are favorable for long life of the reservoirs on account of the small amount of silt and débris carried by the streams."

Report of progress of stream measurements for the calendar year 1902, F. H. NEWELL (*Water Supply and Irrig. Papers, U. S. Geol. Survey, Nos. 82, pp. 199; 83, pp. 304, figs. 7; 84, pp. 200, figs. 2; 85, pp. 250, figs. 2*).—These 4 papers give the results of hydrographic measurements made during the year 1902, the first 2 covering the territory east of the Mississippi and the last 2 that west of the Mississippi. "These papers contain, for the various gauging stations, the original data as collected, and the results obtained from the discussion of these data, also such other information as is of interest in hydrographic studies."

The agricultural importance of collecting and utilizing the waters of mountain areas, F. W. TOUSSAINT (*Fühling's Landw. Ztg., 52 (1903), No. 19, pp. 689–695*).—A general discussion of this subject.

Drainage and the agricultural sanitation of soils, L. FAURE (*Drainage et assainissement agricole des terres. Paris: Ch. Béranger, 1903, pp. XIV + 279, figs. 120, dgms. 4*).—Under the head of drainage the removal of water by means of tile drains

is considered, and under agricultural sanitation the use of open and covered ditches for this purpose. Principles and practical methods are given full treatment, especially in their engineering aspects.

Drought, drainage, and subirrigation, W. CLATWORTHY (*Queensland Agr. Jour., 13 (1903), No. 2, pp. 133–137*).—A brief account of experiments in which there was used "for the purpose of subirrigation and drainage combined a 2-in. percolating, porous pipe made in 18-in. lengths, which served admirably the double purpose of irrigation and drainage for small areas. . . . The number of pipes per acre, laid 15 ft. apart, was about 2,000, the cost of which was 10s. per 100 ft. at the factory, making the total cost for pipes alone £15 ($75) per acre."

The value of water power, L. KOCH (*Fühling's Landw. Ztg., 52 (1903), No. 19, pp. 712–715*).—A brief discussion of the relative cost of steam and water power.

Roller gins for cotton, F. MAIN (*Jour. Agr. Prat., n. ser., 6 (1903), No. 40, pp. 443–447, figs. 5*).—Several improved roller gins are described.

Time and cost of making earthworks, M. RINGELMANN (*Jour. Agr. Prat., n. ser., 6 (1903), No. 40, pp. 447–450*).—Simple methods of making estimates of these factors based on an examination of the character of the soil.

On the reduction of nitrates by sewage, LETTS, R. F. BLAKE, and J. S. TOTTON (*Chem. News, 88 (1903), No. 2289, pp. 182, 183*).—A brief account is given of a study of this subject with reference to the bacterial purification of sewage.

The misuse of physics by biologists and engineers, W. S. FRANKLIN (*Science, n. ser., 18 (1903), No. 464, pp. 641–657, figs. 2*).—In this paper the author argues that there is a sharp line of demarcation "between systematic physics and what we may call statistical physics . . . suggesting in a general way the error of the indiscriminate application of the philosophy of the exact sciences in the study of natural phenomena." The author's position in brief is "that the idea of quantitative relationships and the idea of one-to-one correspondence in general, as these ideas are known in physics, are inapplicable and necessarily fruitless in such fields as physical psychology and meteorology."

MISCELLANEOUS.

Twenty-sixth Annual Report of Connecticut State Station, 1902 (*Connecticut State Sta. Rpt. 1902, pp. XV*).—These pages accompany part 4 of the report and contain the organization list of the station, an announcement concerning the work of the station, a brief report of the board of control, and a financial statement for the year ended September 30, 1902.

Sixteenth Annual Report of Nebraska Station, 1902 (*Nebraska Sta. Rpt. 1902, pp. 129*).—This includes the organization list of the station, a review of station work during the year, a financial statement for the fiscal year ended June 30, 1902, and 3 articles abstracted elsewhere.

Annual report for the year 1902 of the Agricultural Experiment Station of Ploti (*Rap. An. Sta. Expt. Agron. Ploty, 8 (1902), pp. XXII + 151, pls. 2, figs. 2, charts 5*).—Detailed reports in the Russian language, with summaries in French, covering the work of the station during the year on meteorology (see p. 454), in the chemical laboratory (see p. 456), and in the experimental field and vineyard (see p. 463). The work during 1902 was mainly a continuation of that of previous years (E. S. R., 14, p. 340).

Nineteenth Annual Report of the Bureau of Animal Industry, 1902 (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 651*).—This includes a report of the chief of the Bureau reviewing the different lines of work during the year, 15 articles noted elsewhere in this issue, and 6 articles already noted from other sources as follows: Scabies in cattle (E. S. R., 14, p. 191); feeding native steers (E. S. R., 14, p. 598); the relation of protein in cotton-seed meal, cowpea hay, and wheat bran

(E. S. R., 14, p. 605); the water content of creamery butter (E. S. R., 14, p. 1115); the physiology of milk secretion (E. S. R., 13, p. 884; 14, p. 608); and takosis, a contagious disease of goats (E. S. R., 15, p. 304).

Statistics are given on the value of animals sold and slaughtered on farms in 1899, imports and exports of animals and animal products, receipts and shipments of live stock during 1902, and on the wool product of the United States in 1902. Some agricultural experiment station work is reviewed, a list is given of State sanitary officers having charge of live stock matters, and the rules and regulations of the Bureau of Animal Industry issued in 1902 are included.

Brief articles based largely upon consular reports are included on the following subjects: Death of cattle supposed to be due to *Strongylus micrurus;* demand for American horses in France; horse breeding in Germany and France; importation of cattle into Cuba; meat and cattle trade in Barcelona; German meat inspection; fees for inspecting meat in Germany; meat inspection expenses in Germany; the price of pork in Germany; meat imports into England; price of beef and scarcity of cattle in Belgium; meat and dairy products in New Zealand; slaughtering of cattle for jerked beef in River Plate districts, 1899 to 1902; exports of animal products from the Transvaal; sausages in Spain; jerked beef exports to Cuba; frozen meats and statistics of live stock in Uruguay; meat, butter, and eggs in Russia; Russia's export of poultry; numbers of live stock in United Kingdom; loss of live stock in Australia; live stock statistics of France; exports of animals and animal products from Argentina; wool production in Australasia; Australian wool for the United States; wool trade in Australia; imports of Angora goatskins; imports of mohair at Bradford, 1897–1902; salt for sheep; cattle food from sugar cane in the West Indies; milk powder in Sweden; Persian lamb, Gray Crimmer, and Astrakhan; and the musk ox.

Reprints from Bulletins Nos. 47, 50, and 52, and Annual Reports 8 to 11 (*Oklahoma Sta. Bul. 59, pp. 200*).—The articles reprinted are as follows: Reports of wheat raisers (E. S. R., 12, p. 850); experiments with wheat, 1900 (E. S. R., 12, p. 846); manuring the soil (E. S. R., 13, p. 235); the potato crop (E. S. R., 13, p. 845); variety tests of cabbage (E. S. R., 13, p. 853); feeding experiments, 1896–1899 (E. S. R., 11, p. 1069); wheat culture experiments, 1898–99 (E. S. R., 11, p. 1036); destruction of insects (E. S. R., 11, p. 1067); disease among horses (E. S. R., 11, p. 1090); summary of results of experiments with field and orchard crops (E. S. R., 11, p. 1036); means of preventing Texas fever (E. S. R., 12, p. 691); hog cholera (E. S. R., 12, p. 692); diversified farming in Oklahoma (E. S. R., 12, p. 640); summary of press bulletins (E. S. R., 12, p. 697; 13, p. 598; 14, p. 406); wines and wine making (E. S. R., 12, p. 693); grape growing (E. S. R., 12, p. 648); fungus diseases of grapes (E. S. R., 12, p. 657); insects affecting the grape (E. S. R., 12, p. 664); insecticides and fungicides (E. S. R., 12, p. 664); stock feeding (E. S. R., 12, p. 677); some Oklahoma feeding stuffs (E. S. R., 12, p. 677); cotton-seed meal as pig feed (E. S. R., 13, p. 583); cowpea hay for swine (E. S. R., 13, p. 584); the orchard (E. S. R., 13, p. 553). Several of the above articles have been abridged. The bulletin is intended to furnish information frequently asked for by new settlers in the Territory, and as no new matter has been included in the bulletin it will not be sent to the regular mailing list.

Bulletins and annual reports of Arizona Station, W. O. HAYES (*Arizona Sta. Index to Vol. III, Buls. 33–40, and Ann. Rpts. 1900–1901, pp. 339–365*).—A general index.

Legislation relating to farmers' institutes in the United States and the Province of Ontario, Canada, J. HAMILTON (*U. S. Dept. Agr., Office of Experiment Stations Bul. 135, pp. 53*).

A few good books and bulletins on nature study, school gardening, and elementary agriculture for common schools, D. J. CROSBY (*U. S. Dept. Agr., Office of Experiment Stations Circ. 52, pp. 4*).

History of German agriculture, T. von der Goltz (*Geschichte der Deutschen Landwirtschaft. Stuttgart and Berlin: J. G. Cotta, 1903, vol. 2, pp. VI+420*).—The first volume of this work has been noted (E. S. R., 14, p. 718). This second volume, which completes the work, treats of German agriculture in the nineteenth century. Agricultural reform in the first half of the century, the agricultural development along scientific lines since 1850, and the causes and character of the recent agricultural crisis in Germany are discussed.

Agricultural education in Germany (*Jour. Bd. Agr. [London], 10 (1903), No. 2, pp. 184–193*).—An outline of the scope of the agricultural educational work carried on in Germany. Courses of studies are given in some instances, with the number of hours devoted to each. One of the special features of German agricultural education is the advanced lecture course for owners, managers, agents, and farmers, which has recently been introduced at a number of the colleges and universities. This course is held for 1 week in winter. The year's progress in agriculture and natural science, jurisprudence, political economy, and all other subjects which may be of interest and importance to owners, managers, and farmers is summarized by 20 or 30 university and Government lecturers.

Agricultural returns for Great Britain, 1903 (*London: Bd. Agr., 1903, pp. VI+53*).—Tables showing the acreage under crops and grasses and the number of horses, cattle, sheep, and swine in each county of Great Britain, with summaries for the United Kingdom.

NOTES.

Alabama Station.—C. M. Floyd has been appointed farm superintendent, vice T. U. Culver, who has resigned to engage in farming. A small herd of Herefords and additions to the Shorthorn and Angus herds have recently been purchased. Feeding experiments with four lots of grade Shorthorn steers are in progress. The veterinarian has inoculated several carloads of thoroughbred Hereford cattle as a protection against Texas fever. These will be sold at auction in February.

Connecticut State Station.—Max Silverman, assistant chemist, resigned his position December 1, 1903.

Connecticut College and Storrs Station.—Dr. B. F. Koons, for many years president of the Storrs Agricultural School and later of the college which grew out of this school, died December 17 at the age of 55 years. The cause of his death was cancer of the throat. At the time of his death Dr. Koons was consulting entomologist to the Storrs Station and professor of natural history in the college. He had been connected with the institution for over 20 years. The station has arranged for cooperation with the Dairy Division of this Department in investigating the principles involved in the manufacture of varieties of soft cheese similar to those common in western Europe. An expert in the manufacture of soft cheeses has been engaged for this work and curing rooms will be erected.

Georgia Station.—D. A. Duffee has become foreman of the horticultural department of the station.

University of Illinois.—Press reports state that the appropriation act of the State legislature for the University of Illinois includes an item of $100,000 for extension of the engineering department. It is planned to start a State engineering experiment station, where advanced work in engineering may be carried on. The "station" will provide not only for undergraduate instruction, but for the working out of new problems in engineering which are of importance to the construction and transportation industries of the State.

Iowa Station.—W. W. Smith has been elected assistant in animal husbandry.

Kentucky Station.—G. N. Keller has been appointed assistant entomologist and botanist.

Cornell University.—A journal to be known as the *Cornell Countryman* has recently been started by the students of the college of agriculture.

South Carolina Station.—Two small flocks of Shropshire and Southdown sheep have been added to the stock of the station.

South Dakota College and Station.—The new $12,000 barn provided for by the last legislature is nearly completed. This barn has been made of sufficient size to amply accommodate the stock of the college farm and experiment station for several years to come. One-third of the space, or 40 by 60, is to be used for animal feeding experiments, and a similar space is to be used for classes in live-stock judging and farm mechanics. The barn is a frame building with cement floor, and has a complete set of drains which empty into a large cistern. Experiments will be conducted in the future on the value of liquid manure as compared to other manure. The college now has representatives of 17 different breeds of live stock and intends to add several more the coming year.

West Virginia University.—Extensive preparation has been made for the winter school for farmers, which will include a course of 100 lectures on various phases of agriculture during January and the early part of February. The course will last 4 weeks, with 5 lectures each day on such subjects as dairying, poultry industry, horticulture, veterinary science, animal breeding and feeding, plant diseases, economic relations of farming, chemistry of soils and fertilizers, agriculture and geology, agricultural physics, rural water supply, rural schools, farming as a business, etc. Arrangements were made for the meetings of the State Grange, the State Live Stock Association, and the Conference of Farmers' Institute Instructors to be held during the winter school, and also a meeting for the purpose of organizing a State Dairymen's Association. The regents of the university have established a department of dairying in the school of agriculture, and a dairy herd and modern apparatus for home dairying and for a working laboratory in this department have been provided. It is stated that at present there is not a creamery in the State, only one cheese factory, and comparatively few up-to-date, well-managed dairies.

Wisconsin College and Station.—During the week ended December 12 the Wisconsin farmers' institute field workers were in attendance at the agricultural college and experiment station, receiving instruction to better aid them in the conduct of their meetings among the farmers of the State. About 25 workers registered for the week's instruction. The benefits of bringing the institute workers into such close connection with college and station will be apparent to all. The college announces a two weeks' farmers' course to begin February 5. Only persons 25 years of age or over will be admitted to the course. No fees are charged residents of the State. Half a dozen agricultural experts from other States will assist the instructors in making this course intensely practical and helpful to the busy farmer. Special attention will be given to corn judging and to stock judging. A number of animals will be slaughtered for a study of carcasses and various parts of the same. Attendance at the college of agriculture the present year is as follows: Graduate students, 3; four-year course students, 57; short course students (two winter terms of 14 weeks each), 308; dairy students (12 weeks' course, 5 months' previous experience in creamery or cheese factory required), 148.

Wyoming University and Station.—Henry G. Knight, of the State University at Seattle, Wash., has accepted the position of chemist in the university and station recently vacated by E. E. Slosson, who has been granted leave of absence for 8 months, but whose return to the university is uncertain. Some changes are being made in the requisition system of the station which will make the director more definitely responsible for the station expenditures; and the station work is being reorganized so as to separate it more definitely from the university and relieve the station workers from teaching duties as rapidly as this can be brought about.

Bills before Congress.—The following bills and resolutions have been introduced in Congress relative to the publications of this Department: A joint resolution providing for the publication of 200,000 copies of the Special Report on the Diseases of Cattle, prepared by the Bureau of Animal Industry; a resolution looking to the reprinting in one volume, and with such revision as may be needed to bring the same up to date, of numerous publications issued by the Bureau of Animal Industry on hog cholera and swine plague; a joint resolution providing for the printing of an additional 42,000 copies of the Yearbook of this Department for the purpose of supplying the same to the students of the various agricultural colleges; a joint resolution directing the publication of 8,500 copies of the set of food charts prepared by this Office several years ago; and a bill increasing the edition of the Yearbook (now 500,000) to 1,000,000 copies and the Department's quota to 60,000 copies, and increasing the edition of the report of the Bureau of Animal Industry (at present 30,000) to 150,000 copies.

Hon. H. C. Adams, of Wisconsin, a member of the Committee on Agriculture of the National House of Representatives, introduced a bill in that body January 4 to provide for an increased annual appropriation for agricultural experiment stations. The initial increase named is $5,000, with an additional $2,000 a year until a total of $15,000 is reached. These funds are "to be applied only to paying the necessary expenses of conducting original researches or experiments bearing directly on the agricultural industry of the United States."

The emergency appropriation made last year to eradicate the foot-and-mouth disease has been amended so as to make $250,000 of the appropriation immediately available "to meet the emergency caused by the ravages of the Mexican cotton-boll weevil and other insects and diseases affecting cotton."

A bill extending the franking privilege to the State and Territorial departments of agriculture in mailing "documents relating to agriculture to the farmers within the borders of their respective States or Territories."

Meeting of Horticultural Inspectors.—The Association of Official Horticultural Inspectors met in Washington November 17 and 18. No formal papers were presented, the time being occupied with a discussion of the topics which had been suggested by the vice-chairman, J. B. Smith, in the announcement of the meeting.

The question as to what provisions in inspection laws are likely to prove unconstitutional if tested was thoroughly discussed. It developed during this discussion that nurserymen's associations and various horticultural inspectors had submitted the inspection laws of different States to competent attorneys for opinions on their constitutionality. The unanimous opinion of attorneys on these points indicated clearly that no inspection law is constitutional which contains requirements discriminating against nurserymen living outside the State, for the reason that it is an interference with interstate commerce. It appears, therefore, to be illegal to require the fumigation or other treatment of nursery stock before it is admitted into a State, although it is legal to require its fumigation after it has been introduced and before it is distributed. A resolution was adopted to the effect that no State law should discriminate against nurserymen of other States, and that fumigation or other treatment should not be required before the introduction of stock from outside States, but only after its introduction, and then only in case similar treatment is required of local nurserymen.

Discussing the attitude of nurserymen's associations toward inspection laws, G. G. Atwood suggested that an attempt be made in all States at cooperation between inspectors and nurserymen in the enforcement of inspection laws. As long as nurserymen and inspectors are at odds harm results to both parties. More drastic measures are taken by inspectors, with the result that more stock is eradicated or destroyed, and the nurserymen suffer loss; while the active opposition of nurserymen brings about a loss of respect for the opinions of inspectors. In Georgia and Maryland the sentiment of nurserymen was said to be in favor of inspection, while in New York, according to G. G. Atwood, decided objections have been raised against inspection before the introduction of nursery stock, but at present the nurserymen are inclined to abide by the inspection laws. In Ohio complaint was made that there is too much formality and delay in the operation of the inspection law; otherwise, nurserymen are favorably disposed toward the inspection laws. In New Jersey J. B. Smith found conditions under which he believed that nurserymen should be allowed to sell stock, whether it is infested or not, to men who are willing to buy the stock with the full knowledge of its condition. Similar experience had also been had in Georgia.

As the result of this discussion, the association adopted a resolution to the effect that inspectors should attend to the technical scientific matters concerned in all cases, and should not be required to take any part in civil or criminal proceedings resulting from violation of inspection laws.

Concerning the protection to which a nurseryman is entitled against scale-infested surroundings, it appeared that in many States the premises of nurserymen were located in the midst of badly infested surroundings, in some instances with infested orchards within a distance of a half mile. Under such circumstances infestation might readily be spread from such orchards to nursery stock. On this account nurserymen in various States have complained that it was unfair to them to allow infested orchards to stand, while the nurserymen were required to destroy infested stock. C. V. Piper stated that in the State of Washington the general sentiment of orchardists and nurserymen was that inspection was absolutely unnecessary, and a burden upon both nurserymen and orchardists, since remedies had been found by which the scale can be controlled, and infestation is so general that orchardists could not hope to secure stock perfectly free from it.

In the discussion of this question some attention was given to the distribution of the San José scale on forest trees and shrubs other than fruit trees. In the Eastern States the scale has not been found on forest trees except in the immediate vicinity of orchards, while in Washington it has been found in forests at least one-half mile from any orchard.

Regarding the selling of nursery stock exposed to infestation which has subsequently been fumigated, it was shown that fumigation is often imperfectly done, or the chemicals are impure or are not properly mixed, with the result that fumigation is not satisfactory. A discussion of potassium cyanid sold in drug stores brought out the fact that in using it for destroying granary insects it has frequently been found of inferior quality, and cases were cited in which the purity of the drug varied from 28 to 98 per cent. It was stated, however, that in the future almost the total output of potassium cyanid would be of 98 per cent purity, which is the strength recommended as standard in fumigation work.

Where fumigation is properly performed, the consensus of opinion seemed to be that it is effective and reliable, especially in cases of comparatively slight infestation. In Maryland fumigation is regarded as rendering nursery stock free from infestation, and in Delaware it is assumed to be superior to a certificate of inspection, since inspection has sometimes failed to detect the presence of the scale. H. E. Summers stated that in Iowa San José scale does not exist in nurseries. J. B. Smith stated that in New Jersey infested nursery stock is allowed to be sold after fumigation, under a declaration of the fact that the trees have been infested. Fumigation is recommended, but all trees which are found infested even with dead scales after fumigation are destroyed. This procedure was considered by others to be inconsistent and was declared to weaken the case for fumigation.

In a resolution bearing upon the formula to be used in fumigation and the attitude of nurserymen's associations toward inspection laws, the association recommended the use of the 1:2:4 formula in fumigation, and expressed the opinion that it is possible to frame inspection laws so as to avoid trouble with nurserymen and at the same time to protect the interests of both the nurserymen and fruit growers. The cooperation of the nurserymen and inspectors was urged.

Some attention was given also to the question of treatment of infested orchards. W. E. Britton stated that in Connecticut excellent results had been obtained from a wash made of equal parts of sulphid of potash and lime diluted with water. Calcotheon gave poor results in New York, and E. P. Felt had also found that salt has no insecticidal value in the lime, salt, and sulphur mixture. The salt was therefore omitted in spraying experiments, and a mixture was made containing 25 lbs. of lime, 20 lbs. of sulphur, and 60 gal. of water. In various experiments the proportion of lime and sulphur varied considerably, and an attempt to determine the exact chemical composition of the mixture obtained was unsuccessful. Certain adhesive substances added to the lime and sulphur mixture were found to cause it to adhere to the tree for a longer period. Whale-oil soap at the rate of 1½ lbs. per gallon of

water was used by orchardists in New York with good results. Crude petroleum when applied for a series of years was found to increase the size of the lenticels and the thickness of the bark, and the trees were injured in other ways. In New Jersey the use of oil is now largely confined to pear trees, which are believed to receive a positive benefit from such treatment. On all other fruit trees the lime-sulphur mixture is used almost exclusively.

In Ohio A. F. Burgess found that salt could advantageously be left out of the mixture, but that it must be thoroughly boiled. The length of the boiling period varied from 30 minutes to 1 hour, according to the custom of inspectors in different States. J. B. Smith called attention to the desirability of devising some method by which the lime-sulphur mixture can be prepared without boiling, since the boiling process is considered by many horticulturists to be a troublesome operation. Several inspectors had noted the fungicidal value of the lime-sulphur mixture. This remedy is especially valuable in the treatment of leaf curl, and perhaps for certain other important fungus diseases.

In a discussion of the effect of cold weather upon San José scale, it was said to be unaffected by 30° F. below zero in New Jersey, while in Georgia 98 per cent were reported killed by a temperature of 4° below zero, and in Iowa the scale was unable to endure the winter, except in the extreme southern part of the State. Attention was called to the fact that frequently from 80 to 90 per cent of the scale die during the winter, under normal conditions.

The following officers were elected for the coming year: S. A. Forbes, chairman; J. B. Smith, vice-chairman; J. B. S. Norton, secretary.

International Live Stock Exposition, 1903.—This exposition, held in Chicago from November 28 to December 5, 1903, was generally conceded the most satisfactory which has been held, the exhibits of fat stock, breeding cattle, sheep, and hogs being very satisfactory, while those of horses were unusually fine. As in earlier years, the agricultural colleges and experiment stations were well represented, the parts which they took as exhibitors and in judging being briefly summarized below.

Prof. C. F. Curtiss, of the Iowa Station, one of the directors and a member of the executive committee of the association having the management of this show, acted as one of the judges, as did also E. A. Burnett, W. L. Carlyle, John A. Craig, W. A. Henry, W. J. Kennedy, W. J. Rutherford, and Thomas Shaw.

Special cash prizes for cattle, sheep, swine, and dressed animals, and feed and forage products were provided for the agricultural colleges and experiment stations, and there were entries from the Iowa College and Station, the Minnesota Station, the University of Nebraska, the Ohio State University, Purdue University, and the Wisconsin Station. Aside from the prizes taken in this special "college" class, a considerable number were taken by these institutions in the general classes open to all.

The grand prize in the fat-stock class of the show was won by Challenger, a two-year-old grade Hereford steer, selected from a feed lot and fattened by the University of Nebraska, which also took first prize in the college class. The second prize in this class went to Purdue University, the third to the University of Nebraska, the fourth to the Minnesota Station, and reserve to the Iowa College. The Minnesota Station took the first, second, third, and fourth prizes and reserve for yearling cattle; and for calves the first prize went to the Iowa College, the second to the Minnesota Station, and third, fourth, and reserve to the Iowa College. On the best 5 steers or spayed heifers under 3 years of age, the first prize was awarded to the Minnesota Station, and reserve to the Iowa College.

In the college sheep classes, open to all pure-breds and grades, the first and second prizes for yearling wethers were awarded to the Wisconsin Station, and the third to the Minnesota Station; wether lambs, first and second prizes to the Wisconsin Station, and third to the Iowa College; and the Wisconsin Station took prizes for the champion wether and the best 5 wethers under 2 years of age.

In the college exhibit of swine the first, second, and third prizes for yearling barrows, prize for champion barrow, and for the best 5 barrows under 2 years of age were all awarded to the Iowa College. The first prize for a general exhibit consisting of 5 head of cattle under 3 years of age, 5 sheep under 2 years, and 5 hogs under 1 year was awarded to the Minnesota Station, and the second to the Iowa Agricultural College.

In the dressed-carcass competition the first prize for yearling carcass and champion was awarded to the Iowa Station for a steer which had received the fifth prize in the live exhibit. The first and second prizes for dressed carcasses of yearling wethers were awarded to the Wisconsin Station, and the third prize to the same institution for the carcass of a lamb. In the case of hogs of the bacon type, weighing from 100 to 200 pounds, the first prize was awarded to the Iowa College for a Berkshire, this being the animal which had received the first prize before slaughtering, and the second prize was taken by the Minnesota Station.

The University of Nebraska had an exhibit of feeding stuffs, very well arranged to show the amount of materials required for balanced rations, and the composition and percentage of digestible nutrients. It was the only exhibitor in this class and was awarded a first prize.

A feature of the exposition was the students' judging contest for the Spoor Trophy, which was this year limited to teams from the Iowa, Kansas, Ohio, Minnesota, and South Dakota agricultural colleges. In this competition the Iowa College won the trophy and the Ohio University team was awarded second place, Minnesota third, and Kansas fourth. As regards the rank of the individual students competing, one of the Iowa team was given highest standing, with one of the Kansas team a close second; third place was awarded to one of the Iowa students and fourth to one of the Minnesota students.

Monday, November 30, was agricultural college students' day at the show, and delegations were present, among others, from Illinois, Iowa, Michigan, Minnesota, Nebraska, Ohio, South Dakota, and Texas, and throughout the exhibition the number of instructors and students present from various agricultural colleges and stations in the United States and Canada was noticeably large. It is safe to say that the colleges and stations have exercised a decided influence on the live-stock industry, and one which will be even more important in the future.

A fine oil portrait of C. F. Curtiss was presented to the Saddle and Sirloin Club, a local association of men interested commercially in the live-stock industry, by Prof. W. A. Henry on behalf of the alumni of the Iowa Agricultural College, the donors of the portrait.

New building at the Nova Scotia Agricultural College.—An agricultural college has been located on the Provincial Farm at Truro, N. S., and an agricultural building is nearing completion. It is an attractive stone and brick structure, with a frontage of 98 ft. by a depth of 55 ft., and contains a basement and two main floors. The building will cost about $30,000. The basement contains a blacksmith shop, a carpenter shop, students' laboratory, and storerooms. On the first floor are located a large chemical laboratory, a class room, offices, and cloakrooms, and a horticultural workroom, the latter communicating directly with the greenhouses in the rear of the building. The second floor contains an assembly room 52 by 60 ft., a class room, and rooms for students and instructors.

The courses of instruction at the college will be suited especially to the needs of farmers and farmers' sons. The institution will include departments of agriculture, horticulture, agricultural chemistry and physics, nature study, English and mathematics, and institute, demonstration, and research work. Short courses of about 2 weeks each held during the winter will be made a feature. In addition to a regular staff of instructors for the longer courses, specialists will be engaged to assist in the instruction. Short courses in animal industry and stock judging and in dairying

are to be given the present winter, beginning the latter part of January, in which several professors from the Ontario Agricultural College will assist.

The stock of the farm has recently been increased by the purchase of several high-grade Herefords. A new poultry house has been built during the past season, and 1,200 chicks were raised on the farm, 1,000 being fattened in crates. These were sold for 18 cts. a pound, or about $1.50 per pair.

Essex County Laboratories.—The new county buildings at Chelmsford, England, erected at a cost of about $60,000 by the Essex County Council, were formally opened recently by the Earl of Onslow, president of the Board of Agriculture. They are under the control of the Essex Education Committee, and comprise chemical, physical, and biological laboratories and class rooms, as well as agricultural and horticultural museums and libraries, and are designed to afford opportunities for systematic instruction in agriculture and horticulture, as well as in pure science.

Rooms are provided for the examination of soils, manures, seeds, etc., and for other scientific work in connection with agriculture and horticulture. There is also a large dairy in the basement for instruction in butter and cheese making and the treatment of milk. In connection with the dairy school a short course of one week's duration will be given in milking and the proper treatment of milk for market. There is a school garden a short distance from the buildings which contains 3 acres and is provided with a potting shed and hothouses.

In addition to the more purely agricultural and horticultural courses of lectures and practical work, classes are held in chemistry, physics, and biology, largely for the training of teachers. The County Council offers several scholarships and a number of the classes are free to selected candidates, who must be residents of Essex County. The influence which the improved facilities will exert on local agricultural and horticultural affairs was spoken of by Mr. E. N. Buxton, chairman of the Essex Education Committee, in an address delivered at the inaugural proceedings.

Normal Training Classes for Rural Teachers.—The ten county normal training classes provided for by the last legislature of Michigan have been located by the State Superintendent of Public Instruction in the following towns: Evart, Charlevoix, Cadillac, Standish, Kalkaska, Mancelona, Ithaca, Pontiac, Saint Johns, and Port Huron. One-year and two-year courses are provided, and in the course of study suggested by the Superintendent of Public Instruction elementary agriculture is required in both semesters of the one-year course and the first year of the two-year course, and is elective throughout the second year of the two-year course. Applicants for admission to either of the courses must subscribe to a declaration that it is their purpose to engage in teaching in the rural schools or in the lower grades of the graded schools in the State.

Girls' Industrial College.—According to a note in *Gardening*, the Girls' Industrial College of Texas, which was opened to students in September last, will make a special feature of horticulture and floriculture. Three new greenhouses 18 by 40 ft. have just been completed, and will be gradually stocked with an assortment of bedding and decorative plants. A small nursey has also been established, and a course of instruction in growing, grafting, budding, etc., will be afforded students who desire it. The campus of the institution embraces about 70 acres, a large part of which will be devoted to forestry and landscape gardening.

A New General Index.—A general index to the *Hygienische Rundschau*, Volumes I to X, 1891–1900, has just been issued by the editor, Dr. R. Thiele. It comprises author and subject indexes, an index to original contributions to the journal, and lists of books and of illustrations, and makes a volume of 432 pages. As the *Rundschau* is largely an abstract journal, and includes in its scope many subjects relating to agricultural science, this general index to its first ten volumes may often prove helpful to station workers in bacteriology, animal diseases, etc. A large number of

entries are given under foods, dairy products, meat, wine, water, bacteriology, hygiene, animal diseases, immunity, disinfectants, etc.

Miscellaneous.—Press reports state that Dr. C. W. Dabney has resigned as president of the University of Tennessee, to accept the presidency of the University of Cincinnati. The resignation is effective September 1 next. His acceptance is stated to be conditioned on an income of $250,000 per annum for the Cincinnati institution.

Since the retirement of Prof. W. H. Brewer no provision has been made for carrying on the course in agriculture at the Sheffield Scientific School, which was formerly in his charge, and the course has now been discontinued.

A note in *Science*, taken from the London *Times*, states that the late Charles Seale-Hayne, M. P., has, under his will, provided for the establishment of a College of Science, Art, and Agriculture in the neighborhood of Newton Abbot, open to students of the county of Devon. Details will be left to the executors. It is thought that about £150,000 will be handed over for the college.

The German Government has under consideration a project for the establishment of a von Behring Institute modeled after the Pasteur Institute in Paris. The principal objects of the new institute will be the promotion of research in serum therapy and the preparation of sera of various kinds.

The Board of Agriculture of Great Britain has made arrangements for the examination of apparatus used in the Lister-Gerber and other similar milk tests. This service is rendered by the National Physical Laboratory, which has adopted a scale of fees for test bottles, pipettes, and measuring glasses, only one-half the full fee being charged for apparatus which is found to be below the standard. Apparatus found to be accurately graduated is marked with the monogram of the laboratory.

At the recent Apple Congress held in St. Louis a resolution was adopted which favored the making of all apple barrels 17⅛ inches in diameter at the head, with staves 28½ inches in length, and the barrel to hold 3 bushels. Bushel boxes were recommended to be 11½ by 11½ by 20 inches on the inside. This makes a box containing 2,645 cubic inches, whereas the present box used for apples contains but 2,150 cubic inches, approximately the legal bushel.

The revenue acts of Great Britain have been modified so as to exclude from duty molasses imported into the country to be used exclusively for feeding stock. An allowance of one shilling per hundredweight is also made to refiners on molasses produced in Great Britain from sugar on which import duty has been paid, if the molasses is to be used as stock food.

O

EXPERIMENT STATION RECORD.

VOL. XV. FEBRUARY, 1904. No. 6.

Continental State Aid for Agriculture is the subject of a pamphlet recently received, which deals especially with the matter of government aid in Denmark and Hungary. The author is Mr. T. S. Dymond, lecturer on agricultural chemistry at the Essex County Laboratories at Chelmsford, England.

Mr. Dymond writes from the standpoint of one familiar with the conditions in Hungary from personal observation and study, having recently acted as conductor of a party of English farmers, landowners, and others interested in agriculture who made a tour of that country. His pamphlet will be a surprise to many as indicating how liberally and along how many different lines the Hungarian government is lending its aid to agriculture. These various enterprises are grouped under the general heads of agricultural education, experimental and research work in agriculture, and commercial development.

The system of agricultural education in Hungary includes, as in other European countries, schools of various kinds for elementary and secondary instruction, as well as the higher institutions. For the sons of peasant farmers there are twenty-one tillage schools which give two-year courses of training in practical farming, and in addition a large number of winter schools of agriculture in the villages. Itinerant instruction is also given by a staff of over two hundred traveling lecturers and experts, who for the most part are attached to the agricultural ministry.

Of the higher institutions, the capstone of the system is the agricultural academy at Altenburg. This ranks among the first agricultural colleges of Europe, and is intended for the training of men who are to fill the highest agricultural positions. There are four agricultural colleges intended for the gentry or large farmers, which Mr. Dymond ranks with the very best English colleges. The agricultural academy has an average attendance of about 160 and the agricultural colleges about 125 students each.

The institutions for special industries include the veterinary college at Budapest, "a huge and splendidly equipped institution," an arboricultural college and four schools for forestry, a dairy high school and four schools for dairymen and dairywomen, a horticultural college and five schools for gardeners, schools for poultry farming, bee farming, and meadow culture, and a viticultural course and eight schools for vine dressers.

Included in this system for agricultural instruction is a system o eighty model peasant farms, in as many counties, each equipped witl the implements and stock considered most suitable for its district In 1897 there were only nine of these farms, which indicates th steady growth in this respect. The government also maintains fiv large state farms which, while primarily intended for other purposes also serve for education and demonstration. Parties of farmers ar carried by the railways to these state farms at reduced fares from al over the country. A great agricultural museum is maintained a Budapest, whose educational value was illustrated by the interes taken in it by the party of practical men whom Mr. Dymond con ducted through that country.

"The whole of this enormous scheme is supported and in mos cases maintained by the state. Every year further developments tak place, old institutions are enlarged and new institutions built, and th policy of the government clearly is not to wait till the demand becomes imperative, but, by the provision of the fullest facilities fo instruction, to encourage the people to take advantage of it. In this as in every other agricultural development in Hungary, the govern ment leads the way and the people follow. . . . One important fea ture must be clearly impressed—that in every institution for highe teaching, and even those intended for the training of peasant farmers education is associated with research, it being realized that for th future of agriculture to be prosperous it is important not only to teac the students what is known already, but to impress upon their mind by this association how incomplete is our knowledge and how muc remains to be discovered."

The system for agricultural experimentation in Hungary has bee described in these pages.[a] This is comprehensive and well organized and is said to resemble the experiment station system of this countr more than of any European country

The measures which are taken by the government for the commer cial development of agriculture are especially interesting, both fron the methods followed and the success which has attended them. Th Hungarian government has not hesitated to foster by direct financia aid farming in any depressed part of the country, or any branch o agricultural industry that is capable of development, even to th point of embarking on industrial enterprises itself. In proof of thi may be cited the government ownership of the principal railways and of silk, hemp, flax, sugar, and many other factories in connectio with the state farms, the ownership and management of over thre million acres of forest, and the carrying on "to the highest possibl advantage" of 163,466 acres of land in its five great state farms.

[a] E. S. R., 13, p. 4.

These state farms, often spoken of as stud farms, serve not only as models to the whole country, but they produce the best stallions, the best bulls, and the best seed for distribution throughout the country, thus providing an effectual means for the improvement of stock of various kinds; and in the performance of this service they are so well managed that they are said to yield an annual revenue of a million and a half dollars to the state. More than three thousand stallions are owned by the state and hired out for public service at small fees. These animals are all under military control, and the men of the cavalry regiments serve their three years upon the stud farm, thus not only saving the state a heavy bill for labor, but gaining a large amount of knowledge and experience in horse breeding and management which they are able to turn to account on returning to their own farms.

Equally interesting are the steps taken by the government for the development of cattle breeding, the improvement of dairy cattle, the elimination of contagious diseases, and the fostering care of the poultry industry, for which a state farm and school have been established on the crown estate of Gödöllö. Here the most suitable breeds are reared, and the cock birds are exchanged with the farmers for common poultry. In 1901 nearly eight thousand cocks were sent out in this way, and a similar system of exchange is followed in furnishing eggs for hatching. Local egg-collecting stations have been established, mostly in connection with the local cooperative dairies, which aid the farmers in marketing their eggs. By systematic sorting, and by eliminating the German middlemen, the farmers are able to realize from 30 to 40 per cent more for export eggs. Under this system the exports of poultry and eggs have increased 80 per cent in five years.

To encourage silkworm culture, a home industry said to be carried on by 100,000 peasant families, the state has established 145 nurseries for the propagation of mulberry trees, a silk-breeding station for providing and distributing the eggs, twenty-four cocooneries or depots for collecting the silk, and five silk factories.

While Mr. Dymond admits that this state aid in the commercial development of agriculture has been a gigantic success in Hungary, and that "the country is going ahead by leaps and bounds as a direct consequence," he calls attention to some of its obvious disadvantages. He points out, however, the advantages of the centralized system of agricultural instruction, as applied to the whole country, and draws a comparison between it and the lack of system of Great Britain. In the latter country "it is the system of decentralization, of remitting to the county councils the duties of agricultural education, under which title almost all scientific development of agriculture is now carried on in this country [England], that is the difficulty in the way of the systematic application of any scheme to the whole country. The great

variation in different parts of our country necessitates, of course very different treatment, but the time must surely soon come when the experimental period of agricultural education has proved what the right treatment for each part of the country is, and every county should be persuaded to carry out its share of the work."

Mr. Dymond expresses the belief that the commercial development of agriculture in Great Britain "would take place far more quickly if agricultural education were better systematized in the whole country." Taken in connection with the present agitation for industrial education in England, Mr. Dymond's conclusions from his observations at home and abroad are full of interest. They are in harmony with the trend of thought and the tendencies in this country, where the relation between commercial development in agriculture and agricultural education is becoming more apparent every year.

The recent bulletin of the Vermont Experiment Station on the flow of maple sap is worthy of more than passing notice, both on account of the comparative novelty of the subject and the systematic character of the work which it reports. There has been very little research in this field, and what is known has been gained largely by inference from studies of quite a variety of trees and plants rather than from work done on the sugar maple primarily. This interesting and attractive bulletin of one hundred and forty pages records the most thorough and extensive series of investigations which have been made anywhere on the maple-sugar industry, and occupies a unique place in experiment station literature.

Maple sugar is distinctly an American product, as the sugar maple does not grow in Europe except in the arboretum; and in this country maple-sugar making is confined within rather restricted limits. The product is said to have been known to the American Indians prior to 1673. The art of making it was learned from them by the early Vermont settlers, who depended almost entirely upon the maple for their domestic sugar supply. Indeed, within a generation or so it was used to a considerable extent in place of "sale" sugar in the localities where it was made. Now, however, maple sugar and sirup are regarded as luxuries, commanding a relatively high price and being much sought for by certain people on account of their characteristic flavor; but they are so extensively adulterated and imitated as to make the pure products quite difficult to obtain.

The average annual maple-sugar crop of the United States is placed at approximately forty-five million pounds, although it fluctuates considerably with the season. The census figures show variations from less than thirty million pounds in 1899, which was an unusually poor year, to nearly fifty-three million pounds in 1859. It is made principally in Vermont, New York, Ohio, Michigan, Pennsylvania, and New

Hampshire, in the order named, and brings to the comparatively few farmers operating sugar bushes approximately three million dollars and upward annually. Vermont has long been famed for its maple-sugar industry, and produces from one-fourth to one-third of all the sugar and sirup made in this country. It seems especially appropriate, therefore, both from the standpoint of tradition and supremacy in production, that the Vermont Station should take up the study of this time-honored agricultural industry, and make the phenomena of the flow of sap upon which it depends the subject of scientific investigation.

The work was begun in 1897 and was continued each year for five seasons. This gave opportunity for studying the relations of climatic and other conditions to the flow and sugar content of the sap, and showed how important in this respect is the character of the preceding season. A variety of conditions were also represented in the trees under observation, as to the amount of exposure they were subjected to in groves and in the open, the distribution of the limbs, size of the trees, and other factors likely to have a bearing on sugar production. The studies embraced the physiological problems of sap pressure and flow, including the source and direction of pressure, the relation of tree temperatures, and the direction and rate of movement, as well as a variety of practical problems in the management of the sugar orchard, such as the tapping of trees with reference to the points of the compass, the height on the tree trunk and the depth and size of the orifice, and a variety of other points.

The bulletin clearly shows that certain conditions which influence the production of sugar are within the control of the farmer, and suggests the possibility of improvement in a number of lines. For example, the studies of trees in different locations brought out the marked advantages of exposure to the sunlight to enable the tree to store up during the growing season the starch which is later transformed into sugar. Too thick growth and shading by other trees, notably evergreens, were also detrimental in this respect. Great differences were found between individual trees in regard to the sap flow and its richness in sugar, certain trees yielding much more profitable returns than others. These matters have a practical bearing in the management of sugar orchards, and suggest their own remedies.

The bulletin furnishes a scientific basis for the intelligent discussion of a wide range of practical questions relating to this industry. As such it will serve a very useful purpose, and will help to round out our knowledge in another branch of farm practice.

AGRICULTURAL SCIENCE AT THE ST. LOUIS MEETING.

E. V. Wilcox, Ph. D.,
Office of Experiment Stations.

The fifty-third annual meeting of the American Association for the Advancement of Science, held at St. Louis, December 28, 1903, to January 2, 1904, was the occasion for the presentation of many papers relating to agriculture and agricultural investigation. The most of these were given before affiliated societies—The Society for the Promotion of Agricultural Science, The Society for Horticultural Science, The American Breeders' Association, and The Association of Economic Entomologists, although several papers in this field were presented before the association proper. Mention of the meeting as a whole was made in the last issue (p. 421).

HORTICULTURE.

At the first meeting of the recently formed Society for Horticultural Science, papers of a general nature were presented, in addition to symposia on shading and cover crops. L. C. Corbett discussed Coordinaton of Horticultural work, urging that local problems require special treatment and should be solved largely by local workers, and that in cooperative work a coordination of results must be based on a detailed, uniform system of note taking. Attention was called to the necessity of securing in this manner reliable data on the cultivation and the varieties of common cultivated plants, which the society might well assist in. As a result of this paper a committee was appointed to consider the matter and report at the next meeting.

D. G. Fairchild described the mangosteen and called attention to its value. It was suggested that experiments be made to determine the possibility of growing this fruit in Hawaii, Porto Rico, and perhaps in Southern Florida. The fruit has recently been grafted on a comparatively hardy stock, so that its cultivation in these countries is considered possible. The mangosteen apparently requires a very moist soil. The seeds are planted singly in pots, and the trees should not be transplanted until about 2 ft. high.

R. A. Emerson presented a report on the principles underlying the use of cover crops. Orchards are more easily injured in winter on bare ground than on ground under cover crops. Peaches mature the wood earlier on cover crop plats. Cover crops may decrease the

moisture by transpiration, but may conserve or even increase the moisture by their action as wind-breaks, thus preventing evaporation, and also by the absorptive action of the added humus. They may also prevent loss of heat from the soil and deep freezing. The amount of transpiration of plants under actual field conditions is not known and needs systematic study. Cover crops may be classified in two groups, according as they are winterkilled or not, and their value depends in a considerable degree upon the class to which they belong. In experiments in Nebraska it was found that rye has a drying effect on the soil and that the most successful cover crops are those which are killed by the frost. The roots of fruit trees are hardier in a soil containing 20 per cent of moisture than in one containing 15 per cent. The effect of cover crops in preserving this moisture is therefore very important. Their effect upon soil temperatures is not well understood, but the soil is protected from deep freezing by their presence, especially through their action in holding snow upon the ground. In a comparative test there was 18 in. of snow on ground occupied by cover crops, while check plats showed only 2 in. Dry soils were found to freeze and thaw much more rapidly than wet soils. Cover crops should stand erect. Millet is considered as the best cover crop in Nebraska.

In the symposium on shading L. C. Corbett discussed the practice in a general manner, reviewed the work which has been done in shading tobacco, citrus fruits, studies of humidity and temperature of the soil, and the effect on plant foliage, earliness of crops, and decrease in yields. It was argued that the practice is best applicable to plants grown for foliage. B. M. Duggar called attention to the fact that many studies on etiolation have been published, but few studies on shading from a horticultural standpoint. In general there appears to be more acid in plants under shade and the reserve materials are greatly diminished. Attention was called to the desirability of carrying on quantitative work to determine the amount of transpiration of plants.

The subject of shading strawberries was presented by V. A. Clark and O. M. Taylor. Varieties of strawberries were grown on different soils. In some varieties the yield was increased, in others diminished. When a heavy form of cheese cloth was used in shading in a test of 16 varieties, the yield was diminished 13 to 70 per cent.

P. H. Rolfs discussed the subject of shading pineapples and citrus fruits. This practice was first tested in the South as a protection against frost. It has been found that on light Florida soils shading doubles the amount of soil moisture. Orange trees require considerable light, but shading prevents transpiration and thus partly compensates for the diminished light. In shading the shoots grow longer.

Good results were obtained by the use of a wind-break 20 ft. high. This allows access of light but checks the wind and prevents evaporation. Pineapples grown under shade are larger and the fruit is more tender.

H. J. Webber presented a paper on the growing of tobacco and pineapples under shade. Experiments in shading tobacco in Connecticut have shown that the percentage of lanceolate leaves best adapted for use as wrappers is considerably increased by shading. Experiments are being made for the purpose of obtaining a race of tobacco which will give the desired texture. In a discussion of the subject of shading the fact was brought out that the use of lath lowers the temperature surrounding the plats, while cheese cloth has the opposite effect.

V. A. Clark discussed the subject of Seed Selection According to Specific Gravity. Experiments were made on wheat, grape, and various other seeds. A series of solutions was arranged of different density for the purpose of testing seeds. Variations in specific gravity were found in closely related plants. A correlation was noted between the size and the specific gravity of the seeds, except in the case of the seeds of egg-plant, in which species the largest seeds had a low specific gravity. In tomatoes it was found that dark seeds are of a lower specific gravity than white seeds. A correlation was also noted between specific gravity, rapidity of germination, and viability of seeds. Peas of the low specific gravity were found to be soft, with poorly developed cotyledons. Buckwheat of low specific gravity showed a loose connection between the kernel and seed coats. In general, heavy seeds of all species are of high protein contents.

Several other papers of this society were presented at a joint session with the American Breeders' Association.

PLANT AND ANIMAL BREEDING.

An organization of plant and animal breeders was effected, to be known as the American Breeders' Association. A constitution and by-laws were also adopted and a large programme was presented, including the following papers:

W. Saunders presented an account of wheat breeding in Canada. Advantage was taken of Russian investigations, during which it was found that certain varieties of wheat matured considerably earlier than the average varieties. Ladoga wheat was imported from Russia and crossed with Red Fife. Other varieties were also imported from Russia and India from low and high altitudes. The Preston wheat, obtained by crossing Ladoga and Red Fife, ripens earlier than Red Fife and yields better. Later a bald variety called Stanley was obtained. Experts in England and Minneapolis score Red Fife, Stanley and Preston about the same. Great increase in the gluten content

was observed in the cross between the Russian and Indian varieties of wheat known as Early Riga.

H. J. Webber discussed the work of plant breeding in the Department of Agriculture. This work began in 1893. The chief lines are improvement of cotton, increased resistance of cereals to alkali, breeding oats, potatoes, tobacco, corn, and wheat, and increasing plant resistance to disease. Cotton with a long staple makes a better yield and a more durable fabric, and in general black seeds are desirable. Attempts are being made to secure Sea Island cotton with a larger boll which will open well and render picking easy. Nearly all crosses between the upland and Sea Island cotton are larger than either parent, while the Egyptian variety is comparatively long in staple and not too fine in fiber.

E. Davenport discussed the subject of Thremmatology, which was defined as meaning evolution as encouraged by man. The causes of variation and heredity were examined. A paper by H. De Vries on Investigation of Heredity in Sporting Varieties was presented by the secretary of the association. Attention was called to the desirability of studying the diversified forms of sporting varieties, on account of the possibility of finding accidental types exhibiting desired characters. These variations arise from internal and external causes not wholly understood, but such monstrosities may assist in throwing light on the causes of variation.

C. S. Scofield described a system of score cards adapted to the use of breeders. A general review was presented of the problem, and attention was called to the desirability of devising score cards which would allow for a detailed description of the variety of plant which was being studied. These cards should not be made too comprehensive, but are perhaps most valuable when adapted simply to a single species.

J. D. Funk spoke on Commercial Corn Breeding. A corn breeder should have only one aim, viz, increased production. The selection of the most productive ears from comparative breeding tests constitutes the essential part of the speaker's system of breeding. The breeding fields were described in detail. All defective stalks are detasseled. Brief mention was made of the possible increase of oil and protein content in corn. During the numerous tests made by the speaker only 2 strains of corn have been developed with remarkably high yields. By the use of seed corn obtained from these strains the average crop has been increased about 10 bu. per acre. Satisfactory reports have been received from this corn wherever it has been planted in the central corn belt. The speaker considered increased production as immensely more important than changes in chemical composition.

C. P. Hartley discussed the subject of Corn Breeding. Attention was called to the fact that all varieties of corn cross readily, and that

therefore in breeding experiments careful isolation of the plats is necessary. Crosses with Mexican varieties of corn are found very unproductive, or even sterile, while crosses between sugar corn and field corn sometimes show a blending of starchy and sugary parts in the same kernel. The starchy tendency, however, is the dominant character and prevails in three-fourths of the offspring. The dark color in corn has a tendency to show at the base of the kernel. In a test with red ears it was found that certain ones produced 100 per cent of red corn in the third generation.

D. G. Fairchild discussed the subject of Plant and Animal Introduction, calling attention to the work which the Department of Agriculture has been doing in agricultural explorations throughout the world. The possibility of breeding plants resistant to disease was discussed by W. A. Orton, who referred to the results already obtained in breeding watermelons resistant to wilt, potatoes resistant to Phytophthora, cowpeas and cotton resistant to wilt.

F. B. Mumford presented a paper on The Influence of the Size of the Parent on Birth Weight. During the speaker's experiments it was found that the sire has but little influence on the birth weight of the progeny. The influence of the male as to size and other characteristics of the offspring appears not to be manifested conspicuously until after the birth of the young. Evidence was obtained that certain characteristics of the parents never appear until late in the life of the offspring.

C. F. Curtiss spoke of some breeding experiments with domestic animals. An attempt is being made to produce a race of sheep especially adapted to western ranches, and Shorthorn cattle are being crossed to produce blue-gray hybrids. A number of other papers were presented, especially on Distributing Valuable New Varieties and Breeds, by W. M. Hays; Experiments in Corn Breeding, by C. G. Hopkins; Breeding from Tame *v.* Wild Species, by H. W. Groff; Theoretical Studies in Breeding, W. J. Spillman; Relation of Life History Studies to Breeding, by W. T. Swingle; Grape Breeding, by S. A. Beach; Breeding Hardy Fruits in the Northwest, by N. E. Hansen; Bean Breeding, by R. A. Emerson; An Application of the Theory of Evolution to Breeding, by O. F. Cook; and Studies in Inheritance in Mice, by C. B. Davenport.

Secretary Wilson was elected president of this association, and W. M. Hays secretary, with H. J. Webber as chairman of the plant section and J. Dryden as chairman of the animal section.

SOCIETY FOR THE PROMOTION OF AGRICULTURAL SCIENCE.

This society held a number of sessions, alone and in conjunction with the Society for Horticultural Science and the Association of Economic Entomologists. L. H. Pammel presented an account of

Some Unusual Plant Diseases in Iowa. Notes were given on the occurrence and prevalence of *Cylindrosporium padi*, septoria disease of currants and gooseberries, black knot, and the bacterial carrot disease. The latter was said to be very prevalent during the season of 1903.

The Water-Soluble Plant Food of Soils was discussed by H. Snyder. Data were presented showing the amount of phosphoric acid removed from the soil by wheat and several other crops at different stages of growth. In a specific instance the amount of wheat growing on 1 sq. yd. of soil contained 1,106 gm. of dry matter and 10.18 gm. of phosphoric acid. It was shown that the amount of water which, according to Hellriegel, would be required to produce this 1,106 gm. of dry matter in wheat, "could dissolve only 1.9 gm. of phosphoric acid from the soil upon which the wheat was grown," using the methods for extracting given in Bulletin 22 of the Bureau of Soils, except that the water was left in contact with the soil for 15 days instead of 20 minutes. The conclusion was drawn that over 81 per cent of the phosphoric acid of the wheat crop was secured from forms insoluble in water. It was calculated that the wheat crop mentioned in Bulletin 22 would require more water-soluble phosphoric acid than was contained in the soil to a depth of 8 ft., and the limit to the capacity of crops for absorbing water was pointed out.

J. B. Weems presented a paper on The Relation of Research to Scientific Agriculture, referring to the necessary mental and physical equipment of investigators, and discussing the difficulties met with by many. The responsibility of overloading promising investigators with tedious routine work was placed upon those in authority at various institutions.

C. E. Bessey presented an informal account of agriculture in the Caucasus Mountains. The geography and general topography of the country were described. The steppes north of the Caucasus are like the Great Plains of America. The chief crops are hay, wheat, and corn. Improved farm machinery are in use and the cattle are of fair conformation. The sheep are of a very dark color. The Caucasus Mountains are occupied by farmers who raise wheat, rye, and barley. South of the Caucasus corn is grown extensively, and there are improved races of hogs and horses, and also the big-tailed sheep.

The Relation of the Date of Digging to the Development of Potato Rot was discussed in a paper by L. R. Jones and W. J. Morse. During the reported experiments it was found that sound tubers were not infected during storage. It was determined that there is more loss from rot in early digging than in late digging.

W. R. Lazenby discussed The Waste Products and the Keeping Quality of Apples. During the speaker's experiment 25 standard varieties of apples were tested to determine the percentage of waste.

The average waste was found to be 23 per cent. Another test with carefully selected apples showed a waste of only 13 per cent. The percentage of water was found to be highest in the best samples of apples (90 per cent), while it was 85 per cent in the second grade and 81 per cent in cull apples. Apples were picked, beginning the middle of September, and every week thereafter, until November. This test was made on 10 varieties and the samples were stored in the cellar. Neither the earliest nor the latest picked apples kept longest, and apparently the best time for picking apples in Ohio is about the middle of October.

In a discussion of the paper attention was called to the fact that this work corroborated the work of this Department in storing apples, and the further fact was brought out that some varieties must be picked early in the morning in order to keep best.

D. G. Fairchild presented a paper on Hop Culture in Europe. In America male hop plants are numerous, while in Europe the male plants are not tolerated in the hop field. It was argued that the variety of hop is of more importance than the soil or climatic conditions. Little work has been done along this line, and the field of hop breeding is therefore open.

Various other papers presented before this society are noted elsewhere.

BOTANY.

A large programme of botanical papers was presented before Section G of the association, the Botanical Society of America, and other bodies. B. T. Galloway gave an address as past-president of the Botanical Society of America, on the subject of the Twentieth Century Botany. The advances thus far made on the subject of botany were outlined in a general manner, and special attention was given to a discussion of the present requirements of the botanist and the problems to be solved in the future. The speaker urged the consideration of botanical questions from a practical view-point, and stated that the doctrine of science for science's sake is less applicable at present than in the past. It was also argued that a successful scientist should be a practical man of affairs, possessed of an abundance of common sense. The dangers of too great specialization and consequent limitation of view were pointed out. The speaker stated that important advances in the future are to be expected in morphology, physiology, and pathology.

J. H. Harris presented a paper on The Dehiscence of Anthers by Apical Pores. Most plants which possess this character occur in South America, there being 1,200 species in that country, and only 400 in the rest of the world. Its importance is not clearly understood, but according to investigations thus far pursued it appears to be closely correlated with the distribution of bees, and is therefore apparently an arrangement to favor cross-fertilization by this method.

Among other botanical papers of economic importance may be mentioned The Distribution of Some Iowa Plants, by L. H. Pammel; Unpublished Notes on the Uredineæ, by M. A. Carleton; The Histology of Insect Galls, by M. T. Cook; and The Type of the Genus Agrostis, by A. S. Hitchcock.

ECONOMIC ENTOMOLOGY.

The entomological papers were presented before the Society for the Promotion of Agricultural Science, and the Association of Economic Entomologists. L. O. Howard gave an account of the work of the Department in combating the cotton-boll weevil. This work has been prosecuted for a number of years, and has included experiments with a number of insecticides and a test of cultural methods. The results thus far obtained indicate that by proper attention to cultural details a fairly successful crop of cotton can be produced, even in the worst infested localities. The outlook is therefore not believed to be so gloomy as has sometimes been supposed.

A paper on the same subject was presented by E. D. Sanderson, who outlined the work of the Texas Station in combating this insect. Attention was called by this speaker also to the desirability of combining proper cultural methods with insecticide treatment. No cotton plants should be allowed to stand in the fields over winter, and other material in which the weevil could be successfully concealed or carried from place to place should be destroyed.

The same speaker discussed a card index system for entomological records. The literature of this subject was briefly discussed, with special reference to schemes for keeping a correspondence record, accessions catalogue, and an experiment record.

F. M. Webster discussed the subject of Buffalo Gnats in the Mississippi Valley, with special reference to the life history of these insects. Gnats are most abundant along the Mississippi between Cairo and New Orleans. A historical account was given of the various outbreaks of this pest, with statements of losses. The gnats are most prevalent in years of high water. There appear to be two forms of female, one sterile and one fertile. The sterile female is apparently the only form of gnat which wanders far away from water courses and is the one to which the losses of stock are due. The worst outbreaks of this insect are due to overflow from the Mississippi, and these outbreaks have become less frequent and less serious since the establishment of substantial levees.

C. P. Gillette spoke on The Insects of the Year in Colorado. Grasshoppers were very numerous and experiments were made with fungi in controlling them. Apparently the Australian grasshopper fungus was quite ineffective, while *Empusa grylli* destroyed a number of grasshoppers. The speaker tested the use of a mixture of horse

manure and Paris green without very good results. Army cutworms occurred in unusual abundance. There were 2 broods of this species. Notes were also given on gooseberry fruit worm, plant lice, and false chinch bugs.

W. Lockhead discussed Injurious Insects of Ontario. The Hessian fly and pea weevil were unusually abundant. It was stated that there are many voluntary observers studying the habits of these insects. The pea weevil can now be controlled by proper insecticide and cultural methods. The clover-seed midge destroyed about one-fourth of the clover seed of Ontario, and is considered a very serious pest. The lime-sulphur-salt treatment was found to be exceedingly effective for San José scale and pear psylla. Notes were also given on squash bug, asparagus beetles, and cucumber beetles.

J. Fletcher spoke on The Insects of Canada. Clover thrips is always abundant on clover blossoms in Canada, but it is not certain how much injury this insect does. It apparently damages oats. Notes were presented on oyster-shell bark-louse, asparagus beetles, cutworms, pear-leaf blister-mite, cabbage maggots, onion maggots, horn-fly, fleas, and bedbugs. The author argued that all insecticide formulas must be made as simple as possible in order to induce farmers to apply them properly.

H. Osborn discussed Ohio insects with special reference to fall webworm, apple maggot, Capsidæ, and leaf hoppers.

E. D. Sanderson spoke of the injurious insects of Texas for 1903. There are apparently 3 species of grain plant lice in Texas. The chinch bug has 3 broods and is reported to have caused considerable loss during the year. Insect injury to cotton was chiefly due to grasshoppers, white grubs, white-lined sphynx, and *Loxostege similalis*. Pecans were injured by a species of Phylloxera and by *Acrobasis caryæ*. Notes were also given on the fowl tick, sweet-potato weevil, and *Aphis scotti*, which was referred to as a new species injurious to plums.

T. B. Symons discussed the Maryland insects. The San José scale is now controlled by lime-sulphur-salt wash. Economic notes were given on apple aphis, strawberry weevil, fruit-tree bark-beetle, tent caterpillars, cucumber beetles, asparagus beetles, melon aphis, strawberry aphis, scurfy bark louse, and oyster-shell bark-louse. The cigarette beetle was said to be in almost every tobacco warehouse in Maryland and great difficulty has been experienced in exterminating it. The speaker recommended a regular inspection of tobacco warehouses.

F. L. Washburn spoke of injurious insects in Minnesota. Notes were given on plant lice and white grubs, especially *Lachnosterna rugosa*, which were said to be unusually abundant and injurious to sorghum, wheat, barley, evergreen trees, and other plants. Mention

was also made of the injuries from grasshoppers, chinch bug, and Hessian fly. Some evidence was presented by the author for the apparent occurrence of 2 broods of this insect in Minnesota.

M. V. Slingerland gave an address on Insect Photography. The history of the work was outlined, with special reference to the development of microphotography and half-tone work. Attention was called to the occasional abuse of photography in scientific work, and suggestions were given regarding the field of greatest usefulness of photography in illustration. Necessary apparatus and methods of preparing specimens were outlined.

The same speaker gave an account of New York grape pests, with special reference to the grape-root worm and grape-leaf hopper. Experiments in spraying with arsenate of lead gave promising results in controlling the root worm. The leaf-hoppers were successfully captured by the use of a large sticky shield, or were destroyed by a weak oil or soap spray. The grape fruit moth can be controlled by hand picking. Infested fruits may be recognized and picked off for about $2 per acre. The same speaker also presented a general paper on insect depredations in New York, with special notes on plant lice, pear psylla, slugs, rose chafer, cabbage maggots, onion maggots, plum curculio, apple bucculatrix, and apple-leaf blister-mite.

Arsenate of Lead as a Remedy for Codling Moth was the subject of a paper by A. F. Burgess. Experiments were made on an orchard of 1,700 trees. Without treatment only one-fourth of a crop had been obtained. Disparene and arsenate of lead were used, being applied 3 times. The quantity of perfect apples varied from 7 to 81 per cent, while the cost of application ranged from 7 to 13 cents per tree.

The same speaker discussed the treatment of nursery buds. Peach buds were fumigated with hydrocyanic-acid gas or were dipped in whale-oil soap. The buds were not injured by either treatment. The gas was found to be very effective in killing the San José scale while whale-oil soap was less so. The speaker also presented a paper on economic insects in Ohio for 1903, with special reference to chinch bug, Hessian fly, apple aphis, cankerworm, white grubs, grape-root worm, woolly aphis, San José scale, grape berry moth, willow curculio, and oyster-shell bark-louse.

F. M. Webster discussed the relation of the systematic and the economic entomologist. The systematist may greatly assist the economic entomologist in identification of species. Attention was called to the great need of care in description of species. Mention was made of nomenclatural troubles and uncertainties. The same speaker presented a paper relating to the distribution of *Myochrous denticollis*, *M. squamosus*, asparagus beetles, and harlequin cabbage bug.

C. P. Gillette discussed the question of what credit is necessary to be given. Attention was called to the difference between skilled and

unskilled assistants, and it was urged that original and independent work of assistants was most worthy of recognition and personal credit in the publication of entomological literature.

O. H. Swezey discussed the life history of *Liburnia campestris*. It was found that the larvæ appear about 2 weeks after the time of pairing of the adult insects. The young nymphs reach full growth in about 6 weeks. *L. lutulenta* was compared with the above species and notes were given on hymenopterous parasites of this insect.

The sessions of Section I on Social and Economic Science, were devoted to the labor problem; the economic aspects of the new agriculture; the status of instruction in social and economic science in schools, colleges, and universities; and on commerce, finances, and government. The session which proved to be most interesting and developed the most lively discussion was that on the economic aspects of agriculture, previously referred to (p. 422).

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Chemical methods for the determination of the fertility of the soils with respect to phosphoric acid, K. K. Gedroitz (*Zhur. Opuitn. Agron.* [*Jour. Expt. Landw.*], *4* (*1903*), *No. 4, pp. 403–432*).—The author reviews his previous investigations on this subject, and reports further pot experiments with oats and mustard on 19 widely different soils. The pots contained 5 kg. of dry soil and were fertilized with various amounts and combinations of nitrogen, phosphoric acid, potash, and lime.

The phosphoric acid was determined separately in the straw and grain of the harvested crops, as well as in the roots in a few cases. The solubility of the phosphoric acid of the soil in 2 per cent citric and acetic acids was also determined. From a comparison of the data thus obtained the conclusion is drawn that plants vary widely in their capacity for utilizing the phosphoric acid of the soil. There was no close agreement between the amounts utilized by the oats and mustard on the same soil, and similar results are reported for 12 different kinds of plants grown on the same soil, namely, sandy chernozem.

It was further shown in studies on 19 different samples of soil that there was no agreement between the availability of the phosphoric acid of the soil as measured by solubility in 2 per cent citric or acetic acid and the amounts taken up by plants. In studies of the relative assimilability of the phosphates of iron, aluminum, and calcium by flax, oats, and mustard, as compared with their solubility in citric and acetic acids, it was found that as regards the yield produced the relative efficiency of these phosphates was, beginning with the highest, aluminum phosphate, calcium phosphate, and iron phosphate. As regards solubility in 2 per cent acetic acid, the order was calcium phosphate, aluminum phosphate, and iron phosphate, the latter being almost insoluble in acetic acid. The aluminum and calcium phosphates were about equally soluble in 2 per cent citric acid, thus showing a closer agreement with the actual availability of these phosphates as determined by means of the plant.—P. FIREMAN.

Studies in soil analysis, A. Atterberg (*K. Landt. Akad. Handl. och Tidskr.*, *42* (*1903*), *No. 3, pp. 185–253*).—A discussion of methods of mechanical soil analysis, and suggestions for a new terminology of soil grains. The relation of soil particles of different diameters to hygroscopicity, air content, volume, weight, capillarity, etc., were studied experimentally, as well as the rapidity of drying out, the flocculation of fine sand grains, the relation of sandy soil to plant roots, etc.—F. W. WOLL.

On recent efforts to simplify soil analysis, Emmerling (*Oesterr. Chem. Ztg.*, *6* (*1903*), *No. 18, p. 412*).—This is a brief note on an address before the International Congress of Applied Chemistry at Berlin in 1903, and refers to Rodewald's method of determining the fineness of the particles of a soil by means of its hygroscopicity, the importance of the determination of the loss on ignition, the comparatively little value of determinations of nitrogen by means of the Kjeldahl method, and the substitution of weaker solvents for stronger acids like hot hydrochloric acid in the chemical analysis of soils.

Chemical analysis of soils, R. CORRADI (*Bol. Chim. Farm., 42 (1903), pp. 482–486; abs. in Chem. Centbl., 1903, II, No. 14, p. 805*).—In continuation of a previous article (E. S. R., 14, p. 834) the author describes methods of determining chlorin and manganese and explains a correction for the presence of coarse particles. Some results of examination of samples of Sicilian soils rich in lime and poor in nitrogen are reported, and the general subject of fertilizer requirements of soils is discussed.

Contribution to the knowledge of the molybdo-phosphoric acid reaction, C. REICHARD (*Chem. Ztg., 27 (1903), No. 68, pp. 833–835*).—This is an account of a study of this reaction under varying conditions of proportion of reagents and presence of certain acids (hydrochloric, tartaric, citric, and oxalic). The results obtained indicate that the molybdic reagent used in amounts furnishing as much as 30 parts of MoO_3 to one part of P_2O_5, in case of solutions containing as little as 0.000186 gm. of phosphoric acid per cubic centimeter after several hours' standing, gives no trace of a precipitate. In the majority of cases to insure the precipitation of one part of P_2O_5, it is necessary to add 200 parts of ammonium molybdate, and that the solution of molybdate should be of at least 4 per cent strength.

The presence of hydrochloric acid was found to seriously interfere with the formation of the yellow precipitate, but this was overcome by neutralization, preferably with ammonia. Dilute solutions of the acid interfered more with precipitation than stronger solutions. The organic acids were variable in their behavior toward the reaction, but in all cases interfered with precipitation. Oxalic acid was especially marked in its preventive action. Neutralization of the organic acids in a measure prevented interference with precipitation, and it appeared to be immaterial whether ammonia or the other alkalis were used for this purpose.

A method for the estimation of chlorids, bromids, and iodids, S. BENEDICT and J. F. SNELL (*Jour. Amer. Chem. Soc., 25 (1903), No. 11, pp. 1138–1141*).—In continuation of a previous article (E. S. R., 14, p. 225) the authors outline the following method for the determination, either gravimetrically or volumetrically, of the 3 halogens:

"For the determination of the iodin, a suitable quantity of the substance (containing not over 0.5 gm. iodin or 0.15 gm. chlorin, if tenth-normal solutions are to be used) is dissolved in water and made up to about 50 cc. in a 100 cc. glass cylinder with close-fitting glass stopper. Neutral potassium iodate is added in about twice the quantity necessary to react with all the bromin and iodin believed to be present. The mixed solution is acidified with 4 or 5 cc. fifth-normal (30 per cent) acetic acid and shaken with 30 to 40 cc. carbon bisulphid until all the liberated iodin has been taken up by the latter. The aqueous phase is now separated from the carbon bisulphid phase by filtration through a wet filter, and the carbon bisulphid is thoroughly washed with cold water on the filter. The filtrate and washings are reserved for the chlorin determination. The carbon bisulphid solution is transferred to another beaker by puncturing the filter and is covered with 20 to 25 cc. of 75 per cent alcohol. Any carbon bisulphid left adhering to the filter is rinsed down into the beaker with a portion of the 75 per cent alcohol. The iodin is now titrated with sodium thiosulphate with constant stirring. No starch indicator is necessary.

"For the determination of the chlorin, the aqueous filtrate from the carbon bisulphid is treated with 5 cc. fifth-normal nitric acid (sp. gr. 1.18) to liberate the bromin and is boiled in a covered beaker until colorless. The excess of iodate is next destroyed by adding a quantity of potassium iodid slightly in excess of the amount necessary to react with it. The solution is again boiled until colorless, 2 or 3 cc. more of the dilute nitric acid being added, if the color is not completely discharged after 10 or 15 minutes' boiling. A minute or two after the color has completely disappeared the solution is taken from the flame, cooled, and neutralized with sodium carbonate. To secure exact neutralization, a little calcium carbonate may be added at first and

then sodium carbonate solution until a precipitate just forms. The chlorin is then determined by titration with standard silver nitrate, using potassium chromate as indicator."

The results of 12 analyses of mixtures of potassium iodid and bromid and sodium chlorid are reported. These show a very close agreement between the calculated and determined amounts of the halogens.

On the formation of nitric acid by electrical energy, C. W. VOLNEY (*Trans. Amer. Electro-Chem. Soc., 1903, pp. 285–289; abs. in Jour. Chim. Phys., 1 (1903), No. 4, p. 325*).—In experiments to determine the rapidity of decomposition of NO into NO_2 and N by means of electrical discharges, the following results were obtained: In 5 minutes 2.7 per cent, in 10 minutes 3.3 per cent, in 20 minutes 3.58 per cent of NO was decomposed. Various equations explaining the reaction are given.

The oxidation of atmospheric nitrogen by electrical discharges, F. VON LEPEL (*Ber. Deut. Chem. Gesell., 36 (1903), pp. 1251–1260; abs. in Jour. Chim. Phys., 1 (1903), No. 4, p. 310*).—After a brief review of the work of other investigators on this subject, the author describes a large series of experiments made to determine the influence of various factors, such as the nature of the electrodes, the rapidity of rotation of the anodes, and the nature of the solution in the apparatus, upon the production of nitric acid by means of a continuous current.

The determination of nitrogen by the Kjeldahl method, S. P. L. SÖRENSEN and C. PEDERSEN (*Ztschr. Physiol. Chem., 39 (1903), No. 6, pp. 513–525, fig. 1*).—The Kjeldahl method was found to give good results with such substances as creatin, creatinin, and uric acid. The results, however, were believed to be a little too low; while those by the Dumas method was considered a little too high.

Methods of analysis of separator skim milk, C. BARTHEL (*Nord. Mejeri Tidn., 18 (1903), No. 35, pp. 71, 72*).—A comparison of the Adams and Gottlieb methods for the analysis of skim milk. The results presented show that if the fat content in the skim milk is greatly increased through the application of self-cleaning pasteurizers, the stirrer of which is turned at a considerable speed, the Adams method fails to show any appreciable increase in the percentage of fat in the skim milk, while Gottlieb's method gives all the fat contained therein.—F. W. WOLL.

A further contribution to the methods of fat determination, M. MÜLLER (*Fühling's Landw. Ztg., 52 (1903), Nos. 21, pp. 767–771; 22, pp. 831–834*).—The author found it extremely difficult, if not impossible, to prepare casein free from fat by ordinary methods of fat extraction. In tests with casein, beef, and yeast the Lehmann method was considered the most satisfactory. The Soxhlet method gave results much too low, and the Dormeyer method much too high. The percentages in the case of yeast were 1.891 by the Soxhlet method, 4.908 by the Lehmann method, and 5.456 by the Dormeyer method. In tests with the brains of horses the results by the 3 methods were respectively 49.924, 50.192, and 50.75 per cent. The 3 methods were therefore considered of nearly equal value on substances rich in fat.

Olive oil and its substitutes, L. M. TOLMAN and L. S. MUNSON (*U. S. Dept. Agr., Bureau of Chemistry Bul. 77, pp. 64, pls. 2*).—The nature and extent of the investigation reported in this bulletin are outlined in an introductory note by W. D. Bigelow, Chief of Food Laboratory. The bulletin proper contains statistics of the olive-oil trade; an account of the manufacture of olive oil; the methods of analysis used, with a full discussion concerning the interpretation of results; and analyses of a number of salad oils sometimes fraudulently substituted for olive oils, olive oils of known origin, and of commercial olive oils.

A briefer account of the work relating to the pure olive oils and the olive oil substitutes has been noted from another source (E. S. R., 15, p. 223). The bulletin is summarized by the authors as follows:

"(1) The olive oil consumed in this country is largely imported from France and Italy. The amount produced in California is relatively small, although reports warrant the statement that California is capable of supplying the entire home demand.

"(2) The cost of production of California oil is so much higher than that of the French and Italian oils that it competes with difficulty with the imported oils in the American market, even after the latter have paid duty amounting to 50 cts. per gallon.

"(3) The retail prices of the best grade of oil from the 3 sources are much the same, but the average prices of the imported oils are much less than that of the California oil, owing to the large amount of lower grade foreign oils that is marketed in this country.

"(4) In the examination of olive oils for adulteration, a complete analysis is usually necessary to reveal the real nature of the oil. In cases of gross adulteration the qualitative tests, specific gravity, and index of refraction will often show the nature of the adulterant and the extent to which it is employed.

"(5) The adulteration of foreign oils imported into this country is practiced to a much less extent than is popularly supposed. Only 5 of the 61 samples obtained from the custom officers were found to contain other than olive oil, and none of these contained cotton-seed oil.[a] On the other hand, oils bought upon the market, bearing labels indicating a foreign origin, were found to be quite extensively adulterated with cotton-seed oil. It seems, therefore, probable that these adulterated oils bearing foreign labels are labeled and modified after leaving the port of entry, neither the domestic nor the foreign producer being responsible for them. This practice is equally injurious to the interests of the Calfornia, French, or Italian manufacturer of pure olive oil and the consumer.

"(6) The results of analyses of oils of known purity show that there is a wide range in the various values ordinarily considered of importance in indicating the purity of an oil. This is especially true of the iodin number, the melting point of fatty acids, and the percentage of solid fatty acids. The California olive oils generally have a higher iodin number, a lower melting point of fatty acids, and a lower percentage of solid fatty acids than the French and Italian oils.

"(7) All samples containing other than olive oil were sold as pure olive oil, although in one case a careful observation of the label revealed the fact that the oil was an olive-oil substitute."

The estimation of moist gluten in flour, M. Arpin (*Ann. Chim. Analyt., 7 (1902), Nos. 9, pp. 325–331; 10, pp. 376–381; 11, pp. 416–420; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 21, pp. 1004, 1005*).—A study of the errors involved in estimating moist gluten and similar problems led the author to the conclusion that the method is so subject to error as to make it quite unsatisfactory, and he recommends abandoning the estimation of moist gluten and falling back on the nitrogen content of flour as a means of judging of its gluten content.

Colorimetric determination of chlorophyll in different plants, B. Jönsson *Bihang K. Svenska Vetensk. Akad. Handl., 28 (1902), III, No. 8, App., pp. 30, pl. 1*).

Report on the examination of foods, drugs, and public water supplies, R. O. Brooks (*Trenton, N. J.: State Lab. Hyg., Chem. Dept., 1903, pp. 30*).—Of the 341 samples of foods examined, 40.8 per cent was found adulterated. The percentage of adulteration of drugs was much higher. Analyses of 19 samples of water are given.

The theories of indicators, J. Stieglitz (*Jour. Amer. Chem. Soc., 25 (1903), No. 11, pp. 1112–1127*).—This article discusses (1) the chemical changes involved in the change of color of indicators and (2) the cause of the characteristic differences in sensitiveness of such indicators as phenolphthalein and methyl orange toward various acids and bases.

Under the first head the ionization theory of Ostwald and the chromophoric theory are considered. The first is considered inadequate, ionization and change of

[a] Two samples recently received from the custom-house have contained cotton-seed oil.

color being in the opinion of the author merely a coincidence. The conclusion is reached that "the color change must be primarily due to a change of constitution involving a chromophoric complex."

It is held that as regards the sensitiveness of indicators "too much emphasis can not be laid on the fact that the lack of sensitiveness of phenolphthalein in laboratory practice in the titration of a weak base like ammonia or of methyl orange in the titration of a weak acid like acetic acid is ultimately due chiefly to the fact that a weak base or a weak acid is very much weaker (less ionized) in the presence of its own salts than in pure aqueous solutions."

The testing of chemical reagents for purity, C. KRAUCH, trans. by J. A. WILLIAMSON and L. W. DUPRÉ (*New York: D. Van Nostrand Co., 1903, 3. ed., pp. 350*).—This is an authorized translation of the third edition of this work, containing many additions and corrections as well as references to English works, in place of many of the original references to German works.

Comparison of different types of calorimeter, J. S. S. BRAME and W. A. COWAN (*Jour. Soc. Chem. Ind., 22 (1903), No. 22, pp. 1230–1233, fig. 1*).—Comparative tests of the Lewis Thompson, William Thomson, F. Fischer, and Mahler bomb calorimeters with reference to their use in determining the calorific power of fuels (coal) are reported. The Mahler calorimeter gave the most satisfactory results.

A new form of platinum resistance thermometer, specially adapted for the continuous-flow calorimeter, H. T. BARNES and D. MCINTOSH (*Phil. Mag. and Jour. Sci., 6. ser., 6 (1903), pp. 350–352*).

Fourth session of the International Commission for Uniform Methods of Sugar Analysis, F. G. WEICHMANN (*Jour. Amer. Chem. Soc., 25 (1903), No. 11, pp. 1208–1215*).—A summary of the proceedings of the session held at Berlin, June 4, 1903.

Report of the principal chemist upon the work of the government laboratory for the year ended March 31, 1903, T. E. THORPE (*London: Govt. Lab., 1903, pp. 26*).—A brief summary is given of the work of this laboratory in connection with the revenue departments (customs and excise) and with other government departments.

Report of the chemical department of the Royal Agricultural Academy, 1902, H. G. SÖDERBAUM (*K. Landt. Akad. Handl. och Tidskr., 42 (1903), No. 2, pp. 103–121, figs. 3*).—Of the subjects investigated by the department during the year and treated in this report, mention may be made of experiments to determine the content of assimilable plant food in a soil through treatment with very dilute acids; the effect of increasing quantities of nitrate of soda on the quantitative and qualitative development of sugar beets on Gottland marsh soils; culture trials with barley on clay soil from Ultuna; determination of the lime content of oats grown on limed and unlimed soil; culture trials with precipitated phosphate of calcium manufactured through electrolysis, for the determination of its value as a fertilizer for peas; culture trials with oats, with a view of determining the effect of increasing lime fertilization with different phosphatic fertilizers; culture trials with oats for the purpose of determining in how far the action of different phosphatic fertilizers depends on the character of the nitrogenous fertilizers applied at the same time; and analysis of Rippert's preservative for barnyard manure. The usual accounts of the administration of the department, officers, donations, etc., completes the report.—F. W. WOLL.

BOTANY.

Botanical work in the Philippines, E. D. MERRILL (*Philippine Bureau Agr. Bul. 4, pp. 53, pl. 1*).—An account is given of investigations on the Philippine flora between 1611 and the present day. This report includes notes on the investigations of the Spanish botanists, as well as the botanical work published on the Philippine flora in Europe and America, together with sketches of the herbaria, libraries, and

botanical gardens of Manila. Notes on the work accomplished since American occupation and a bibliography of the more essential books relating to the botanical work in the Philippines are also given.

A study of the distinguishing characteristics of oat varieties, DUFOUR and DASSONVILLE (*Rev. Gén. Bot., 15 (1903), No. 175, pp. 289–309, figs. 3*).—The authors have made a botanical study of color, awns, size, form, weight, proportion of seed to chaff, size of pedicels, and the cicatrix at the base of the grain, as characters for the differentiation of the numerous varieties of oats. They conclude that there is no one character upon which to base varietal differences, but that many varieties may be distinguished by a combination of characters.

The color of the grain is one character which is the most easily recognized and one of the most important, but in using this character for the differentiation of species it is necessary to consider the color of the grain in mass rather than that of individual seed since slight variations are frequently noticed in individuals of the same variety.

Descriptions are also given of the seed of a number of other species of Avena and directions given for distinguishing them from those of *A. sativa.*

The effect of gases and fumes upon cultivated plants, U. BRIZI (*Staz. Sper. Agr. Ital., 36 (1903), No. 4–5, pp. 279–384, pls. 2, figs. 4*).—Attention is called to the effect of gases and fumes from various industrial establishments, such as gas works, chemical works, smelters, foundries, etc., in their bearings on crop production, as well as the important legal aspect of the subject. A review and summary is given of considerable literature relating to the subject, and the author gives the results of his observations and experiments along this line.

The effect of sulphur dioxid, sulphurous and sulphuric acids, hydrochloric acid, fumes of various minerals, such as arsenic, zinc, mercury, etc., the vapors arising from the manufacture of superphosphates and sulphuric acid, nitric fumes, coal smoke, illuminating gas, etc., upon a large number of economic plants is shown, and experiments are reported which were conducted to discover, if possible, some means of preventing or moderating the injurious effects produced by these agents. Many of the gases, especially the sulphurous and hydrochloric acids, rapidly plasmolyze the cell contents of the plant, causing a discoloration that is often mistaken for a fungus attack, and finally result in the disorganization of the chloroplastids. Coal smoke was found to be injurious principally from the mechanical effect of its deposition on foliage, although the gases often had an important effect on the plants. A bibliography of more than 100 titles completes the paper.

Influence of medium on the acids of plants, E. CHARABOT and A. HÉBERT (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 17, pp. 1009–1011*).—After briefly summarizing previous investigations regarding the formation of ethers, alcohols, and acids in plants, an account is given of the author's investigations on the influence of the medium in which plants are grown on the volatile acids which they contain. At the same time the variation in the alkalinity of the ash of the plants was studied.

The experiments were made on peppermint cultivated in soils to which different mineral salts were added, and the results compared with check plants grown in the standard soil. The quantity of volatile acids was determined in leaves from different parts of the plant and the averages taken.

In general it was found that mineral salts added to the soil increased the amount of volatile acid in the fresh leaves, but this difference seemed to be apparently due to differences in the hydration of the plants. It was less noticeable when compared with the dry weight of the leaves. It was found that the chlorids and sulphates slightly increased the proportion of volatile acid to dry weight of the leaf, the nitrates reducing it slightly, while disodium phosphate increased the proportion very materially. Tables are given showing the proportion of the volatile acids to the total acid of the plants. The salts which favor the reduction of water in the plants tended to increase the proportion of volatile acids to the total acids.

In considering the effect of different salts on the ash, the authors found that at the beginning of plant growth the ash of the above-ground parts of the plants was more alkaline than the roots. As the plants developed the alkalinity of the ash of the aerial parts of the plant decreased and that of the roots increased, until finally the ash of the roots was decidedly more alkaline than that of the aerial organs. This indicates that mineral salts in general increased the proportion of combined acids in the aerial organs of the plant, while in the roots the differences are less noticeable.

Influence of medium on the formation and evolution of perfumes by plants, E. Charabot and A. Hébert (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 26, pp. 1678–1680*).—The results of a study on the effect of different culture media in the production of perfume by plants are reported, in which it is shown that whatever stimulates the transpiration and chlorophyll functions of the plant favors the evolution of perfumes.

Influence of formaldehyde on the growth of white mustard, Bouilhac and Giustiniani (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 19, pp. 1155–1157*).—Experiments were conducted to discover whether one of the higher plants would be able to directly assimilate formaldehyde.

White mustard was grown in flasks placed in a greenhouse in such a way as to receive a very feeble illumination. The object of this was to cut off as much as possible the carbon dioxid assimilation of the plant, and as a possible substitute a few drops of formaldehyde were added to the different flasks. After a few days the plants did not seem to suffer from the poisonous action of the formaldehyde, and under the conditions of the experiment the formaldehyde rapidly disappeared.

After carrying on the experiments for some time and comparing the plants with normally grown specimens, it was concluded that traces of formaldehyde were not injurious to the white mustard, and that that substance could be assimilated by it and serve as a source of carbohydrates where there was an insufficiency of light for the chlorophyll assimilation. In a repetition of the experiment, in which the amount of light was still more reduced, all the plants died, showing that a certain amount of light is necessary for the white mustard to assimilate formaldehyde.

On the nutrition of plants deprived of their cotyledons, G. André (*Compt. Rend. Acad. Sci. Paris, 136 (1903), Nos. 23, pp. 1401–1404; 25, pp. 1571–1573*).—The results of experiments on the nutrition of bean seedlings deprived of their cotyledons are given. An equal number of seedlings were planted under similar conditions, the only difference being that one lot had had their cotyledons removed. After growing for some time the plants were carefully examined and their fresh weight and dry matter determined.

One hundred plants grown under normal conditions increased in weight 129.17 gm., while an equal number of plants without their cotyledons increased only 51.54 gm. The increase in ash, water, etc., is shown. The principal difference was found in the organic matter which was formed by the chlorophyll in the plant, the gain for the plants possessing their cotyledons being more than double any of the others.

The nutrition of tissues in plant galls, C. Houard (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 24, pp. 1489–1491*).—Attention is called to the abnormal condition of the tissues in galls produced by various insects. These tissues are formed by numerous cells which are rich in protoplasm and nutrient material, and they serve to a considerable extent for the nutrition of the parasite. The modifications produced in the fibrovascular bundles to provide for the nutrition of these tissues have been investigated, and in the present paper the author reports upon some of the modifications.

If the parasite is an external one, such as the scale insect or some of the Hemiptera, the fibrovascular bundles are greatly hypertrophied and the phloem is greatly developed in the vicinity of the parasite. If the gall-producing animal lives in the

bark, the cortical cells, which serve for its nutrition, derive their sustenance through the phloem of the annular bundles. In case the parasite lives deep within the tissues there is a decided modification of the wood of the stem and the parasite is brought in contact with the nonlignified portions of the woody tissue cells and with the thin wall cells of the secondary phloem. If the parasite lives within the pith a number of different modifications are produced, all of which are described.

In general, in the galls produced on stems, the nutrition of the abnormal tissues adjacent to the parasite is secured through the fibrovascular bundles, or other small bundles which are specially produced under the stimulating action of the parasite.

Cyanogenesis in plants, W. R. DUNSTAN and T. A. HENRY (*Proc. Roy. Soc. [London], 72 (1903), No. 482, pp. 285-294*).—In this paper, which is the third of a series on the same topic, the authors give an account of phaseolunatin, a cyanogenetic glucosid of *Phaseolus lunatus*. It is stated that the white cultivated beans, commonly known as Lima beans, have never been known to be poisonous, but the colored ones as well as the plant in a semiwild state have frequently exhibited marked poisonous properties.

Previous investigations have been made to determine the presence of hydrocyanic acid in this plant, but it was found not to exist as such but to be probably in the form of a glucosid. In the authors' investigations the beans were powdered and moistened with cold water and in a few minutes the odor of hydrocyanic acid became perceptible. An attempt was made to estimate the amount of hydrocyanic acid produced, as well as to isolate and determine the constitution of the glucosid phaseolunatin. The glucosid proved to be a cyanogenetic one, differing however from the glucosids amygdalin, lotusin, and dhurrin. This glucosid seems to be present throughout the entire life cycle of *Phaseolus lunatus* and associated with it was the enzym required for its hydrolysis.

The constant presence of these substances has led the authors to believe that these glucosids play some definite part in the metabolism of the plants. The reason for the disappearance of cyanogenetic glucosids from the seeds of this bean, as well as from the bitter almond when cultivated, is attributed to the stimulus to the metabolism of the plant resulting from improved nutrition and environment.

Teratological forms of Sterigmatocystis nigra deprived of potassium, M. MOLLIARD and H. COUPIN (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 26, pp. 1695, 1696*).—The effect of depriving this fungus of potassium was studied by means of water cultures in which this substance was omitted. This produced marked morphological changes in the fungus, which were particularly apparent in the conidia. The spores seemed to be formed with great difficulty, while the conidia were very proliferous. The conidia were also smaller and less cuticularized.

A study of a unicellular green alga occurring in polluted water, with special reference to its nitrogenous metabolism, HARRIETTE CHICK (*Proc. Roy. Soc. [London], 71 (1903), No. 475, pp. 458-476, pl. 1*).—A study is reported of a small, unicellular, green alga, which was noticed as frequently present in sewage and sewage materials when these had been kept for some time, particular reference being paid to its nitrogen metabolism. Diluted ammoniacal solutions were found to have become infested with this alga, a fact that seemed of interest in the physiology of the plant.

Pure cultures were prepared and grown in various media. While chlorophyll-bearing plants in general prefer their nitrogen in the form of nitrates, these are found to readily assimilate nitrogen in the form of ammonia and to present the best growth when grown in cultures containing ammonia or various ammoniacal compounds. This feature of the nitrogen assimilation of the plant is believed to be a specialized characteristic developed from the growth of the plant in water, which contained comparatively large amounts of ammonia such as are found in sewage and sewage-polluted water.

The present status of knowledge concerning the root tubercles of leguminosæ and their functions, K. Störmer (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), No. 4, pp. 129–146, figs. 3*).—A critical review is given of some recent publications regarding the nature and functions of root tubercles on leguminous plants.

A contribution to the mycorrhiza problem, L. Hiltner (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), Nos. 1, pp. 9–25; 2, pp. 67–82, pl. 1, figs. 3*).—A contribution is given to the knowledge of the biology and physiology of endotrophic mycorrhiza, such as are found on the roots of a number of forest trees and shrubs, as alders, Eleagnus, Podocarpus, Myrica, various conifers, etc. The roots of these plants are attacked by species of the fungus Frankia, which produce characteristic tubercles or galls. Through these, the author argues, free atmospheric nitrogen is assimilated, as is done in the case of leguminous plants infested with bacteria. The host plant resorbs the rich nitrogenous material secreted by the bacteria in mycorrhiza and in the organisms themselves. The same phenomena are believed to extend to other plants, particularly to gingko and various conifers. The second part of the paper discusses the nutrition of forest trees through mycorrhiza.

A contribution to the mycorrhiza subject, F. W. Neger (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), No. 9, pp. 372–376, fig. 1*).—This article gives an account of experiments in the sterilization of soil by superheated steam, chloroform, and ether, the effect of the treatment being studied on the growth of wheat and mustard.

Mycorrhiza formations on pine trees and high moors, C. von Tubeuf (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), No. 7, pp. 284, 285, fig. 1*).—The author calls attention to the claim that mycorrhiza can not be produced in humus soils, and shows figures of roots of *Pinus sylvestris*, in which an abundant production of mycorrhiza is evident.

Form of root tubercles on moor plants, C. von Tubeuf (*Naturw. Ztschr. Land- u. Forstw. 1 (1903), No. 6, pp. 237, 238, figs. 2*).—A discussion is given of the formation of tubercles on the roots of a number of moor plants, the outgrowth being due to mycorrhiza.

A contribution to the knowledge of the purple melic-grass, C. von Tubeuf (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), No. 6, pp. 238–246, figs. 2*).—Studies are reported on the purple melic-grass (*Molinia cærulea*). This grass is quite abundant in certain parts of Europe, growing in sandy regions, and the author describes its method of propagation, the occurrence and significance of mycorrhiza upon its roots, and their possible influence on nitrogen assimilation.

The form and structure of the mycodomatia of Myrica cerifera, J. W. Harshberger (*Proc. Acad. Nat. Sci. Philadelphia, 55 (1903), pt. 2, pp. 352–362, pls. 2*).—The occurrence of coralline tuberculous outgrowths on roots of *Myrica cerifera* is noted, this host plant not having been previously included in a list of the higher plants known to be infested by these outgrowths.

The author reviews the synonomy of the fungi which cause these peculiar developments, and is led to believe that the species in this instance is *Frankia brunchorstii*. A study has been made of the galls and the fungus producing them on the waxberry, and it was found that the mycodomatia grew on the short adventitious roots put out by the stems of waxberry bushes whenever they were covered by sand. On some of the smaller roots the galls were comparatively simple, but later by the increase in the number of the forked fiber-like swellings they became aggregated into clumps the size of a walnut.

A study was made of the fungus in order to determine its relative position, and the writer believes that the genus Frankia should be placed among the Oomycetes, close to Pythium and Peronospora.

ZOOLOGY.

Cusack's glossary of biological terms, W. E. CLARKE (*London: City of London Book Depot, 1903, pp. 165, figs. 251*).—A list of the more common technical terms used in the description and discussion of plant and animal species in laboratory and class-room work. The volume is intended as a guide for students in familiarizing themselves with the meaning of these terms.

First lessons in zoology, V. L. KELLOGG (*New York: Henry Holt & Co., 1903, pp. X+363, pl. 1, figs. 257*).—This volume is intended for the use of pupils in grammar schools and high schools in which laboratory facilities are not provided. It is written to serve as a guide in the personal observations of pupils. The subjects discussed in the volume, include the life history of mosquitoes, silkworms, dragon flies, toads, and certain species of birds, the anatomy of various types of animals, classification, relationship of animals to one another, and notes on the rearing, collection, and distribution of various animal species.

A review of papers on agricultural zoology presented at the Cercle d'Études during the year 1901–2, J. POSKIN (*Bul. Cercle d'Études Agron.* [*Brussels*], *1903, No. 7, pp. 323–334*).—Brief notes on the literature discussed before this body on the subject of economic mammals, birds, batrachians, moths, worms, mites, and insects.

Zoological yearbook for 1902, P. MAYER (*Zool. Jahresber., 1902, pp. VIII+584*).—As in previous years this report contains brief abstracts of the work done during the year in various lines of zoology, in connection with classified bibliographical lists.

Author index to the zoological yearbooks for 1891–1900, E. HENTSCHEL and E. SCHOEBEL (*Autorenregister zu den Zoologischen Jahresberichten für 1891–1900. Berlin: R. Friedländer & Son, 1903, pp. 226*).—A list of all the names of authors whose works have been mentioned in the zoological yearbooks during the period 1891–1900.

International catalogue of scientific literature. L—General Biology (*Internat. Cat. Sci. Lit., 16 (1903), pp. XIII+144*).—This number of the international catalogue is prepared along the lines followed in previous numbers, and includes literature relating to general biology, methods and apparatus, general morphology, physiology, and cytology.

Animals useful to agriculture, C. LANDES (*Jour. Agr. Prat.* [*Toulouse*], *99 (1903), No. 3, pp. 142–171*).—Notes are given on the economic relations of birds, with special mention of the feeding habits of a number of species, and on insectivorous mammals, reptiles, batrachians, and beneficial insects.

Catalogue of Canadian birds, II, J. MACOUN (*Ottawa: Geol. Survey of Canada, 1903, pp. 219–413*).—This part of the author's catalogue of Canadian birds includes a discussion of the distribution and habits of birds of prey, woodpeckers, flycatchers, crows, jays, and blackbirds.

The economic value of birds to the State, F. M. CHAPMAN (*Albany: New York State Forest, Fish and Game Com., 1903, pp. 66, pls. 12*).—The author discusses the economic relation of birds to forests, fruits, and field crops. A brief discussion is given of the laws which have been passed for the protection of birds and of modifications which should be made in these laws.

Brief mention is made of the methods ordinarily employed in studying the food of birds, and statistics are given on the feeding habits of various water birds, grouse, doves, hawks, owls, cuckoos, woodpeckers, flycatchers, crows, jays, blackbirds, robins, sparrows, swallows, etc. A number of species are illustrated in colors by L. A. Fuertes, and a brief bibliography of articles relating to the food of American birds is also given.

The economic value of our native birds, H. A. SURFACE (*Pennsylvania State Dept. Agr., Zool. Quart. Bul. 1 (1903), No. 2, pp. 16, fig. 1*).—An analytical key is

given for the determination of families of Pennsylvania birds, together with brief notes on the economic importance of these families.

Birds in relation to agriculture, GUNNING (*Transvaal Agr. Jour., 2 (1903), No. 5, pp. 1–3, pls. 5*).—The feeding habits of vultures, falcons, hawks, buzzards, and eagles are described with reference to the economic relations of these birds to agriculture. All of the species are believed to do more good than harm, under ordinary conditions.

The bird as the laborer of man, W. T. L. TRAVERS (*Trans. and Proc. New Zealand Inst., 35 (1902), pp. 1–11*).—Attention is directed to the agency of birds in controlling the ravages of insect pests, and a number of specific instances are noted in which birds are shown to have been of economic importance in the control of these pests.

Observations on birds, S. P. JAMES (*Sci. Mem. Med. and Sanit. Depts. India, n. ser., 1902, No. 2, pp. 99–106*).—Experiments were made in allowing species of Anopheles and Culex to feed on birds infected with proteosoma and halteridium. Sparrows and pigeons were used in these experiments. It was found that sparrows were susceptible to both forms of parasites, while pigeons became infected only with halteridium. Both Culex and Anopheles were found to feed readily on sparrows and pigeons when confined in cages with mosquito netting upon the walls. No change in temperature was observed in these birds after infection with the malaria parasites, but the normal temperature of a sparrow was found to be 106 to 107.5° F., and of a pigeon 107 to 108° F.

Our smallest birds and their habits, W. WHYTE (*Trans. and Proc. Perthshire Soc. Nat. Sci., 3 (1902–3), No. 5, pp. 238–245*).—Notes are given on the feeding habits and economic relations of the goldcrest, firecrest, blue tit, coal tit, long-tailed tit, and common wren.

Annual report of the Ornithological Society of Munich for 1901–2, C. PARROT (*Jahresber. Ornithol. Ver. München, 3 (1902), pp. 392, pl. 1*).—In this report notes are given on the proceedings of the various meetings of the society, and a number of papers which were read are reproduced. These cover a variety of subjects and are largely concerned with the habits and biological relations of a number of birds, including *Phylloscopus bonellii, Ortygometra porzana, Clavicola riparia,* etc.

The duck hawk (Falco peregrinus anatum) in Iowa, B. H. BAILEY (*Proc. Iowa Acad. Sci. 1902, pp. 93–98*).—Notes are given on the feeding habits and biology of this bird.

A rabbit drive in Riverina, New South Wales, DAISY M. BATES (*Jour. Dept. Agr. West. Australia, 7 (1903), No. 2, pp. 111–115*).—A description of a rabbit drive undertaken for the purpose of reducing as far as possible the injury from the excessive number of rabbits. During this drive about 4,000 rabbits were secured.

Soil and topographical influence upon the color and size of the European mole, V. P. VRADI (*Selsk. Khoz. i Lyesov., 211 (1903), Oct., pp. 175–183*).—Notes are given on dark and light forms, and in general upon the distribution of color forms of the European moles in various regions. The occurrence of certain color forms in different months of the year is shown in tabular form.

The destruction of rats on ships as a means of preventing the introduction of plague, NOCHT and G. GIEMSA (*Arb. K. Gesundheitsamte, 20 (1903), No. 1, pp. 91–113, figs. 9*).—According to the extensive investigations reported by these authors the safest and most practical method of destroying rats on shipboard consists in the production and proper distribution of carbon monoxid. This gas can be easily and economically produced, and detailed notes are given on suitable apparatus for producing it. The gas is extremely poisonous to rats and is perfectly harmless to the most delicate fabric.

The monthly bulletin of the division of zoology, H. A. SURFACE (*Pennsylvania State Dept. Agr., Mo. Bul. Div. Zool., 1 (1903), No. 7, pp. 32, pl. 1*).—Brief notes

are given on insect remedies for November, treatment for San José scale, destruction of rats, protection of birds, notes on game laws, etc.

Game laws for 1903, T. S. Palmer, H. Oldys, and R. W. Williams, Jr. (*U. S. Dept. Agr., Farmers' Bul. 180, pp. 56, figs. 5*).—This is a revised and condensed form of Bulletin 16 of the Division of Biological Survey (E. S. R., 13, p. 532). The special purpose is to present in a brief form information regarding the game laws and requirements concerning the shipment and sale of game.

METEOROLOGY—CLIMATOLOGY.

Monthly Weather Review (*Mo. Weather Rev., 31 (1903), Nos. 7, pp. 309–364, figs. 12, charts 9; 8, pp. 365–406, figs. 8, charts 10; 9, pp. 407–448, charts 10*).—In addition to the usual reports on forecasts, warnings, weather and crop conditions, meteorological tables and charts for the months of July, August, and September, 1903, recent papers bearing on meteorology, etc., these numbers contain the following articles and notes:

No. 7.—Special contributions on Note upon Economical Shapes for Cutting Envelopes of Balloons (illus.), by C. F. Marvin; Benjamin Thompson—Count Rumford (illus.), by D. T. Pierce, jr.; On Curves Representing the Paths of Air in a Special Type of Traveling Storm (illus.), by W. N. Shaw; The Meteorological Work of the Expedition to the Bahamas, by O. L. Fassig; and Observations of Solar Radiation with the Angstrom Pyrheliometer at Asheville and Black Mountain, N. C. (illus.), by H. H. Kimball; and notes on the "guns" of Lake Seneca, N. Y.; variation of gravity over the deep sea; Weather Bureau men as instructors; the droughts of 1901–1903; the rain maker in Australia; meteorology in the universities; the movements of the air within areas of high and low pressure; and meteorology in the summer schools.

No. 8.—Special contributions on The Periodicity of Sun Spots and the Variations of the Mean Annual Temperatures of the Atmosphere, by C. Y.; and hurricane on September 11 in the Bahamas.

Report of the meteorologist, W. H. Bishop (*Delaware Sta. Rpt. 1902, pp. 152–158*).—Monthly summaries of observations at 3 places in Delaware on temperature, pressure, precipitation, relative humidity, and prevailing winds during the year ended June 30, 1902, are given, with a summary of observations on temperature and precipitation during the calendar year 1901. The summary for 1901 is as follows:

Annual summary of meteorological observations in Delaware, 1901.

Place of observation.	Temperature. Highest.	Lowest.	Mean.	Total rainfall.	Number of days on which 0.01 in. or more of rain fell.
	Deg. F.	*Deg. F.*	*Deg. F.*	*Inches.*	
Newark	(July 2) 100	(December 22) 6	51.1	44.62	84
Dover	(July 1) 103	(January 20) 9	53.3	46.75	75
Seaford	(July 1) 102	(December 22) 9	53.8	36.73	84

Meteorological summary for 1901, C. A. PATTON (*Ohio Sta. Bul. 135, pp. 103–115*).—This summary includes notes on the weather and tabulated daily and monthly records of observations at the station at Wooster, Ohio, on temperature, precipitation, cloudiness, direction of the wind, etc., and for comparison, similar data for previous years and for other parts of the State. The following is a summary of results:

Summary of meteorological observations in Ohio.

	For the experiment station. 1901.	1888–1901.	For the State. 1901.	1888–1901.
Temperature (°F.):				
Mean	48.7	49.2	50.2	50.8
Highest	(July 1, 22, 28, and 29) 95.0	(Aug. 8, 1891) 99.0	(July 22) 109.0	(July 4, 1897) 113.0
Lowest	(Dec. 21) −11.0	(Feb. 10, 1899) 21.0	(Feb. 23) −20.0	(Feb. 10, 1899) −39.0
Mean daily range	20.1	20.05		
Greatest daily range	(Apr. 30) 43.0	(Oct. 6, 1895) 55.0	(Dec. 14) 61.0	(Sept. 28, 1897) 67.0

Meterological observations obtained by the use of kites off the west coast of Scotland, 1902, W. N. SHAW and W. H. DINES (*Proc. Roy. Soc.* [*London*], *72* (*1903*), *No. 477, pp. 13–15*).—A summary is given of the results of observations on humidity and temperature made by means of 40 kite ascents during July and August, 1902, 2 from a small island in Crinan Bay, Argyllshire, the rest from the deck of a small tug steaming in Jura Sound or neighboring sea.

"Kites were raised on 71 occasions, but on 31 of them the force of the wind, even when assisted by the speed of the tug at 7 knots, was not sufficient to raise the recording instruments. On those occasions an experimental form of registering air thermometer alone was carried. The average recorded height of ascents with instruments was 5,900 ft. (1,940 meters), and average computed height of the 71 ascents 4,200 ft. (1,400 meters); a height of 12,000 ft. (3,700 meters) was passed on two occasions, and 15,000 ft. (4,500 meters) was reached once, but the record was lost owing to the

breaking away of the highest kite." The fall of temperature for each 500 meters of ascent was as follows:

Fall of temperature in degrees centigrade for each 500 meters of ascent.

Height.	July.		August.	
	Ascents.		Ascents.	
Meters.		*Degrees C.*		*Degrees C.*
0 to 500	22	3.0	13	2.6
500 to 1,000	16	2.8	11	2.8
1,000 to 1,500	9	2.2	9	2.3
1,500 to 2,000	2	2.0	7	2.1
2,000 to 2,500	1	2.0	3	2.0
2,500 to 3,000	....	....	2	2.0
3,000 to 3,500	....	....	2	1.7

"The range of fall for the first 500 meters varied from 4 to 1° C. The smallest fall was associated with an inversion of temperature gradient not far from the surface. An inversion of temperature gradient with very dry air above a layer of clouds was shown also on one of the occasions of steepest gradient near the surface. The steep gradients observed in the lower strata are shown to be associated with anticyclonic conditions preceding the approach of a depression, and by examples of five occasions it is shown that the characteristic of the passage of a depression is that the isothermal lines of the diagram open out as the depression comes on, the average diminution of gradient for the change of barometic condition amounting to as much as 50 per cent." The average Crinan temperature gradient was almost identical with that given by Hann, "and with the conventional correction in use in this country for the reduction of temperature to a common level, viz, 1° F. per 300 ft."

As regards the differences between the temperatures as observed in the free air at the same height as the summit of Ben Nevis and those recorded on the mountain itself, it was noted that "the differences are always in favor of the free air, which is shown to be on the average 2.6° warmer than the mountain summit."

Meteorology, J. L. SOUTTER ET AL. (*Transvaal Agr. Jour., 1 (1903), No. 2, pp. 55, 56*).—Monthly summaries are given of observations on rainfall and shade maximum and minimum temperatures (for Sept.–Nov.) at Pretoria and Johannesburg during 1902, and on rainfall at Vereeniging during the year ended November 30, 1902. The average monthly rainfall at Pretoria for the 10 years ended June 30, 1902, is also reported. The average yearly rainfall at Pretoria during 10 years was 26.91 in.; the rainy days 89, occurring mainly from November to March, inclusive.

Meteorology of New Zealand (*Trans. and Proc. New Zealand Inst., 35 (1902), pp. 579–597.*)—This contains a comparative summary of observations on pressure, temperature, rainfall, wind movement, etc., for 1902 and 38 previous years at Aukland, Wellington, and Dunedin; the average spring, summer, autumn, and winter temperatures of 1901 and 1902 at these three places; brief remarks on the weather of each month of 1902; a record of earthquakes reported during the year; and records of Milne seismographs at Wellington and Christchurch during 1902.

Organization of observations on agricultural meteorology at experiment stations, B. B. VINER (*Trudi Syez. Dyeyat. Selsk. Khoz. Opuitn. Dyela.; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 4, pp. 509, 510*).

Climate of the Argentine Republic, W. G. DAVIS (*Buenos Ayres: Min. Agr., 1902, pp. 154, charts 26*).—The text of the present work, which is printed in Spanish and English in parallel columns, "is essentially a reproduction of the chapter on climate which appeared in the first volume of the Second Census of the Argentine Republic (May 10, 1895), published in 1898, but the tabular values have been modified to correspond to the five years' observations made since the original article was written. . . . The mean values, deduced from long series of observations made

prior to 1896, have been but slightly modified by the additional five years' results, the greater scope of the present volume being due to the more extended period of observations and the increase in the number of stations."

The characteristic peculiarities of climate which prevail in the northern, central, and southern sections of the littoral, Mediterranean, and Andine divisions of the Republic, whose climatic differences depend principally on their latitudinal situation and elevation, are discussed and detailed data are given relating to temperature of the air and soil, pressure, humidity of the air, evaporation, sunshine and clouds, rainfall (including rain, snow, hail, and thunderstorms), and wind. The principal climatic features are charted.

As would be expected of a region covering 33 degrees of latitude and a wide range of altitude, there are great differences of climatic conditions in Argentine Republic. Starting with a mean temperature of 23° C. on the eastern border of the intertropical district (north of the Tropic of Capricorn), the mean temperature drops to less than 14° on the western border, the rainfall declining from 1,600 to 50 mm. In latitude 30 to 31°, 8 to 9° farther south, the eastern pampas region has a mean temperature of 19° C., which rapidly falls as the slopes of the Cordilleras are ascended. At the same time the rainfall declines from 1,000–1,200 to less than 100 mm. Ten degrees farther south there is little change from east to west, the mean temperature being 13 to 14° C., the rainfall 200 to 400 mm. At the extreme south, in latitude 55°, the climate is rigorous. In Tierra del Fuego the mean summer temperature is 8 to 9° C., the winter temperature 2 to 3°. Snow occurs during every month of the year and rains are frequent. The mean annual precipitation of Staten Island is 1,400 mm., although less than half as much falls in Tierra del Fuego.

Agricultural climatology, Grégoire and Vandervaeren (*Bul. Cercle Études Agron. [Brussels], 1903, No. 8, pp. 355–359*).—A plan for concerted observations on this subject in Belgium is outlined.

WATER—SOILS.

The industrial uses of water, H. de la Coux, trans. and rev. by A. Morris (*New York: D. Van Nostrand Co., 1903, rev., pp. 364*).—Treats of the composition, effects, and defects of water from an industrial standpoint—for use in boilers, dye, print, and bleach works; in textile industries; soap works, laundries, tanning, paper-making; photography; sugar-refining; making ices and beverages; cider making; brewing; and distilling. Methods of purifying waters and correcting their defects are described.

Soil temperatures and vegetation, D. T. MacDougal (*Mo. Weather Rev., 31 (1903), No. 8, pp. 375–379, figs. 7*).—This is an account of experiments with an automatic apparatus for determining soil temperatures, described in a previous number of the Record (E. S. R., 14, p. 125). The installation of the apparatus in the grounds of the New York Botanical Gardens is described, and records obtained with it during 14 months are discussed.

The records show that "the maximum daily temperatures occurred between 8 and 11 p. m., and the minimum 12 hours later, or between 8 and 10 a. m. The optimum temperature for absorption by roots lies well above that of the soil at the depth at which the observations were made. It follows, therefore, that the temperature of the soil approaches this optimum most nearly, and offers most favorable conditions for the taking up of watery solutions at a time of the day when the amount of water thrown off by the shoot and of mineral matter used in metabolism are nearing the minimum by reason of the absence of light, lowered air temperature, and consequent increased humidity of the air." The influence of these inharmonious conditions in causing guttation excretions from plants is explained. The greatest variation in temperature recorded during 24 hours was 2° C. (3.6° F.) on June 28 and July 16. The maximum temperature recorded was 13.2° C. (56° F.) in July, and the minimum −3° C. (26.6° F.) in December, giving a total annual variation of 16.2° C. (29.4° F.). "Both the maxima and minima are higher in January than in December and are still higher in February, at which time the temperature of the air reaches its annual minimum. As a consequence of the above conditions the roots of plants at a depth of a foot (30 centimeters) in this locality find increasingly more favorable conditions for activity after the latter part of December. . . . The approach of the spring season in this locality therefore finds the root systems and absorbing organs of the vegetation which penetrates the soil to the given depth in a state of comparatively great activity, and it needs but the exposure of a few days or even of a few hours in some plants to allow for very marked development of the stems, leaves, and flowers."

A notable difference in temperature of the aerial and subterranean portions of plants was observed, and the influence of this condition on the transport of fluids and solutions from one part of the plant to another is explained.

Investigations on the influence of the volume of the soil on the yield and composition of plants, O. Lemmermann (*Jour. Landw., 51 (1903), No. 3. pp. 279–285*).—The results here reported confirm those of previous experiments (E. S. R., 14, p. 1056) in showing a decided relation between the yield and the volume of the soil in which the crop is grown. The experiments here reported were made in 2 series of pots, in one of which each pot contained 30 and in the other 15 kg. of soil. All of the pots except those used as checks were supplied with a sufficient amount of the necessary fertilizing constituents.

The author concludes that the larger yield with the larger pots and the smaller yield from the smaller pots had no relation to the supply of plant food, but depended entirely upon the space which was available for the root development of the individual plants.

On the lime requirements of soils, and its determination, Immendorff (*Oesterr. Chem. Ztg., 6 (1903), No. 18, p. 412*).—This is a brief note on an address before the International Congress of Applied Chemistry at Berlin in 1903. The calcium compounds which are considered of importance in relation to plant nutrition are calcium carbonate, calcium combined with humus acids, zeolitic lime compounds, and calcium silicate. As regards their lime requirements, the author classifies soils as follows: (1) Acid soils, prominent among which is sour moor soil, and in which the author recommends that humus acid be determined by means of Tacke's method; (2) neutral soils tested by means of boiling with sulphuric acid and titration; and (3) alkali soils, which almost always contain calcium carbonate, which may be detected by means of hydrochloric acid. In the author's opinion soils should not contain less than 0.25 per cent of soluble calcium salts. In case of alkali soils the physical properties must also be taken into consideration.

The importance of calcium and magnesium salts in the nutrition of plants, Gössel (*Chem. Ztg., 27 (1903), No. 78, p. 952*).—A brief account is given of experiments with water cultures and soils to test the accuracy of Loew's hypothesis regard-

ing the necessity of maintaining a certain ratio between calcium and magnesium compounds in the soil. The results indicate that plants grow well in media containing more magnesium salts than lime salts. The highest yields were obtained in water culture with 0.4 part of lime (CaO) to 1 part of magnesia (MgO) and hence the results did not bear out Loew's hypothesis.

Fertility of soil according to the most recent data, S. BOGDANOV (*Selsk. Khoz. i Lyesov., 210 (1903), Sept., pp. 628–667*).—The author attempts a systematic discussion of the question of the fertility of the soil, giving a summary of his previous articles on the subject (E. S. R., 12, p. 725) and supplementing it with results obtained by other investigators. He gives especial attention to the sulphur requirements of plants, which he believes have heretofore been underrated, and reports experiments made in 1898 and 1899 with special sulphate fertilizers in comparison with other more common fertilizing materials on white mustard grown in pots of clayey chernozem. The application of sulphuric acid in form of sodium sulphate greatly increased the yield in both years.—P. FIREMAN.

The green sandstone soils of Lower Bavaria and the Oberpfalz, PUCHNER (*Vrtljschr. Bayer. Landw. Rath., 8 (1903), No. 3, pp. 530–533*).—Physical and chemical examinations of several of these typical soils are briefly reported. The results show that the soils are as a rule light and have only medium retentive power for moisture. They need phosphoric acid most of all, occasionally potash, and usually nitrogen.

Some investigations on the physical properties of soils, W. BAGGER (*Ugeskr. Landm., 48 (1903), Nos. 12, pp. 133–135; 13, pp. 152, 153*).

A new theory of the soil, A. D. HALL (*Nature [London], 69 (1903), No. 1777, pp. 58, 59*).—A critical review of Bulletin 22 of the Bureau of Soils of this Department (E. S. R., 15, p. 457).

On the origin, properties, and applicability of Swedish moor soils, R. TOLF (*Svensk. Mosskult. Tidskr., 17 (1903), No. 4, App., pp. 32*).

Worn-out farms, W. M. MUNSON (*Maine [Univ.] Bul., 6 (1903), No. 2, pp. 9–24*).—A general discussion of the causes of soil exhaustion and of practical means for the restoration of worn-out lands.

Studies in soil bacteriology, F. D. CHESTER (*Delaware Sta. Rpt. 1902, pp. 46–78, figs. 6*).—Studies are reported on the variation in the number of bacteria in soils, the effect of stirring and pulverizing soil on its bacterial content, the effect of mineral fertilizers on the development of soil bacteria, the predominating bacteria in a soil sample, and on the nitrogen-assimilating bacteria of soils.

In the previous report (E. S. R., 14, p. 232) the author showed the wide variation in the number of bacteria in soils of adjacent plats bearing different cover crops. The variation within narrow horizontal limits was investigated, samples being taken at intervals of 12 in. and the number of bacteria per gram of dry soil determined. The determinations, which are given in tables, show that within a range of 5 ft. the number of bacteria in the soil do not vary greatly. In order to test further the limit of variation, plats were planted with peas and vetches and at intervals of 10 ft. soil samples were removed for examination, the sample being taken to a depth of 8 in. The determinations made in these experiments indicated that a fairly reliable average of the number of bacteria in the soil of the field can be obtained by taking samples at intervals of 10 to 20 ft. and thoroughly mixing them.

The effect of stirring and pulverizing soil on its bacterial content was investigated to see what relation tillage would bear to the development of soil bacteria. Samples of soil were collected and thoroughly mixed, all lumps being reduced to uniform size. This mixing and pulverizing was assumed to be equivalent to thorough tillage. The bacterial content of the soil was determined immediately after filling the pots and at

intervals of a week to 10 days. It was found that stirring and pulverizing the soil stimulated the development of soil bacteria. The number per gram of dry soil increased from 2,000,000 to 12,600,000 in 24 days.

The effect of mineral fertilizers on the development of soil bacteria was investigated, the experiments being conducted in galvanized-iron pots. The soil samples were placed in the pots and a complete fertilizer composed of sodium nitrate, potassium chlorid, and sodium phosphate was added to each. Bacterial analyses of the soil in the pots were made at intervals and the results showed that even the liberal use of mineral salts, which act as great stimulators to plant growth, were without appreciable effect on the bacterial development.

A study was made of the predominating bacteria in a soil sample, which was examined by methods of dilution and culture. It was found that 3 species of bacteria predominated. The first, which is designated as "Bacterium A" and to which the author has given the name *Streptothrix soli* n. sp., was represented by 1,600,000 per gm. of dry soil; the second, *Bacterium flocosum* n. sp., 1,200,000; and *Bacillus delavariensis*, 300,000. These different organisms are described in considerable detail and their relationship pointed out.

Studies are reported on the nitrogen-assimilating bacteria of soils, the author reviewing the investigations of Berthelot, Winogradsky, Beijerinck, and others. A preliminary report is given of his own studies of oligonitrophilous bacteria, which were isolated from Delaware soil. Three organisms, designated as *Azotobacter I*, *Pseudomonas I*, and *Bacillus I*, were studied. At the end of 28 days the first species had shown no gain of nitrogen in its culture, seeming to indicate that this organism when growing alone in pure cultures in nitrogen-free media is without the power of utilizing free atmospheric nitrogen. The other 2 organisms showed a decided increase in the amount of nitrogen, the gain in the case of the Pseudomonas species being 4.3 times the original content, while for the Bacillus the gain was 3.4 times the original content. The characters of these organisms are briefly described.

The activity of bacteria in soils, F. MUTH (*Verhandl. Naturw. Ver. Karlsruhe, 16 (1902-3), pp. 69-124, figs. 20*).—A summary of information on this subject.

FERTILIZERS.

Cover crops as green manure, C. L. PENNY (*Delaware Sta. Bul. 60, pp. 44, figs. 2.*)—This is a discussion of this subject based on yields and analyses of crops grown on the station plats in a series of experiments begun 2 years ago in cooperation with this Department. In connection with the report of the results of this investigation the author summarizes "the generally accepted views of the present day on plant nutrition in so far as it relates to the use of cover crops," incorporating much of the data which have been reported in previous bulletins of the station.

The tabular data reported include the weights per acre of the portion above ground of each crop in the state in which it was harvested, with the percentage content of nitrogen, potash, and phosphoric acid, and the weight per acre of each of these constituents; the air-dry weight per acre of the roots of several crops, in some cases in 2 layers, the first 8 in. and the next 4 in., with the percentage composition; the weight per acre and the percentage of the portion above ground and of the roots separately, both on the air-dry basis, and the weight per acre of the 3 chief constituents; for comparison a money valuation of each crop, the nitrogen being rated at 12 cts. a pound, the potash at 5 cts., and the phosphoric acid at 3 cts.; the relative yield of dry matter, nitrogen, potash, and phosphoric acid found in the tops and the roots, stated as a percentage of these respective constituents found in the whole crop; the moisture content of the surface soils used to grow the cover crops, both plowed and unplowed; and the moisture content of the corresponding subsoils.

The 8 crops giving the highest money valuation for the nitrogen, potash, and phosphoric acid produced per acre were as follows: Rye and vetch \$25.84, rape \$24.99, crimson clover \$22.37, cow horn turnips \$21.01, soy beans \$20.44, rye and

vetch $19.68, vetch $19.64, and red clover $17.90. Three of these crops contained a considerable proportion of their fertilizing value in the roots, viz, "the cow horn turnip 42 per cent, the alfalfa 40 per cent, and the red clover 30 per cent. None of the remaining 5, the soy bean, the cowpea, the vetch, the rape, and the crimson clover, had more than 10 per cent of the total value in the roots. Of the 'nitrogen gatherers' the alfalfa showed the highest relative value in the roots, while the red clover was but a trifle lower. On the contrary the crimson clover had, at least in this experiment, the lowest relative value in its roots, viz, 5 per cent. The preponderance in most cases was due chiefly to the greater weight of the tops, but due also in a less degree to the higher percentage of nitrogen and potash usually found in the tops. The potash was invariably richer in the tops, sometimes nearly threefold richer; the nitrogen was likewise richer with but one exception, the red clover. The phosphoric acid was nearly equally distributed, sometimes richer in the tops and sometimes in the roots. The relative amount of dry matter in the tops and roots, at least in the case of crimson clover, was variable both with the particular field of clover and with the stage of growth; the percentage composition was likewise subject to considerable fluctuation."

It is the author's opinion in view of these facts that the relative fertilizing value of the roots of plants is often overrated. "In many cases, at least, it is small, sometimes quite insignificant." The crops as a whole showed an average of only 4 per cent of the total roots below a depth of 8 in. The value of the phosphoric acid furnished by the crops was comparatively insignificant, the most important element being the nitrogen. The highest potash value, $8.07 per acre, was found in rape, being 32 per cent of the total value. The cow horn turnip furnished $7.14 worth of potash and the rye and vetch $6.76 worth, this being in each case about 34 per cent of the total value. The changes which the organic matter of green manures undergo in the soil by which they are rendered available as plant food are discussed in detail, and the great benefit due to improvement in physical condition by the use of such manures is explained.

On the management and effect of barnyard manure, Schneidewind (*Oesterr. Chem. Ztg., 6 (1903), No. 18, p. 412*).—This is a brief note on an address before the International Congress of Applied Chemistry at Berlin in 1903, calling attention to the fact that the most effective manure is made up of the fresh liquid portion combined with the decomposed solid portion and litter. Such manure may be obtained by the separate storage of the solid and liquid manure, but this method is as a rule impracticable. The use of sulphuric acid effectually prevents loss of nitrogen, but it also interferes with the proper decomposition of the manure. All preservative material, such as lime, gypsum, copper sulphate, etc., as well as the various acid salt preparations which are found in the market, are useless. Peat and earth are the most serviceable preservatives that can be used.

Nitrate of soda containing perchlorate and its effects on plant growth, H. Pellet and G. Fribourg (*Ann. Sci. Agron., 2. ser., 1902–3, II, No. 2, pp. 199–225, fig. 1*).—In this paper, which was presented to the International Congress of Applied Chemistry at Berlin in 1903, the authors give results of investigations by themselves and others on this subject, especial attention being given to methods of chemical examination of nitrate of soda containing perchlorates.

It is shown that commercial nitrate of soda may contain considerable amounts of perchlorates, the proportion varying from traces to 1.5 per cent. In some samples the amount present runs as high as 3.2 per cent to 6 per cent of perchlorates calculated as potassium perchlorate. The injurious effects which have frequently been observed as a result of applications of nitrate of soda have generally been attributed to potassium perchlorate. The investigations of de Caluwe, however, have demonstrated that sodium perchlorate in the proportion of 1 per cent is also injurious to vegetation and that potassium perchlorate and chlorate are much less injurious than sodium perchlorate.

The authors show that it is comparatively easy to determine the perchlorates and associated chlorates in commercial nitrate of soda. It is necessary simply to determine (1) the chlorin in the original sample and (2) the total chlorin in the calcined nitrate. The difference corresponds to the chlorin in the form of chlorates and perchlorates. By treatment of the solution left after the determination of chlorin in the original sample with lead nitrite the chlorin corresponding to chlorates is obtained. Nitrate of soda containing perchlorates as a rule contains little chlorate. Commercial nitrate always contains a certain amount of potash. It is recommended, therefore, that a complete analysis of nitrate of soda shall include determinations of chlorates, perchlorates, and potash, the chlorates and perchlorates, however, being calculated as sodium salts.

The utilization of the nitrogen of the air, A. Wiesler (*Oesterr. Chem. Ztg.*, 6 (*1903*), *No. 19, pp. 434, 435*).—This article discusses the fixation of free nitrogen by means of calcium carbide.

Fertilizer experiments with carbide nitrogen (calcium cyanamid), P. Bolin (*Landtmannen*, *14* (*1903*), *No. 39, pp. 609–611*).—The experiments were conducted on a clay soil, barley and oats being grown on the plats. The effect of the fertilizer was found to be 60 to 70 per cent of that of nitrate of soda, according to the quantities applied which varied from 150 to 225 kg. per hectare (134 to 301 lbs. per acre).—F. W. WOLL.

Experiments on methods of applying fertilizers (*Verslag. Proefstat. Suikerriet, West Java, 1903, pp. 108–111*).—Forty-four samples from a soil top-dressed with nitrate of soda and sulphate of ammonia, tested 10, 25, and 40 days after the application, showed that the distribution of the nitrogen in the soil from this source was mainly confined to a surface layer 5 cm. in depth. Where sulphate of ammonia had been applied in small depressions made into the soil, the distribution of this substance in a horizontal direction 10 days after the application varied from 6 to 9 cm. These samples showed only traces of nitrate nitrogen in the surface layer of the soil, but samples taken 15 days later plainly showed its presence. The lower layers of the soil showed neither ammonia nor nitrates and not until 40 days after the application and after a rain of 100 mm. was nitrate detected 30 cc. below the surface.

Culture trials with a fertilizer manufactured from beet-molasses refuse, H. G. Söderbaum (*K. Landt. Akad. Handl. och Tidskr.*, *42* (*1903*), *No. 2, pp. 85–94*).—The fertilizer experimented with was manufactured by the Wenck process, in which the refuse from the beet molasses, after this has been used for the manufacture of sugar or alcohol, is mixed with calcium carbonate and dried. During the drying a definite quantity of sulphuric acid is added. The resulting product forms a solid, pulverizable mass containing 10 to 12 per cent of potash, 3 to 4 per cent of nitrogen (largely in organic form), and about 0.1 per cent of phosphoric acid.

Experiments with the fertilizer were conducted in glass or zinc cylinders of 0.3 square meter surface, filled with sandy soil. The fertilizer was applied to barley oats, potatoes, and sugar beets, being compared in different trials with sulphate of potash, kainit, 37 per cent potash salt, or nitrate of soda. The yields of barley with the molasses fertilizer were similar to those obtained with sulphate of potash, whether much or little potash was added, the maximum returns being obtained with applications of 200 kg. per hectare (189 lbs. per acre) of potash in the form of sulphate of potash and of 300 kg. of molasses-fertilizer potash.

In the oat experiments, in which the molasses fertilizer was compared with nitrate of soda, the former gave a decided increase in yield over that obtained in the cylinders which did not receive any fertilizer, but the increase was only about half as large, on the average, as that obtained in the nitrate of soda cylinders, and the effect was somewhat more pronounced in the yield of grain than in that of straw. In the potato experiments the molasses fertilizer gave somewhat better results than corresponding quantities of kainit, without depressing the starch content of the potatoes.

The fertilizer is, in general, to be considered primarily a potash fertilizer, and its potash is of about the same value as that of sulphate or kainit. The cost at which it can be manufactured will determine the extent to which it can be used economically.—F. W. WOLL.

Report of cooperative fertilizer experiments in Sweden for 1902, P. Bolin (*K. Landt. Akad. Handl. och Tidskr., 1903, App., pp. 133, charts 2*).—The experiments were conducted in different parts of Sweden by the author under the auspices of county agricultural societies. Two hundred and forty-six experiments, including 6,497 trial plats, were arranged for in all, in 16 different counties. Of these experiments 174 were with spring grains, 47 with root crops, and 25 with pasture. The following fertilizers were applied: Nitrate of soda, poudrette, superphosphate, Viborgh phosphate, Thomas phosphate, steamed bone meal, 37 per cent potash salt, and kainit.

In the discussions of the results obtained, the author calls attention to the fact that an abundant fertilization with nitrogenous fertilizers may in a season of much precipitation, like that of 1902, have a deleterious influence on the yield of crops by developing the vegetative growth of the plants at the expense of seed formation and ripening. An abundant nitrogenous fertilization retards the ripening of the grain, and in seasons when the spring work has been delayed and there is therefore danger of late ripening, a relatively smaller use of nitrate is to be recommended than in the case of early sowing, and late-ripening varieties can stand less nitrogen fertilization than earlier varieties. On the whole, a smaller effect from nitrogenous fertilizers was noted on soils rich in humus than on those low in humus, but even in the case of the former the increased yields obtained were sufficient to pay for the fertilizers used with small grains, 100 to 200 kg. per hectare (90 to 180 lbs. per acre) proving an economical fertilization, whether the nitrate was applied alone or in conjunction with other mineral fertilizers.

The results obtained in the experiments with meadows indicate that nitrate of soda and other nitrogenous fertilizers give best returns on land where the true grasses predominate, or in general on old meadows, while phosphates and potash fertilizers are to be preferred where there is considerable clover mixed with the grasses.

An application of 200 kg. superphosphate per hectare (180 lbs. per acre), or a corresponding quantity of other phosphates, proved sufficient in case of spring grains, when not more than 100 to 200 kg. of nitrate of soda was applied, or when the soil itself was not especially rich in nitrogen from a large humus content.

The average relative weights of 1,000 kernels of oats and of barley from plats that received different fertilization are shown below, that of grain harvested on unfertilized plats being placed at 40 gm.:

Influence of fertilizers on weight of kernels.

	Number of trials.	Weight of 1,000 kernels.				
		Two applications nitrogen + phosphoric acid + potash.	One application nitrogen + phosphoric acid + potash.	Phosphoric acid + potash.	Nitrogen + potash.	Nitrogen + phosphoric acid.
Oats:		*Grams.*	*Grams.*	*Grams.*	*Grams.*	*Grams.*
Clay soils	30	41.39	41.00	41.33	41.39	40.35
Loam soils	19	40.55	42.56	41.51	41.03	40.39
Sandy soils	4	42.54	43.01	42.41	42.62	40.96
Sandy loam soils	6	40.51	40.03	40.96	40.80	38.93
Average	59	41.25	41.65	41.55	41.46	40.16
Barley:						
Clay soils	15	43.65	43.11	41.35	41.99	41.52
Loam soils	11	43.97	43.36	41.98	41.64	41.28
Sandy loam soils	13	43.73	43.17	42.65	43.06	42.19
Average	39	43.78	43.21	41.99	42.23	41.67

The data presented show that the fertilizers applied had in general a favorable influence on the ripening of the grain, both in the case of oats and barley, and on all soils. A rather surprising result is shown in the fact that the fertilization with nitrogen and phosphoric acid both in case of oats and barley gave, on the average, smaller increase in the weight of kernels than the nitrogen + potash fertilizers, which suggests that the potash had at least as much influence on the seed formation as the phosphoric acid. It is noted that the results obtained on this point in the experiments of 1901, conducted by the author, point in the same direction (E. S. R., 14, p. 753).—F. W. WOLL.

Cooperative fertilizer experiments in Malmöhus County, Sweden, 1902, M. WEIBULL (*Kvartalsskr. Malmöhus Läns K. Hushåll. Sälsk., 1903, No. 1, pp. 146–213*).—The report presents a full account of 66 cooperative fertilizer experiments conducted under the auspices of the Malmöhus County Agricultural Society by the author, with results obtained and discussions. Twenty-three of the experiments were with sugar beets, 1 with carrots, 5 with potatoes, and the rest with pastures and small grains.

Samples of the different kinds of soils on which the trials were conducted were subjected to chemical and mechanical analysis, and the crops harvested were also examined chemically. Discussing the value of the analysis of crops grown for determining the fertilizer requirements of soils the author concludes that a single analysis of grain and straw from an unfertilized plat will not disclose the fertilizer requirements of the soil, but this can be done to a considerable degree of certainty by analyses of plants grown under different systems of fertilization. Fertilizer trials on a light clay soil sown to barley and oats showed that the soil was in need of nitrogen first of all, and then of potash, but not of phosphoric acid. The analysis of the soil itself gave evidence that it contained only a small amount of phosphoric acid or lime (nitrogen, 0.13 per cent; phosphoric acid, 0.06 per cent; potash, 0.09 per cent; lime, trace; iron oxid, 2.80 per cent; aluminum oxid, 3.70 per cent). The results of analyses of the oats grown on the various plats were as follows:

Analyses of oats grown on different plats.

	Grain.		Straw.		
	Nitrogen.	Phosphoric acid.	Potash.	Lime.	Magnesia.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Plat A, no fertilizer applied	1.26	0.86	1.61	0.30	0.13
Plat B, nitrogen	1.37	.91	1.41	.28	
Plat C, nitrogen + phosphoric acid	1.36	.96	1.55	.32	
Plat E, nitrogen + phosphoric acid + potash	1.32	.94	2.10	.28	
Plat H, phosphoric acid + potash	1.24	.86	1.86	.36	
Atterberg's standards:					
Maxima	1.95–2.72	0.91–1.09	2.21–2.81	0.58–.75	0.34–.43
Minima	1.20–1.36	.37–.50	.28–.73	.14–.21	.08–.13
Average	1.65	.70	1.45	.37	.22

The results of the analysis of the oats corroborate those obtained in the fertilizer trials, viz, that the fertilizer requirements of the soil are in the following order: Nitrogen, potash, and lime, with some magnesia. Other examples are given illustrating the correctness of this method of determining the specific fertilization which a certain soil demands for the production of maximum and economical yields.

Fertilizer experiments with sugar beets gave the result that the sugar content of the beets was increased slightly, but decidedly, by the application of nitrate of soda, while both phosphoric acid and potash depressed somewhat the percentage of sugar in the beets and reduced their purity. The richest beets were obtained on the plats receiving nothing but nitrate of soda (200 kg. per hectare, or 189 pounds per acre).

viz, 18.6 per cent sugar in the beet, with a purity coefficient of 92, the corresponding figures for the unfertilized plats being 17.8 per cent and 85. The variations in the quality of the beets harvested were of minor importance in all cases, suggesting strongly, therefore, that under normal conditions the quality of sugar beets is not affected to any appreciable extent by the application of the ordinary artificial fertilizers.—F. W. WOLL.

Some plant culture trials with a new artificial fertilizer, A. YSTGAARD (*Tidsskr. Norske Landbr., 10 (1903), No. 8, pp. 357–365*).—The fertilizer experimented with was manufactured by fusing a mixture of phosphatic materials (apatite, rock phosphate, bone ash) with carnallite and kieserite for 10 to 15 minutes at 650 to 800° C. A sample of the fertilizer analyzed by the author contained 20.71 per cent total phosphoric acid, 15.23 per cent phosphoric acid soluble in a 2 per cent citric-acid solution, 9.92 per cent lime, 10.20 per cent magnesia, 6.85 per cent potash, and 16.47 per cent chlorin. The effect of the fertilizer when applied to oats and peas was somewhat better than that of Thomas phosphate, especially as regards the yields of grain obtained.—F. W. WOLL.

Wolters phosphate, P. WAGNER (*Mitt. Deut. Landw. Gesell., 18 (1903), No. 46, pp. 257, 258*).—This material, which is prepared by fusing 100 parts of coarsely crushed phosphorite with 70 parts of acid sodium sulphate, 20 parts of calcium carbonate, 22 parts of sand, and 6 to 7 parts of coal, was compared with superphosphate and Thomas slag in 29 pot experiments during 1903 with oats grown on loam soil. The superphosphate used contained 17.7 per cent of water-soluble phosphoric acid, 18.9 per cent total phosphoric acid; the Thomas slag 18 per cent of citric acid soluble phosphoric acid, 19.9 per cent total phosphoric acid. All of the phosphoric acid of the Wolters phosphate (15.7 per cent) was soluble in citric acid. The Wolters phosphate was as quick acting and as effective as the superphosphate and was apparently much more readily assimilated by plants than Thomas slag.

Experiments of the Royal Bavarian Moor Culture Station on the effect of potash fertilizers on upland moors, A. BAUMANN (*Vrtljschr. Bayer. Landw. Rath., 8 (1903), No. 2, Sup., pp. 425–452*).—The results of experiments with various kinds and combinations of fertilizing materials are reported, from which the general conclusions drawn are that the application of Thomas slag in the spring should under all circumstances be avoided on account of the solubility of harmful constituents of the slag in the acids of the moor soils. Fertilizing with potash and phosphoric acid should, however, be done in the spring rather than in the fall. The best results were obtained in these experiments by using Belgian phosphate with 40 per cent potash salts. In the author's opinion other mineral phosphates might be used with equal advantage.

The fertilizing value of iron sulphate, E. LECLERCQ (*Bul. Cercle Études Agron. [Brussels], 1903, No. 8, pp. 360–362*).—Noting the influence of iron sulphate applied for the destruction of weeds in increasing the vigor and yield of various crops, the author undertook plat experiments to determine the cause of this beneficial effect. In these experiments it was found that 250 kg. of iron sulphate produced as great an effect on oats as 150 kg. of nitrate of soda, not taking into account the benefit derived from the destruction of weeds by the iron sulphate. The author attributes the beneficial effect of the iron sulphate solely to the iron and not to the sulphuric acid.

Recent observations and investigations on the use and action of commercial fertilizers, STEGLICH (*Mitt. Oekon. Gesell. Sachsen, 1902–3, pp. 33–52*).—A general summary.

Analyses and valuations of fertilizers, J. P. STREET, W. P. ALLEN, and V. J. CARBERRY (*New Jersey Stas. Bul. 168, pp. 54*).—This bulletin discusses the trade values of fertilizing ingredients in 1903; the cost, value, and guaranteed and actual composition of fertilizers, home mixtures, and special fertilizers; and reports the

results of examination of 66 samples of standard unmixed fertilizing materials, 390 brands of complete fertilizers representing 101 manufacturers, 24 incomplete mixtures, 34 samples of ground bone, and 7 samples of miscellaneous products.

In addition there are reported the analyses of 6 samples of home mixtures and 18 samples of mixtures especially compounded by manufacturers to order. The materials examined included, in addition to the mixed fertilizers, nitrate of soda, sulphate of ammonia, dried blood, dried and ground fish, tankage, superphosphates, muriate of potash, sulphate of potash, kainit, inner coating of hides, tannery refuse, wool waste, sheep manure, and nitrate of potash. About 37 per cent of the brands of fertilizers examined were deficient in one or more of the different forms of plant food. The averages for all brands of complete fertilizers examined during 1903 were as follows: Total nitrogen, 2.27 per cent; total phosphoric acid, 10.52 per cent; available phosphoric acid, 8.15 per cent; insoluble phosphoric acid, 2.37 per cent; potash, 5.49 per cent; station valuation, $20.50; selling price, $27.57.

Analyses of commercial fertilizers, W. Frear (*Pennsylvania State Dept. Agr. Bul. 114, pp. 115*).—A report on inspection of fertilizers in Pennsylvania during the 7 months ended July 31, 1903, including analyses of 542 samples with a discussion of the results and notes on valuation of fertilizers in 1903.

FIELD CROPS.

The influence of the water content of soils on the yield and growth of different varieties of grain, C. Von Seelhorst and W. Freckmann (*Jour. Landw., 51 (1903), No. 3, pp. 253–269*).—Experiments with different varieties of summer wheat, oats, and barley, grown in pots in which the moisture content of the soil varied in different cases from 40 to 85 per cent of saturation, are reported. The results show that there is a close relation between the yield and the growth of individual plants and the water content of the soil, but that the influence of soil moisture varies widely with different varieties, thus confirming previous results (E. S. R., 14, p. 345).

Miscellaneous field crops in New South Wales, W. Farrer, G. L. Sutton, et al. (*Agr. Gaz. New South Wales, 14 (1903), No. 9, pp. 852–857, 884–887, 903–926, 929–936, 941–944, 947–950, 952, 953, pls. 7*).—The work with field crops, consisting mainly of variety and culture tests with cereals and forage crops, including grasses, roots, and leguminous plants, conducted at the Hawkesbury College, Wagga, Bathurst, Wollongbar, Coolabah, Moree, Belindigarbar, and Glen Innes experiment farms in 1902, is briefly noted. The different crops and varieties grown at the various farms are enumerated.

Varieties of wheat quite rust-resistant when sown before midwinter were badly affected when sown in the spring. Macaroni wheats compared well with other kinds in rust and drought resistance. At one of the farms the viability of seeds of different varieties treated with copper sulphate varied from 2 to 70 per cent.

Field crops at the Queensland Experiment Farms, J. Mahon et al. (*Queensland Agr. Jour., 13 (1903), No. 5, pp. 408–446, pls. 2*).—In connection with reports covering all the work of the different State experiment farms at the Queensland Agricultural College, Westbrook, Hermitage, Biggenden, Gindie, and Cairns, the experiments with a large number of field crops, consisting mainly of variety and culture tests with cereals, grasses, roots, and other forage crops, are briefly noted. The varieties of the different crops under test are enumerated.

Results of experiments with lime as a fertilizer, D. Pryanishnikov (*Zhur. Opuitn. Agron.* [*Jour. Expt. Landw.*], *4 (1903), No. 3, pp. 257–266*).—The use of lime as a fertilizer for a mixture of oats and vetch gave varying results, the percentage of vetch increasing in some instances and decreasing in others when lime was applied.

These differences in the results are considered due to the action of lime on the mineral constituents of the soil in some cases, and on the nitrogenous organic substances in others.

Wheat and yellow lupines gave an increase in yield as the amounts of lime applied were increased to 1 per cent of the weight of the soil. This result with lupines was unexpected. In acid clayey soils, oats was benefited when lime was applied at the rate of $\frac{1}{4}$ or $\frac{1}{2}$ per cent of the soil weight, but when the lime was increased to 1 per cent the yield was greatly reduced. From these experiments the author concludes that lime on other than sandy soil may be beneficial to lupines, while on some soils too great amounts may prove injurious to cereals. In studying the influence of lime on the nitrogen content of the soil in the absence of plants the author found that an application of 0.2 per cent of the soil weight very appreciably increased nitrification in chernozem soil.—P. FIREMAN.

Top-dressing for moorland pastures, H. VON FEILITZEN (*Svensk. Mosskult. Tidskr., 16 (1902), No. 2, pp. 171–185*).—The results of cooperative fertilizer experiments on 24 different farms during the year 1901 indicate that top-dressing moorland pastures is profitable.

The author states that, if the moor is of such a character that a yield of about 4,450 lbs. per acre may be expected, an application of about 85 lbs. of potash per acre with large quantities of phosphoric acid is advisable during the first years of cultivation. The application can later be decreased to such quantities as are taken off in the hay crop or washed out with the rainfall. From 30 to 35 lbs. of phosphoric acid per acre is considered an average application. On land kept in grass for several years a top-dressing with barnyard manure or compost has proved advantageous, especially on incompletely decayed moors.—F. W. WOLL.

On the improvement of natural meadows on humus soils, H. VON FEILITZEN and R. TOLF (*Svensk. Mosskult. Tidskr., 16 (1902), No. 4, pp. 311–322*).

Cooperative forage experiments in Southern Victoria, F. J. HOWELL (*Jour. Dept. Agr. Victoria, 2 (1903), No. 2, pp. 97–120, pls. 13*).—Corn, Amber cane, teosinte, Egyptian corn, Kafir corn, Pearl millet, mangels, beets, and alfalfa were tested, and the yields together with the increase on plats receiving commercial fertilizers are given in tables. Brief notes on the tests and apparent value of the different crops are presented.

The experiments showed that these crops may be grown in succession and supply green forage from the time the spring pastures fail until early-sown winter crops are available. For improvement of corn for forage a greater stooling tendency and a larger proportion of leaf are considered requisite. Amber-cane sorghum and Japanese millet proved successful, and rape produced very large yields. For Long Red and Yellow Globe mangels, yields of 31.31 and 47.56 tons respectively are recorded. The superior yield of the Yellow Globe is believed to be due to the fact that this variety is better adapted to shallow and not very friable soils than the Long Red. Rape and mangels showed the same wide range of adaptability to the soils of the region. Cowpeas and soy beans gave promise of value; and the use of commercial fertilizers on soils of poor and medium quality producing forage crops was found profitable.

Forage plants, D. O. NOURSE (*Virginia Sta. Bul. 145, pp. 15–19*).—This bulletin presents in brief notes the results obtained with a number of forage crops at the station in 1901 and 1902. Several varieties of sorghum, cowpeas, and soy beans were grown in this connection.

Competitive culture of fodder beets, E. VOGLINO (*Concorso per la coltivazione delle barbabietole da forraggio. Turin: G. Derossi, 1903, pp. 27, fig. 1*).—Nine varieties of fodder beets were grown in a prize contest and the methods of cultivation are described and the results reported. The sugar content ranged from 3.66 to 8.28 per cent, and the yields from 367 to 594 cwt. per hectare. It is concluded from the

results obtained that the sugar content of fodder beets in the region concerned i more dependent upon the soil and methods of cultivation than upon the variety. I general the varieties low in sugar content gave the best yields.

Selection of fodder beets, P. Zabrinski (*Zeml. Ghaz., 1902, No. 49; abs. in Zhur Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 3, pp. 356, 357*).—From result obtained by Zaykevich in 1901 the author concludes that the form and specific grav ity of fodder beets bear relation to the sugar content.—P. FIREMAN.

Florida beggar weed, G. d'Utra (*Bol. Agr. São Paulo, 4. ser., 1903, No. 6, pp 251–266*).—In connection with a discussion of the culture, uses, and value of th crop, analyses made before, during, and after the flowering period are reported an compared with the composition of a large list of leguminous crops at the correspond ing stages of growth.

Abnormal growth of carrots, E. Gross (*Deut. Landw. Presse, 30 (1903), No. 97 p. 831, fig. 1*).—The results of observation and experiments carried on for 3 year indicate quite conclusively, according to the author, that transplanting carrots induce abnormal forms. It is stated that conditions similar to those resulting from trans planting are accidentally caused in hoeing or cultivating, and that the occurrence o malformed specimens may be ascribed to this fact. On loose friable soils the abnor mal forms of transplanted carrots were less pronounced than on soils of a hard tex ture. Ten typical specimens of transplanted carrots weighed on an average 192.8 gm each, as compared with 87.7 gm. for specimens which had not been transplanted This difference was partly due to the greater area given each plant in transplanting but mainly to the abnormal branching of the transplanted specimens.

The growth of crimson clover, C. L. Penny (*Delaware Sta. Rpt. 1902 pp. 79–84*).—A comparison was made in 1901 between the weight and the composi tion of roots and tops of crimson clover 3 or 4 weeks before full bloom and durin full bloom. The samples studied were taken from a loose sandy soil and from heav clay.

At the earlier stage of growth the roots of the samples from the sandy soil consti tuted about 40 per cent of the whole plant, and those from the clay soil about 25 pe cent, and at the later stage of growth approximately 32 and 12 per cent, respectively In discussing these results the author calls attention to the greater ease of recoverin roots from the sandy soil, and to the fact that during the interval the samples wer taken the tops on the sandy soil increased considerably less than those on the cla soil, thus materially affecting the ratio between tops and roots. It is further state that root development may possibly be greater in sandy soil. About three-fourths o the roots on both soils were found within 6 in. of the surface, and it is concluded tha quantitatively the manurial value of the crop is almost entirely in the portion nea the surface.

The fertilizing constituents as determined in these experiments are shown in th following table:

Fertilizing constituents of crimson clover at different stages of growth.

Date of cutting.	Portion of plant.	Composition of air-dry substance.			Quantities per acre.			Yield per acre.
		Potash.	Phosphoric acid.	Nitrogen.	Potash.	Phosphoric acid.	Nitrogen.	
		Per ct.	*Per ct.*	*Per ct.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*
Sandy soil:								
April 22	Tops	1.88	0.49	3.35	50.2	13.1	89.6	2,67
April 22	Roots	.59	.40	2.31	10.8	7.3	41.9	1,81
May 17	Tops	1.13	.36	2.16	51.2	16.2	97.9	4,5
May 17	Roots	.54	.36	1.96	11.4	7.7	41.4	2,11
Clay soil:								
April 26	Tops	3.72	.64	3.25	110.3	18.8	96.4	2,9
April 26	Roots	1.88	.44	2.73	19.0	4.4	27.6	1,0
May 22	Tops	2.77	.48	2.63	175.2	30.3	166.4	6,3
May 22	Roots	1.18	.55	2.51	10.2	4.8	21.8	8

The data obtained on the sandy soil show but a small increase in fertilizing constituents during the 4 weeks preceding full bloom, while the results from the clay soil showed a marked gain.

The root surface of 1 gm. of fine roots from a sample produced on the sandy soil and taken April 22 amounted to 208 sq. cm. With this result as a basis, the aggregate surface of the fine roots within the first 2 ft. of soil is calculated to be about 4 times the surface of the land itself.

Clover sickness of soils, B. B. VEENER, N. A. DYAKONOV, and P. S. KOSSOVICH (*Trudi Syez. Dyeyat. Selsk. Khoz. Opuitn. Dyelu., 1901, pp. 31–41; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 4, pp. 484–486*).—It has been observed by the Shatilov Experiment Station that the yield of clover in that region, even on the best farms, is low and that lands newly sown to clover give the higher yields. Phosphates proved to be the most effective fertilizer for clover and the best stand was obtained when sown without a nurse crop.

In the Government of Tula pot experiments with chernozem soil showed that clover sickness really existed and that it was not exclusively due to the lack of plant food.—P. FIREMAN.

Maize on hill and vlei soils (*Agr. Jour. and Min. Rec. [Natal], 6 (1903), No. 19, pp. 681–692, pl. 1*).—Comparative tests of different fertilizer mixtures on corn grown on hill (red loam) and flat (dark-gray clay loam) soils are reported. The results, briefly summarized, were that lighter applications were more profitable than heavier; phosphoric acid was apparently the most needed single element on the hill soil; nitrogen increased the growth of fodder but not of grain, and both nitrogen (nitrate of soda) and potash (muriate) salts retarded germination when applied in the hill; the yield of grain was increased to some extent by the use of potash; the effect of fertilizers was less marked on the flat soil; of the 3 phosphates used—superphosphate, slag, and bone—the first gave the most profitable returns.

The chemical composition of different parts of the corn kernel, C. G. HOPKINS, L. H. SMITH, and E. M. EAST (*Jour. Amer. Chem. Soc., 25 (1903), No. 11, pp. 1166–1179, pls. 2*).—This has been noted from another source (E. S. R., 15, p. 352).

Thirty-fifth annual report of the Flax Supply Association for the improvement of the culture of flax in Ireland (*Belfast: Flax Supply Assoc., 1903, pp. 103*).—The statistics given have reference mainly to the United Kingdom, but in addition statistics regarding the industry in different countries are briefly presented.

The cold storage of hops, C. ARMSTRONG (*Proc. Cold Storage and Ice Assoc., 4 (1903), No. 1, pp. 26–34*).—A brief paper, followed by general discussion.

Oats, DENAIFFE and SIRODOT (*L'Avoine. Paris: J. B. Baillière & Sons, 1902, pp. 848, figs. 213*).—This work presents at some length the description, classification, and anatomical structure of the grain of French and other varieties of oats, together with a consideration of the culture, composition, uses, storing, and national and international commerce of the crop. In addition to the topics mentioned, insects and diseases attacking the oat plant, injurious effects of weeds, cost of production, financial returns, transportation, and tariffs affecting the production and the price of the crop are discussed.

Tests of oats and wheat at Uniontown in 1903, J. F. DUGGAR and J. M. RICHESON (*Alabama Canebrake Sta. Bul. 19, pp. 11*).—The average results of 3 experiments show that fall-sown oats which received 100 lbs. of nitrate of soda per acre yielded 14.75 bu. of grain per acre more than the check tests, while the plats receiving 200 lbs. yielded 25.3 bu. more. Estimating the cost of the nitrate at $60 per ton, the increase with 100 lbs. of nitrate was produced at a cost of 20.3 cts. per bushel, and with 200 lbs., at a cost of 23.8 cts. per bushel. The oats were estimated at 50 cts. per bushel. The average yield of straw on the check plat was 1,070 lbs.; on the plat receiving 100 lbs. nitrate, 1,738 lbs.; and on the plat receiving double this quantity, 2,608 lbs. per acre.

Thoroughly cured sheaf oats from the unfertilized plats and from those receiving the smaller and the larger quantity of nitrate of soda contained 39, 38, and 33 per cent of grain, respectively. A plat of oats sown January 31 and fertilized at the rate of 80 lbs. nitrate of soda per acre showed an increase of 8 bu. per acre over the check plat, which was equivalent to a profit of $1.60. Oats receiving an excessive application of 3,466 lbs. fresh cotton seed per acre yielded 39 bu., or 18 bu. more than the unfertilized crop, while the plat receiving an equal quantity of nitrogen in the form of cotton-seed meal produced only 23.2 bu. per acre. Nitrate of soda at the rate of 160 lbs. per acre on oats sown March 25 proved detrimental. On these late oats 200 lbs. cotton-seed meal per acre was practically without effect.

The results of these and previous experiments were in favor of fall sowing. Seed of Red Rust Proof oats scalded for 10 minutes in water at a temperature of 133° F., produced a crop free from smut, while the oats from untreated seed contained 3 per cent of smutted heads. The scalded seed also produced 1 bu. of grain more per acre than the untreated seed. Of different methods of soil preparation for oats, plowing and harrowing the soil, plowing in the seed, and then rolling the ground gave the best results. Leaving the surface a little rough is considered a partial protection against winterkilling.

Owing to rust, fertilizer experiments with wheat did not give reliable results.

On the improvement of the Swedish potato industry, with a report on culture trials with potatoes, H. JUHLIN-DANNFELT (*K. Landt. Akad. Handl. och Tidskr., 42 (1903), No. 2, pp. 147–180*).

Sugar beet experiment, C. L. PENNY (*Delaware Sta. Rpt. 1902, p. 84*).—Only one test was made. The average weight of the beets was about 5½ oz., the sugar content of the juice by weight 20.7 per cent, and the purity 87.2. The beets lost 19 per cent in topping, and the yield of topped beets per acre was 11,887 lbs. On this basis the yield of sugar would amount to 2,209 lbs. per acre. The experiments in this line thus far conducted by the station are not regarded as conclusive, but the results given above are not considered favorable for the sugar-beet industry in Delaware.

Respiration in the sugar beet, F. STROHMER (*Abs. in Centbl. Agr. Chem., 32 (1903), No. 7, pp. 465–469*).—Experiments were conducted to study the cause of the loss in sugar occurring in stored beets. The respiration products in several series of sample beets, all of the same variety and obtained from the same source, were determined and the influence of various factors was noted. The tops of the beets were removed and only a few buds allowed to remain at the crown. Each sample beet was under test from 70 to 72 hours.

The results did not show that the respiration products of the sugar beet contain other carbonaceous gases in addition to carbon dioxid. The loss of sugar in stored beets was found to be larger than was indicated by the quantity of carbon dioxid exhaled. A definite relation between the original sugar content of the beet and the quantity lost by respiration could not be established, and the total loss in sugar, other conditions being equal, was not parallel with the increase in sugar content. Neither did the quantity of sugar lost during storing and the quantity reduced to nonsugars show any connection. Respiration is regarded as the strongest factor in causing loss of sugar in nonsprouting beets.

Storing at the lowest possible temperature is recommended because it reduces the loss in sugar to a minimum and in other ways preserves the quality. In sprouting beets the loss from reduction to nonsugars is much greater than the loss due to respiration. It is stated that cane sugar in the beet serves as material used in respiration, in which connection it is broken up into carbon dioxid and water and as a reserve substance utilized in the development of new organs, or in growth in general, in which a mere rearrangement of its atoms takes place.

According to results obtained by the author and others the fodder and sugar beet are injuriously affected by a temperature between −1° and −1.1° C. A temperature

of 0° C. will keep beets in perfect condition for weeks. Even slightly frozen beets may be brought back to a normal condition if allowed to thaw out slowly and gradually, which shows that freezing is not necessarily destructive.

There was no indication of a relation between the activity in respiration and the content of either sugar, total nitrogen, or albuminoid nitrogen. A high sugar content was not always associated with an intense activity in respiration.

Intramolecular respiration, which takes place when oxygen is lacking, was also observed in the beet, and at temperatures ranging from 2 to 4° C. perceptible quantities of carbon dioxid were given off. Ethyl alcohol is considered a product of intramolecular respiration in the beet root. The following table shows the range in loss of sugar under normal respiration at different temperatures:

Range of loss in sugar and its carbon dioxid equivalent per 100 kg. of beets during 24 hours of storage.

Temperature.	Sugar.	Carbon dioxid equivalent.
Deg. C.	*Grams.*	*Grams.*
0	2.30– 5.18	3.55– 7.99
5	10.35–18 69	15.98–28.86
10	23.01–29.62	35.52–45.73

Seedling and other canes in the Leeward Islands, 1902–3, F. WATTS (*Imp. Dept. Agr. West Indies, Pamphlet 27, 1903, pp. 39*).—The results obtained with plant and ratoon canes in Antigua and St. Kitt's are briefly summarized. In Antigua seedling cane B 208 gave the best average results. Other promising canes were B 109, B 156, B 130, and B 306. The ratoon crop of these new seedlings retained the promising character.

In the St. Kitt's experiments Caledonian Queen and B. 208 headed the list of plant canes. Among the ratoon canes B. 306 gave the best results. The data obtained seem to indicate that selection affects the resulting canes to some extent. Cane tops proved superior to cuttings for planting, and Bordeaux mixture was most efficient in protecting the tops and cuttings against the attacks of fungus diseases and thus insuring the growth of the buds. Placing the tops and cuttings vertically and covering the ends produced better results than other methods of planting.

Ridge v. level culture for sweet potatoes, R. A. EMERSON (*West. Fruit Grower, 13 (1903), No. 4, p. 22*).—An account is given of growing sweet potatoes in Nebraska on ridges and with level culture, both with and without irrigation and with and without mulching. Level culture gave considerably the best results on the unirrigated and consequently dry soil. There was considerable advantage, on the other hand, in ridging where the soil was irrigated; and this difference was especially marked when the rows were also mulched. The increased yield secured by ridging on irrigated land amounted to 29 per cent, and to 53 per cent when the ridges were also mulched.

Variety tests of tobacco, E. CHUARD and G. MARTINET (*Chron. Agr. Canton Vaud, 16 (1903), No. 23, pp. 637–643*).—Of 6 American varieties, Improved White Burley showed the greatest adaptability to the new conditions and is considered of greater value for the region than any other of the varieties tested. The seed obtained from America gave a larger yield than the seed produced by this crop.

Report of the tobacco expert, R. S. NEVILL (*Queensland Agr. Jour., 13 (1903), No. 5, pp. 457, 458*).—Six varieties of tobacco, Lax, Blue Pryor, Yellow Pryor, Heston, Conqueror, and Burley, were grown. The season was dry, and of the varieties tested Lax proved by far the most drought-resisting and the only one giving a fair yield.

Wild rice; its uses and propagation, E. BROWN and C. S. SCOFIELD (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 50, pp. 24, pls. 7*).—This bulletin discusses the distribution and habitat of wild rice, together with its life history and natural propagation; gives the botanical description and a discussion of the general morphology of the plant; notes the methods of harvesting the seed and preparing it for food purposes; and presents suggestions for harvesting, storing, and planting. In the consideration of the food value of wild rice its chemical composition is compared with the chemical composition of a number of common cereal grains. Analyses furnished by the Bureau of Soils of this Department, of soil samples taken from wild rice beds near Bemidji, Minn., on the Potomac Flats near Washington, D. C., and from Chesapeake Beach, Md., are reported.

Measurements of wild-rice seed obtained from the Potomac River, Port Hope, Ont., and Minnesota, were made by the authors to show the difference in size of seeds from different regions. The northern-grown seeds were found to be larger and much thicker than the seeds from the Potomac. The results of a series of experiments, partly cooperative, seem to indicate "that wild rice can be successfully grown from seed either by sowing the fresh seed as soon as it is gathered or by keeping it in water over winter and sowing in the spring."

Report on the agricultural work in the botanic gardens and the government laboratory for the year 1902–3, J. B. HARRISON (*Georgetown, British Guiana: Govt. Printer, 1903, pp. 40*).—The results of culture tests of seedling sugar canes and of older varieties are reported. The areas occupied by various seedling varieties in 1902 and 1903 and the number of plantations on which each kind was in cultivation are given in a table. The composition of the soil samples from fields used in this connection is also given. The general deductions from fertilizer experiments in progress since 1891 are similar to those previously noted (E. S. R., 15, p. 857).

The Estate Brody, E. WEISS (*Mitt. Landw. Inst. Univ. Breslau, 2 (1903), No. 3, pp. 437–510*).—The management of an estate devoted to the production of crops in connection with keeping comparatively little live stock is outlined. The cultivation of different crops, the treatment of the different kinds of soils, the rotations followed, the methods of applying fertilizers, and the system of bookkeeping used are described.

The world's grain production in 1903 (*Die Getreideproduktion der Welt im Jahre 1903. Budapest: Min. Agr., Hungary, 1903, pp. 89*).—Statistics for 1903 of the grain production of the world by countries, as published by the Hungarian Minister of Agriculture.

The geographical distribution of grain prices in the United States from 1862 to 1900, T. H. ENGELBRECHT (*Die Geographische Verteilung der Getreidepreise in den Vereinigten Staaten von 1862 bis 1900. Berlin: Paul Parey, 1903, pp. 108, pls. 8*).—The fluctuations in the prices of wheat, rye, barley, oats, corn, buckwheat, potatoes, and hay in different sections of the United States from 1862 to 1900 are discussed and shown in tables and graphical illustrations.

Report of the [Queensland] secretary for agriculture, 1902–3, D. DENHAM (*Queensland Agr. Jour., 13 (1903), No. 5, pp. 375–393, pl. 1*).—This report includes statistical information regarding the production of field crops in Queensland.

Season and crop report of Bengal for the year 1902–3, S. L. MADDOX (*Calcutta: Dept. Land Records and Agr., Bengal, 1903, pp. XXXIII*).—The character of the season is described and detailed statistics of all the important crops of the country are given in tables.

HORTICULTURE.

Report of the horticulturist, C. P. CLOSE (*Delaware Sta. Rpt. 1902, pp. 89–108*).—The subjects considered in this report are the value of spring applications of nitrate of soda for asparagus; thinning experiments with apples and peaches; pollination experiments with pears, peaches, and apples; root forcing of fruit trees; orchard cover crops; and notes on the station orchard.

In the experiment to determine the value of spring applications of nitrate of soda in the culture of asparagus, 200 lbs. was applied per acre in 4 equal portions at intervals of about 10 days. The first application was made about 2 weeks before the cutting season began. The weight of stalks obtained from a half acre fertilized with nitrate of soda was 460 lbs. On the unfertilized half acre the weight was 448 lbs. This slight difference in the yield of the fertilized over the unfertilized plat is not believed to be of any special significance. The use, therefore, of nitrate of soda on asparagus beds during the cutting season is not recommended.

Results of thinning experiments with apples for 1 year show an increase of from $1\frac{1}{2}$ to 3 times as much first-grade picked fruit on the thinned as on the unthinned trees. The yield of second and third grade picked fruit was also usually larger on the thinned trees. As regards dropped fruit, there was about 7 times as much first-grade fruit obtained from the thinned as from the unthinned trees. Of second-grade dropped fruit the greater amount was obtained under the unthinned trees. In total yield, 4 unthinned Lankford trees produced $117\frac{3}{4}$ baskets of apples, while the thinned trees produced $116\frac{1}{4}$ baskets. One of the peculiar features of this experiment was that notwithstanding all wormy fruit was first removed in thinning, at the end of the season 60 per cent more of the thinned fruit was wormy than of the unthinned fruit.

The experiments with peaches included comparisons between the percentages of fancy fruits and firsts obtained from unthinned trees, and from trees on which the fruit had been thinned immediately after the June drop to 4, 6, and 8 in. apart, respectively, and to these same distances apart on other trees about 3 weeks later, when the pits were beginning to harden. The results secured with well-loaded Elberta trees are shown in the following table:

Comparative yield of peaches from thinned and unthinned trees.

Method of thinning.	Fancy fruits.	Firsts.	Yield of thinned as compared with unthinned trees.
	Per cent.	*Per cent.*	*Per cent.*
Unthinned	48	49	100.0
Thinned early 4 in. apart	51	47	85.8
Thinned early 6 in. apart	60	39	104.0
Thinned early 8 in. apart	80	20	71.0
Thinned late 4 in. apart	49	51	101.5
Thinned late 6 in. apart	80	20	71.0
Thinned late 8 in. apart	73	26	84.5

The table shows a considerable increase in the percentage of fancy fruits and firsts due to thinning. The author recalls in this connection that in previous experiments early thinning to 8 in. apart has given the best results. The last column of the table shows the comparative yields obtained on the thinned trees, calling the yield from the unthinned trees 100.

The work in pear and apple pollination is in continuation of that previously reported by the station (E. S. R., 14, p. 252). Out of a total of 612 cross-pollinations between apple blossoms of Paragon, Stayman, Winesap, and Lily of Kent only 1 fruit set. Kieffer and Angouleme pears also proved practically self-sterile.

In testing the self-fertility of Old Mixon, Reeves, Elberta, Globe, Crawford Late, and Fox peaches the self-fertility of the blossoms was found to vary between 70 and 88 per cent, the average being 81 per cent. These fruits may therefore be safely planted in solid blocks without danger of reducing the set of heavy crops of fruit.

An attempt was made to secure an increased root development of young orchard trees by increasing their callusing surface. Strips of bark $\frac{1}{2}$ in. wide were cut from the side of the main root and the larger side roots, with the expectation that numerous new roots would be sent out from these places. The experiment was made with

a number of fruits, but only the results secured with peaches are reported. The data obtained with this fruit show that no more roots were obtained from those trees from which strips of bark had been removed than from the control trees, and the experiment from this standpoint was a failure. However, the removing of the strips of bark appeared to have a very stimulating effect on the growth of the main root in particular and the whole root system in general. The top growth of the trees where 2 strips of bark had been removed averaged 44.7 ft. When one strip of bark was removed the top growth averaged 36.1 ft. With the control trees the top growth was but 23.9 ft., and the root system graded but 62, as compared with a grade of 82 and 89 for the trees from which strips of bark had been removed.

The notes on orchard cover crops have been abstracted from another source (E. S. R., 15, p. 361).

Biennial report of the State board of horticulture (*Utah State Bd. Hort. Rpt. 1901–2, pp. 69, pls. 16*).—This report contains an account of the work of the State board of horticulture in investigating the horticultural work of the State for the 2 years 1901–2. It has been definitely determined that fruit trees, when properly pruned and scraped and then given 2 thorough applications of a lime, salt, and sulphur mixture, may be completely freed from the San José scale. With trees more than 30 years old, however, it has been found cheaper to cut them out than to attempt to spray them. It is not deemed practicable nor advisable to attempt to fumigate trees in combating the San José scale, since the lime, salt, and sulphur treatment is equally effective and costs only about a fourth as much.

Investigations on the codling moth appear to indicate that there are no distinct broods of the worms, but that hatching is continuous after the temperature reaches 65° F. at night. In order to control this pest, therefore, spraying at least once every 20 days throughout the season after the blossoms fall is advised. From 80 to 95 per cent of apples free from worms have been obtained by careful attention to spraying.

An account is given of the work and expenditures of the experiment farm for 1901–2. The farm is designed as a model, as well as for experimental purposes. Some of the canning factories of Utah are described, and an account given of the work they are doing. Pear blight has been controlled in some of the orchards reported on by constant attention to the pruning out of infected parts of the tree. A number of miscellaneous recommendations are made regarding the culture of fruit in Utah, and spraying for the control of insect pests and the diseases of fruit trees.

Report of the fruit expert, W. J. Allen (*Agr. Gaz. New South Wales, 14 (1903), No. 9, pp. 811–847*).—This report deals with phenological data and descriptions of a large number of different kinds of fruits grown at Wagga, Hawkesbury, Bathurst, Moree, Perabore, and Wollongbar orchards. Nearly all kinds of temperate and subtropical fruits are considered. In a 3-years' trial of ringing Zante currants, especially good results were obtained during the first 2 years, which appeared to be favorable seasons for the practice. The third year, however, the practice resulted very disastrously; the vines set no fruit, and in a few cases died, and on the whole it greatly weakened them. From the 3-years' trial the conclusion is drawn that in favorable seasons the practice increases the returns without being harmful or interfering with the longevity of the vine; but where the grower is dependent upon the rains in a dry district, it is both dangerous and undesirable.

The handbook of horticulture and viticulture of Western Australia, A. Despeissis (*Perth: W. A. Watson, Govt. Printer, 1903, 2. ed., pp. 620, pls. 8, figs. 299*).—This is a very comprehensive guide to the propagation, culture, and marketing of all the usual fruits, and, to a more limited extent, vegetables grown in Western Australia.

A laboratory manual in systematic pomology, U. P. Hedrick (*Mich. Agr. Col., pp. 91*).—This manual represents "an effort to place before the students of pomology in the Michigan Agricultural College a means by which an intimate and accurate knowledge of pomology may be acquired."

Judging fruit by scale of points, F. A. WAUGH (*West. Fruit Grower, 14 (1903), No. 5, pp. 1–3*).—This is a paper read before the American Pomological Society at its recent meeting in Boston. It contains suggested scales of points for judging apples and pears, grapes, peaches, plums, and strawberries. A score card originated by A. T. Goldsborough for judging strawberries is also given.

Fruit culture in Costa Rica, C. WERCKLE (*Tropenpflanzer, 7 (1903), No. 9, pp. 425–439*).—A detailed account is given of all of the foreign and native fruits grown in Costa Rica.

Fertilization and hybridization, H. DE VRIES (*Befruchtung und Bastardierung. Leipzig: Von Veit & Co., 1903, pp. 62*).—A lecture delivered before the Holland Scientific Society at Haarlem, May 16, 1903.

The question of varieties, L. H. BAILEY (*West. Fruit Grower, 14 (1903), No. 2, pp. 1–4*).—This is a paper read by the author before the Nurserymen's Convention, with the discussions of the same by nurserymen.

The culture and marketing of orchard and garden fruits, W. F. MASSEY (*North Carolina Sta. Bul. 184, pp. 86–125, figs. 22*).—This bulletin contains an elementary discussion of the classification of plants and the functions of roots, stems, buds, leaves, flowers, etc., with detailed directions for the propagation, planting, cultivation, and marketing of pears, peaches, plums, cherries, quinces, figs, and pomegranates. The best varieties of these various fruits for North Carolina conditions are noted, with brief descriptions of the same.

Experiments in fertilizing orchards, C. LIERKE (*Wiener Illus. Gart. Ztg., 28 (1903), No. 10, pp. 371–376*).—In addition to a discussion of the general requirements of the different fruits as regards potash, phosphoric acid, and nitrogen, figures covering a period of years are given, which show the increased yield obtained by the use of fertilizers containing these elements, and the much smaller yield obtained when any single element was omitted from the fertilizer formula.

Pruning, L. C. CORBETT (*U. S. Dept. Agr., Farmers' Bul. 181, pp. 39, figs. 25*).—This bulletin treats of the methods and principles of pruning as applied to orchard and small fruits, hedges, shade and timber trees, and flowering shrubs.

Some notes on canning fruits and vegetables, W. B. ALWOOD (*Virginia Sta. Bul. 146, pp. 23–47*).—Detailed directions are given for canning tomatoes, snap beans, sweet corn, apples, crab apples, and plums. The work is based on the results secured at the station in putting up fruits and vegetables in a small canning factory.

The detailed portion of the bulletin is preceded by a discussion of the principles which underlie the processing of canned goods. Contrary to the recommendations of several writers on processing tomatoes in a retort at a high temperature, the author finds that cooking the stock at a boiling temperature in an open kettle for 25 minutes is most desirable. When the tomatoes were cooked for 45 minutes in an open kettle at boiling the stock was practically reduced to slop.

The most satisfactory varieties of snap beans used for canning have been the Mammoth Stringless Valentine, and the new Mammoth Stringless Green Pod. Cooking the stock 45 minutes at boiling in an open kettle has quite uniformly produced satisfactory results. Perhaps a little finer grade of stock was secured by cooking for 10 minutes in a retort, at 216° F, and then running the temperature up to 220° just at the close of the cooking.

Country Gentleman and Stowell Evergreen were the varieties of corn used for canning. In one experiment 30 bu. of Stowell Evergreen corn, measured with the husk on, produced 10 cases of packed corn; and 42 bu. of Country Gentleman, measured in the same way, packed 12 cases. Other data along the same line are given.

The Tolman Sweet variety of apples, when sugared and canned, was found to make a very excellent preserve. In cooking crab apples, from 2 to 3 oz. of sugar to each 3 lb. can seemed to be sufficient.

The apple in cold storage, G. H. POWELL and S. H. FULTON (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 48, pp. 64, pls. 6*).—Experiments have been conducted

for 2 years in different apple-growing sections of the country to determine the best methods for harvesting and keeping apples in cold storage. About 180 varieties of apples taken from localities in Kansas, Missouri, Illinois, Michigan, West Virginia, North Carolina, Delaware, Maine, Massachusetts, and New York have been used in the investigation.

Preceding the detailed results of the experiments a discussion is given of the influence of cold storage on the apple industry, the function of cold storage, principles of mechanical refrigeration, and statistics of the extent of the cold-storage warehouse industry in this country. The specific problems investigated were the effect of the degree of maturity at harvesting time on the keeping quality of the fruit, the effects of delayed storage, and of storing at different temperatures. In addition, the influence of different kinds of packages, wrapping of fruit, soil and cultural conditions, fruit from young rapidly growing trees and from old trees, etc., on the keeping qualities of the fruit in cold storage were investigated; as well as the effects of all the above factors on the development of apple scald during and after the removal from cold storage. The keeping qualities of about 180 varieties of apples used in the test are given in comparative notes.

As regards the best time to pick apples for storage, the results indicate that they should have reached full growth and high color before harvesting, but still be firm and hard when picked. Such fruit equals in keeping quality, and often surpasses, partially colored or less mature fruit. It is superior to such fruit in flavor and texture, more attractive in appearance, more saleable, retains its flavor longer, and is less subject to apple scald. Overripe fruit deteriorates rapidly unless placed in cold storage soon after picking.

In experiments with some unusually large Tompkins King and Sutton apples picked from rapidly-growing young trees, the fruit that was but three-fourths colored kept much better than fully colored fruit. When examined in February fully colored Tompkins King showed 28 per cent of physiological decay, while lighter-colored fruit from the same tree, picked and handled in the same manner, showed but 10 per cent of decay. In another instance small, mature fruit from older slower-growing trees kept well until the middle of April; while the commercial limit of fruit from young rapid-growing trees in cold storage was sometimes 3 months shorter. Late varieties of fruits may be picked when they are beginning to mellow, provided they are handled with great care and stored immediately in a temperature of 31 to 32° F. As a further protection, however, such fruit should be wrapped and stored in boxes.

As a means of securing better-colored fruit, pruning to let sunlight into the tree is suggested. Cultivation and cover crops which tend to vigorous growth and lighter-colored fruits may be withheld in part or the orchard seeded down until the desired condition is obtained. More uniform grades can be secured by picking trees over several times. This is especially desirable in the case of a specialist working up a fancy trade in apples.

Relative to the effects on keeping quality of delay in placing fruit after picking in cold storage, the authors found that when the weather at picking time was cool there was no apparent injury from delaying the storage of a large number of varieties of apples 2 weeks after they were picked. With warmer weather, however, a delay of 2 weeks seriously injured the keeping quality of the fruit. Rhode Island Greening, Tompkins King, and Sutton apples picked when the temperature averaged about 62° F., and stored within 3 days, kept firm until the following March without rot or scald; while fruit from the same trees not stored until 2 weeks after picking was badly scalded or decayed by January 1. "None of the immediate-stored fruit was scalded or decayed by the first of February, but the delayed Sutton and Rhode Island Greening apples were soft and mealy, and one-third were scalded at that time, while nearly 40 per cent of the delayed Tompkins King were soft and worthless.

The commercial value of these varieties was injured from 40 to 70 per cent by the delay in storage."

Relative to different temperatures: "The investigations indicate that the ripening processes are delayed more in a temperature of 31 to 32° F. than in 35 to 36° F. The apple keeps longer in the lower temperature, it scalds less, the fruit rots and molds are retarded to a greater extent; while the quality, aroma, flavor, and other characteristics of the fruit are fully as good and when removed from storage it remains in good condition for a longer period." Some fruit when very carefully picked and handled kept very satisfactorily at the higher temperature, but for general commercial work a temperature not higher than 32° F. is recommended.

A discussion is given of the physiological effects on apples in storage of freezing. The injury is seen in a more translucent appearance of the skin of the fruit, a waterlogged and spongy condition of the flesh, and a brownish discoloration of the flesh. "In the practical handling of frozen stock the temperature should be raised very slowly until the frost is withdrawn. If possible, the fruit should not be moved until it is defrosted, as it discolors quickly wherever a slight bruise occurs or even where the skin is lightly rubbed. With these precautions observed it is often possible to defrost stock that is quite firmly frozen without apparent injury to it."

Wrapping fruit with tissue, parchment, or waxed paper or unprinted newspaper was found a valuable means of preserving apples. It appears to retard the ripening of the fruit and to preserve it from decay several weeks or months longer than unwrapped fruit. Thus, the amount of decayed fruit April 29, averaged 17.6 per cent for 6 varieties when wrapped, and 41.7 per cent when unwrapped. Wrapping also prevents the transfer of rot throughout the package, and protects the fruit from bruising and discoloration due to rough handling. A double wrapper proved more effective than a single wrapper. No important difference was noticeable in the efficiency of the different wrappers.

Closed packages for apples have been found most satisfactory. In ventilated packages the fruits are likely to shrivel if stored for any considerable time. Small packages cool quickest and are therefore most satisfactory for delicate fruits or fruits in which it is desired to check the ripening process promptly. Cold-storage fruit was not found to deteriorate more rapidly after removal from the storage house than other apples equally ripe. "Apples should be in a firm condition when taken from storage, and kept in a low temperature after removal. A high temperature hastens decomposition and develops scald."

The effect of cold storage on the development of apple scald was quite thoroughly investigated. The conclusions reached relative to this subject are as follows:

"The scald is probably caused by a ferment or enzym which works most rapidly in a high temperature. Fruit picked before it is mature is more susceptible than highly colored, well developed fruit. After the fruit is picked its susceptibility to scald increases as the ripening progresses. The ripening that takes place between the picking of the fruit and its storage makes it more susceptible to scald, and delay in storing the fruit in hot weather is particularly injurious. The fruit scalds least in a low temperature. On removal from storage late in the season the scald develops quickly, especially when the temperature is high. It does not appear practicable to treat the fruit with gases or other substances to prevent the scald. From the practical standpoint the scald may be prevented to the greatest extent by producing highly colored, well developed fruit; by storing it as soon as it is picked in a temperature of 31 to 32° F., by removing it from storage while it is still free from scald; and by holding it after removal in the coolest possible temperature."

Cold storage for fruit (*Agr. Jour. Cape Good Hope, 23 (1903), No. 5, pp. 520–531*).—This article is largely made up of descriptions of methods of cold storage observed in a number of cold-storage establishments in the United States and also in the refrigerator car service.

Cherries and cherry growing in Iowa, H. C. Price and E. E. Little (*Iowa Sta. Bul. 73, pp. 45-98, figs. 27, chart 1, maps 2*).—Popular directions are given in this bulletin for growing cherries in Iowa. Statistics and maps showing the extent of production are included, together with descriptions of 74 varieties, a large number of which are Russian kinds and seedlings; a series of charts showing the blossoming season of many different sorts for 2 years; and an estimate by growers of the hardiness, freedom from disease, and productiveness of varieties in different sections of the State. The fruit and leaves of many of the varieties described are illustrated.

The Russian varieties of cherries were introduced into Iowa by Professor Budd in 1883, with the hope that they would prove hardy and productive and extend the successful culture of cherries far into the Northwest. Up to the present time they have failed to fulfill these expectations. They have proved much less immune to disease, and otherwise less suited to Iowa conditions than the sorts commonly grown in that State. It is hoped, however, that as they become further acclimated and mingled with the other varieties commonly grown seedlings may be obtained which will prove hardier and more productive than any of the varieties now in cultivation in the State.

An experiment was made to determine the value of netting in protecting cherries from birds during the ripening season. The material used was a light-weight block fish netting, with openings too small for the birds to get through. It was procured in Germany, and is believed to be too expensive for commercial use. One tree thus protected from the birds yielded 52 qts. of fruit, while an unprotected tree yielded but 32 qts. The following year the experiment was repeated, when the covered tree again yielded 20 qts. more of marketable fruit than the uncovered tree. After harvesting the fruit the netting is stored away for use in succeeding seasons. Where only a few trees are grown for family use it is believed that this method of protection may prove satisfactory.

In the authors' discussion of stocks on which to propagate cherries, they state that because of the severity of the winters in the Northwest neither the Mazzard nor Mahaleb are satisfactory, and that no definite conclusions have yet been reached regarding the value of native stocks such as Wild Bird cherry (*Prunus pennsylvanica*), Sand cherry (*P. besseyi*), and the Wild Black and Choke cherries. Suggestions are included for top-grafting.

Change in the composition of growing peaches, C. L. Penny and C. P. Close (*Delaware Sta. Rpt. 1902, pp. 87, 88, 98, 99*).—Analyses were made of samples of Elberta peach twigs, buds, blossoms, and fruit at 2 different stages of maturity, and of the shell and kernel of peach pits. The composition of the different parts as regards potash, phosphoric acid, nitrogen, starch, and sugar is shown in the following table:

Composition of Elberta peach twigs, buds, blossoms, and fruit.

	Moisture.	Potash.	Phosphoric acid.	Nitrogen.	Sugar.	Starch.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Twigs	52.87	0.29	0.11	0.50	2.88	16.55
Buds	55.61	.74	.38	1.23	.93	5.10
Blossoms	81.41	.57	.16	.69	2.86	2.06
Entire peach, June 6	87.97	.29	.02	.16	2.95	2.31
Entire peach, June 28	82.76	.33	.05	.18	1.98	3.64
Entire peach, Aug. 25	83.24	.29	.03	.10	7.42	1.98
Flesh of peach, Aug. 25[a]	....	2.32	.24	.63	61.94	7.31
Shells of pits, Aug. 25[a]	....	.33	.08	.19	3.21	25.10
Kernels of pits, Aug. 25[a]	....	1.02	.64	4.08	....	....

[a] Absolutely dry state.

It is stated that the average weight of 100 peaches when thinned June 6 was 2.3 lbs.; June 28, 6 lbs.; and at maturity, August 25, 28.6 lbs.

The orange on Citrus trifoliata (*Pacific Rural Press, 66 (1903), No. 22, p. 337, figs. 3*).—The results obtained in different parts of California from the use of *Citrus trifoliata* stock for oranges are discussed. It appears that in open culture trees on this stock make a very good growth. Satsuma and other varieties of the Mandarin class, varying in age from 5 to 9 years, make a growth in height and spread of from 8 to 10 ft. The stock appears to be especially resistant to drought, and varieties of orange and other citrus fruits worked upon it appear to stand 10° more cold than on any other stock. Trees budded on this stock are also reported to come earlier into bearing.

Production and consumption of oranges and lemons, R. M. BARTLEMAN (*U. S. Consular Rpts., 73 (1903), No. 279, pp. 620–622*).—Some statistics are given on the production and consumption of oranges and lemons in 15 different countries.

Hybrid mangoes (*Agr. News [Barbados], 2 (1903), No. 42, p. 374*).—Attention is called to the difficulty in the improvement of mangoes by hybridization, since the seeds of mangoes are polyembryonic, and it would therefore be practically impossible to tell whether a particular plant was a hybrid or not until it had grown and fruited.

Bush fruits, second report, H. L. PRICE (*Virginia Sta. Bul. 147, pp. 51–78, figs. 9*).—A report was made by the station in 1892 (E. S. R., 4, p. 728), on tests of a number of varieties of bush fruits. The work has been continued, and in the present bulletin an account is given of methods of cultivating raspberries, blackberries, currants, and gooseberries. Descriptions are given of the varieties of each fruit which have proved most successful at the station. The Success Juneberry is described as being more prolific and bearing larger fruit than the wild sorts. A few bushes are recommended for every garden. Such fruits as the Japanese wineberry, Loganberry, and dewberries have proved more or less hardy at the station, but are not considered worthy of cultivation except as novelties.

Grapes and small fruits, W. F. MASSEY (*North Carolina Sta. Bul. 187, pp. 51–74, fig. 1*).—This bulletin contains popular directions for the propagation, culture, and management of grapes, strawberries, raspberries, blackberries, dewberries, gooseberries, and currants.

The author states that since the advent of fungicides it has become possible to successfully cultivate nearly all varieties of grapes in the South. Remarkably good grapes have been produced on the pine barrens of North Carolina. For the Scuppernong and other varieties of the Vulpina class of grapes, which are most cultivated in the South, the author advocates an overhead arbor made with stout posts to which wires are stretched overhead high enough to work under with teams. The use of commercial fertilizers rather than stable manure is advocated. A mixture, consisting of about 3 per cent nitrogen, 8 per cent phosphoric acid, and 4 per cent potash, applied at the rate of about 500 lbs. per acre, is recommended for most soils. A large number of varieties which are thought most useful for cultivation in the South are briefly described.

In the notes on the culture of strawberries directions are given for winter forcing of these fruits in North Carolina. The Loganberry has been found very unproductive. The most successful method of propagating it, in the author's experience, has been to pot old plants in the fall and keep them in a cool house until midwinter and then bring them into a growing temperature; as the side shoots grow to a length of an inch or two, they are removed and rooted in the propagating bed with strong bottom heat. While of no value in North Carolina for market purposes at present, because of its unproductiveness, it is thought possible that the Loganberry may become the parent to better kinds in the hands of skillful improvers.

American vines; their adaptation, culture, grafting, and propagation, P. VIALA and L. RAVAZ (*San Francisco: California Wine Assoc., 1903, pp. 299, figs. 150*).—This is the second edition of this work. It has been translated by R. Dubois and E. H. Twight from the original French and issued as a California edition.

The work summarizes French experience in reestablishing their vineyards on American stocks. It discusses in detail the value of the different American species of grapes and hybrids as stocks for vinifera varieties on different soils and in different localities. An estimate is also given of the character and value of many vinifera hybrids. The concluding chapters deal with methods of culture, grafting, and nursery management. A bibliography of the writings of 72 authors is contained in the appendix. It is believed this book will be found especially useful to California vineyardists, as it shows the early mistakes of the French in the use of miscellaneous American stocks in reestablishing their vineyards destroyed by the Phylloxera, and clearly indicates the best methods, so far as known at present, in building up Phylloxera resistant vineyards.

On the budding of cacao, T. J. Harris (*Bul. Dept. Agr. Jamaica, 1 (1903), No. 11, pp. 255–257*).—Detailed directions are given for budding cacao trees.

The Leeming system (*Planting Opinion, 8 (1903), No. 43, pp. 753–755*).—Under this heading a successful method of coffee culture observed in India is described. The chief characteristics of the system are a thinning out of the trees so that not more than 300 are grown per acre, and a total neglect of pruning and handling the trees. By preventing the trees from overcrowding the leaf disease, drying up at the end of the branches or ripe fruit, and inability to ripen crops are largely eliminated. The trees are not cultivated at all. Drains are dug to a depth of 3 ft. and at intervals of about 20 ft. throughout the orchard. For shade and fertilizer Erythrina is grown. Under this system a heavy crop of berries is secured only every other year; but the amount of fruit is stated to average up heavier than where a small crop is produced every year.

The culture of the Central American rubber tree, O. F. Cook (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 49, pp. 86, pls. 18*).—A discussion is given of the status, botany, and culture of Castilla rubber in Central America, with an account of methods of coagulating the latex, productiveness of Castilla, and the profits and prospects of Castilla culture.

It is shown that "a continuously humid climate is not necessary to the growth and productiveness of Castilla; the indications are rather that the quantity of milk and the percentage of rubber are both increased by an alternation of wet and dry seasons." Shade does not appear to be essential in Castilla rubber culture, plants thriving better in the open than in the dense forest. Experimental plantings of Castilla in Porto Rico and the Philippines are recommended. Gathering rubber from trees less than 8 years old is believed to be undesirable. Profits in rubber culture are not believed to be anywhere near as large as prospective investors have been led to believe. The indications are that Castilla is likely to produce rubber in paying quantities only at low elevations.

Castilla rather than the usual spelling Castilloa is believed to be the correct spelling for this species of rubber.

New caoutchouc from New Caledonia, R. Schlechter (*Tropenpflanzer, 7 (1903), No. 11, pp. 526–530, fig. 1*).—The author describes a new caoutchouc tree (*Alstonia dürckheimiana*), which he found during a botanical trip in New Caledonia.

India-rubber and gutta-percha, T. Seeligmann et al., trans. by J. G. McIntosh (*New York: D. Van Nostrand Co., 1903, pp. 412, pls. 3, figs. 86*).—This book treats very fully of the botany, culture, and preparation of these substances.

New species of gutta-percha from New Guinea, R. Schlechter (*Tropenpflanzer, 7 (1903), No. 10, pp. 467–471, fig. 1*).—The author discovered a tree in New Guinea from which a very satisfactory quality of gutta-percha was secured. German cable manufacturers believe that the material is suitable for their purposes and for other manufacturing uses. A botanical description is given of the plant, which has been given the species name of *Palaquium supfianum*, and illustrations of the different parts of fruit, flower, and leaves.

Modern progress in horticulture, F. W. Burbidge (*Jour. Roy. Hort. Soc.* [*London*], *28* (*1903*), *No. 1–2, pp. 135–141*).—A paper on this subject, written largely from the florist's standpoint.

The daffodil; its root progress from planting to flowering, W. Bartholomew (*Jour. Roy. Hort. Soc.* [*London*], *28* (*1903*), *No. 1–2, pp. 163–180, figs. 16*).—The author investigated the root development of 28 varieties of daffodils grown in soil and in water cultures. The root development made in these 2 media are illustrated for the different varieties and tabular data given showing the diameter of the bulbs used, date of planting, number of days before signs of rooting appeared, time from rooting to flowering, date of flowering, length of root when plumule first appeared, number of rootlets, etc.

Flower culture for distilling in southern France, A. Piatti (*U. S. Consular Rpts., 73* (*1903*), *No. 279, pp. 662–666*).—General notes on methods of culture, with statistics of production, and the prices paid in the Nice district during the years 1898 to 1903. The kinds of plants used in the preparation of essences are the Parme violet, acacia, jonquil, mignonette, roses, orange flowers, jasmine, tuberose, and carnation. Relative to the subject of rose geranium leaves for distilling purposes, it is stated that the annual production reaches about 3,300,000 lbs. One hectare (2.471 acres) produces 55,000 to 66,000 lbs. of leaves, which are sold at from $1.14 to $1.33 per 220 lbs. About 2.2 lbs. of pure essence is obtained from each 2,204 lbs. of leaves.

Manufacture of perfumes in Grasse, R. Guenther (*U. S. Consular Rpts., 73* (*1903*), *No. 279, pp. 666, 667*).—Notes are given on the extent of the perfume industry in the city of Grasse. The annual rose consumption for the purpose of perfume manufacture is estimated at about 2,650,000, and of orange flowers 660,000 lbs. The most important product in the region is the oil of neroli, which is made from flowers of the bitter orange. The so-called oil of roses is manufactured from the grass *Andropogon schœnanthus*. The oil of geranium is produced from flowers of *Pelargonium capitatum*. Other flowers used are jasmine, violets, tuberoses, jonquil, citronella, etc.

The lighter branches of agriculture, Edith Bradley and Bertha La Mothe (*London: Chapman & Hall, Ltd., 1903, pp. 346, pls. 20, figs. 42*).—This is Volume VI of The Woman's Library, edited by Ethel M. M. McKenna. Its purpose is to encourage women to engage in some of the lighter branches of agriculture. Different chapters treat of market gardening, fruit growing, dairying, poultry keeping, and bee keeping. In addition chapters are given on the marketing of produce and women's agricultural settlements. The subjects are discussed entirely from the English standpoint and do not apply, except in a very limited way, to American conditions. The chapter on dairying is perhaps most complete. The chapters on market gardening, fruit growing, and poultry keeping are largely rambling, general discussions, apparently intended rather to inspire than to direct.

FORESTRY.

Shade trees and other ornamentals, F. Garcia (*New Mexico Sta. Bul. 47, pp. 55, figs. 29*).—The planting of shade trees and shrubs in New Mexico is followed to but a limited extent, and the present bulletin is designed to give information regarding those that are available for planting in that region. Suggestions are given on the planting and care of trees, after which a number of species are described.

The author states that black locust, Russian mulberry, box elder, China berry tree, elm, ash, honey locust, and the common pear and apricot seedlings are all adapted to New Mexico conditions. Where a low-headed dense foliage is desired the southwestern species of elder and the Texas umbrella tree may be planted, and where irrigation water is abundant and rapid growth desired various species of

cottonwood may be employed. A number of evergreen shrubs and vines which are adapted to the region indicated are also suggested.

Ornamental and commercial tree planting (*Transvaal Agr. Jour., 1 (1903), No. 2, pp. 22–24*).—An interview with reference to the best method of planting the streets of country towns with suitable trees.

Tree planting for timber and fuel, C. B. McNaughton (*Agr. Jour. Cape Good Hope, 23 (1903), No. 4, pp. 415–431*).—An experiment in tree planting is being made by the municipal authorities of Oudtshoorn, South Africa. This planting is intended not only for a protection of the watershed on which the water supply is caught, but also for the production of timber and fuel. The scheme is highly commended not only for its economic advantages, but from the indirect benefit which is expected to accrue from the successful establishment of a large plantation of selected timber trees.

The author reviews the various conditions of temperature, soil, exposure, etc., and gives directions for the sowing of seed and planting out of trees. A considerable number of trees are described whose value for planting in this locality is believed to be assured and the different species are grouped according to their best uses.

Trees and tree planting in the upper districts of Natal, T. R. Sim (*Agr. Jour. and Min. Rec. [Natal], 6 (1903), No. 18, pp. 657–663*).—Attention is called to the fact that general directions for tree planting over a large area can not be given, as a number of factors must be considered. The different objects for which tree planting is practiced are described and a list of different trees adapted to Natal conditions is given. Most of the species described are of Australian origin, the author stating that European and northeastern American species have not proved altogether satisfactory when planted in that locality.

Progress report of forest administration in Baluchistan for 1901–2, C. B. Sen (*Forest Dept., Baluchistan, India, Rpt. 1901–2, pp. VI+22*).—This is a progress report on the management of the reserve forests in Baluchistan, together with the forest administration report of the Zhob Agency. This area amounts to about 203 square miles, and the question of reserving further areas is said to be under consideration. During the period covered by the report the natural reproduction of the forest was seriously interfered with on account of the extreme dryness of the season.

Brief reports are given on the artificial reproduction in which the value of walnut, ash, tamarisk, black locust, etc., is commented upon. Comparative tables are given showing the output from the different forests for the 3 previous seasons, a decided increase being noted in the output of timber and firewood for the season covered by this report.

The relation between the mountain pine and spruce in Jutland heath culture, P. E. Müller (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), Nos. 8, pp. 289–306; 10, pp. 377–396, figs. 10*).—It is claimed that through the mycorrhiza on their roots a sort of symbiosis is established between the mountain pine and spruce, which should be taken advantage of in forest plantings in Jutland, mixed plantations to be preferred over pure stands.

DISEASES OF PLANTS.

Studies in plant diseases, F. D. Chester (*Delaware Sta. Rpt. 1902, pp. 40–46, figs. 3*).—Brief notes are given on experiments in the treatment of pear canker, pear blight, a blight of currants, a blight of Japanese chestnuts and peach stock, and spraying tomatoes for blight. During the season covered by the report the author attempted to combat the pear canker, or body blight, by thorough application with a brush of a formaldehyde-glycerin mixture composed of formaldehyde (40 per cent) 1 part, glycerin 2 parts, and water 17 parts. This mixture was applied to cankered pear trees with such beneficial results that the author is inclined to recommend it as a treatment for pear canker. Continued experiments are to be conducted along this line.

During the latter part of April the author's attention was called to a milky fluid which was exuding from blighted limbs of pear trees. This fluid was examined and found to be swarming with bacteria. In order to test its virulence dilutions were made of some of this fluid and applied with a camel's-hair brush to pear blossoms. As a result the terminal growth of all shoots whose blossoms were inoculated showed the blight. The organism was separated, grown in pure cultures, and inoculation experiments conducted, in one of which the blight extended down the shoots 14 in. in 4 weeks. In another instance the diseased tissue was observed for 24 in. on the shoot, and all the leaves were blackened. Inoculations made on pear leaves showed that they were easily infected.

A peculiar blight of red and black currants was observed that was found to be due to some sterile fungus. The blight may show itself at any point on a live cane as a black discoloration of the bark around a spur. The cause of this disease is believed to be the same as that described in New York State Station Bulletin 167 (E. S. R., 12, p. 154). As remedial treatment the author suggests cutting out and burning all blighted canes and protecting the healthy ones by a thorough spraying with Bordeaux mixture.

A blight of Japanese chestnuts was investigated in which the cause was determined as a species of Cytospora, possibly *C. ceratophora*. All attempts to produce the disease by inoculation with spores have thus far been unsuccessful. A similar disease was observed on newly set peach trees, and inoculations made with masses of spores resulted in the destruction of the wood about the point of inoculation, but there was no marked spread from that place.

The experiments in the spraying of tomatoes for blight were performed on a plat of about one-fourth acre, the vines being given 2 applications of a 6 : 6 : 50 solution of Bordeaux mixture. The sprayed plants seemed fresher and freer from blight than the untreated ones, but the amount of disease on the unsprayed plants was so slight that little commercial benefit would have arisen from such an experiment.

Letters on the diseases of plants, N. A. COBB (*Agr. Gaz. New South Wales, 14 (1903), No. 8, pp. 681–712, pl. 1, figs. 26*).—Notes are given on banana scab, stigmonose, moldy core of apple, and quince rot.

The banana scab, which is described at considerable length, affects the fruit, rendering it unsightly and seriously impairing its quality. The author has separated a fungus which he believes to be the cause of the scab, but has not yet determined its botanical relationship. The banana scab can be prevented by spraying the plants with Bordeaux mixture, but care must be exercised not to discolor the fruit by the adherence of the fungicides. In addition to occurring on the bananas in Australia a scab disease of bananas from the Fiji Islands is reported.

The stigmonose disease described was due to insect punctures and is said to seriously affect apples and pears in Australia, rendering fruit of certain varieties unsightly and almost worthless. A shot-hole effect is produced on apricot leaves by attacks of several species of thrips, and the author has described this disease as the shot-hole stigmonose of apricot leaves.

The moldy core of apples is described as due to attacks of certain molds on a fruit, entrance being secured through the calyx end of the apple. Different varieties of apple are unequally affected, and a list is given of a number of species indicating their liability to infection.

The paper concludes with a brief description of quince rots caused by species of Alternaria.

A guide to fungus parasites, H. VANDERYST (*Rev. Gén. Agron. [Louvain], 12 (1903), No. 9, pp. 358–368*).—The present paper gives in condensed form descriptions of the Ustilagineæ, their characteristics, distribution in Belgium and elsewhere, host plants, and notes on their economic importance. About 20 species are enumerated.

Some injurious mildews on cultivated plants in German East Africa, P. HENNINGS (*Notizbl. K. Bot. Garten u. Mus., Berlin, 4 (1903), No. 32, pp. 80–82*).—

Brief notes are given on a number of parasitic fungi which have been observed in German East Africa, and descriptions are given of several which are considered as hitherto undescribed. Among those described are *Limacinia tangensis*, which has been found parasitic upon mangoes and also on the cocoanut palm, *Zukalia stuhlmanniana* on seedlings of the cocoanut palm and other species of palms, *Pleomeliola hyphaenes* on the leaves of Hyphaene, and *Asterina stuhlmanni* on pineapple leaves.

Precautions against rust of cereals, H. HITIER (*Jour. Agr. Prat., n. ser., 6 (1903), No. 40, pp. 435, 436*).—Attention is called to the influence of soil, fertilizers, rotations, time of seeding, etc., on the production of cereal rusts. In order to prevent their destructive occurrence the author recommends the selection of resistant varieties, early seeding, and proper fertilization of the crop.

A bacterial disease of rice, P. VOGLINO (*Turin: Derossi, 1902, pp. 48, figs. 11; abs. in Bot. Centbl., 93 (1903), No. 37, pp. 274, 275*).—An account is given of a disease of rice known as Brusone, in which the history, description of the disease, its pathology, etiology, and results of artificial inoculation experiments are included.

This disease, which has been known for some time, has been attributed to a great number of causes, such as climatic conditions, physical conditions of soil, various fungi, etc., all of which are reviewed by the author. From his observations he is led to believe that the disease previously described as due to *Pyricularia oryzæ*, is in reality caused, in many instances at least, by the bacteria which are found present in the discolored tissues and which he has called *Bacillus oryzæ*. He states that bacteria have recently been found in Japan accompanying this disease, and that what has been frequently attributed to the above-named fungus is really caused by the bacteria, the fungus occurring as a secondary agent.

The bacteria are found to develop with great rapidity in acid media, and as the roots seem to be the portion first attacked, the author recommends rendering the soils neutral or slightly alkaline by the addition of lime to them. All attempts to combat the disease by fungicides have failed, and at present the use of lime and the selection of resistant varieties seem to be the most practical means of combating the disease.

The specialization of Erysiphe graminis, E. MARCHAL (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 21, pp. 1280, 1281*).—In a previous publication (E. S. R., 14, p. 667) the author has given the results of his investigations with cross inoculation of the conidia of this mildew on certain grasses. He has continued his investigations and in the present paper reports experiments in cross inoculation with the ascospores of the fungus.

A number of cereals and grasses were inoculated, and as a result of the experiments it is claimed that no difference was observed between inoculations with the ascospores and where the conidia were employed. This is said to prove the specialization of the parasitism of this mildew, it having developed certain physiological races which are well established and which can not be carried from one host to another except within very definite limits.

Notes on the biology of Cystopus candidus, A. EBERHARDT (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 20–21, pp. 655, 656*).—A study was made of the biology of the white rust of cruciferous plants, and it was found possible to cross inoculate a number of host plants with the conidia of the fungus. There appeared to be no specialized forms of the organisms which were limited to certain genera or species of Cruciferæ. Similar investigations with the conidia of the form growing upon salsify showed that this species was confined to this and closely allied host plants.

Some observations on crown gall of apple trees, W. B. ALWOOD (*Virginia Sta. Bul. 140, pp. 187–212, figs. 11*).—Previous to 1896, the author states, there was practically no acquaintance in the State with the crown gall of apple trees, but the inspection work in connection with the San José scale showed that this disease was prevalent and since that date it has increased to an alarming extent.

Experiments are reported in which cuttings were made of diseased roots and stocks grafted upon them, the young plant being set out to determine the development of the fungus. Several varieties of apples were used in this experiment, and as a further experiment inoculations were made into grafts on healthy stock.

The author claims that the organism causing the crown gall gains entrance to the apple seedlings in the nursery. The diseased seedlings may be detected by inspection, the unusual abundance of fibrous roots at and below the crown being an indication of the presence of the disease. Care should be exercised to avoid the planting of such trees, as they will succumb sooner or later to the crown gall. The experiments reported show that the disease may be readily transferred to healthy stock; hence, diseased trees should not be allowed to remain among healthy ones in the orchard.

Inoculation experiments with Nectria ditissima, R. Aderhold (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 24–25, pp. 763–766*).—This is a critical review of a recent paper by Brzezinski,[a] which assigned the cause of apple canker to a new species of bacteria to which the name *Bacterium mali* was given. The author reports a number of inoculation experiments which seem to show that the true cause of canker of apple trees is *Nectria ditissima*, and claims that additional evidence will be required to establish the bacterial origin of this disease.

Fungus enemies of the peach, plum, cherry, fig, and persimmon, F. L. Stevens (*North Carolina Sta. Bul. 186, pp. 23–46, figs. 10*).—The more common and destructive diseases of peach, plum, and cherry are described and notes given for their prevention wherever definite means are known. Attention is also called to the fungus diseases of the persimmon and fig, and requests made that diseased material of these plants should be sent to the station.

The relation between Clasterosporium carpophilum and the gummosis of stone fruits, R. Aderhold (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), No. 3, pp. 120–123, figs. 3*).—A discussion is given of the effect produced by this fungus on the fruit and leaves of cherries and other stone fruits, the material being condensed from a previous publication (E. S. R., 14, p. 776).

A new group of fungi, the Bornetineæ, L. Mangin and P. Viala (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 26, pp. 1699–1701*).—As a result of their studies on phthiriosis of the grape (E. S. R., 15, p. 165) the authors have established a new grouping to include the fungus *Bornetina corium*, the cause of the disease. This fungus has many affinities and the special group to which it is assigned is arranged provisionally between the Ustilagineæ and the Basidiomycetes.

The brunissure of the grape, L. Ravaz and L. Sicard (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 21, pp. 1276–1278*).—The authors have claimed that brunissure is the result of an overproduction of fruit, and they now report analyses of sound and diseased leaves, cuttings, and roots in which comparisons are made of the nitrogen, phosphoric acid, potash, lime, magnesia, and iron contents. The data indicate a considerable influence on the part of the disease in reducing the chemical composition of the tissues of the plant and also the quality of the fruit. In general, the diseased tissues are impoverished, their nitrogen, phosphoric acid, and potash being considerably reduced, while the lime and magnesia contents are higher. The authors conclude that fruit-bearing in excess drains the plant of its fertilizing principles and carbohydrates similarly to the action of parasites.

The black rot of the grape in North Carolina and its treatment, A. W. Edson (*North Carolina Sta. Bul. 185, pp. 133–156, figs. 10*).—The investigations on which this bulletin is based were conducted in cooperation between the U. S. Department of Agriculture, the State Board of Agriculture, and the North Carolina Station. After briefly describing the black rot and its effect upon the grape, the author describes the action of this disease as observed in North Carolina during 1902.

[a] Bul. Acad. Sci. Cracovie, 1903, Mar.

Experiments were conducted in 2 separate localities, and the time of appearance and subsequent reappearance of the fungus in an epidemical form is given. Considerable difference in susceptibility of varieties is noted, Delaware, Brighton, Catawba, Concord, and several others being but little affected, while Goethe and Salem grapes were badly diseased and Niagara was affected the worst of all. Most of the experiments were on the latter variety, although small blocks of other varieties were sprayed. The fungicide used was Bordeaux mixture, several different formulas of the preparation being used, and as a rule 6 applications were given the vines. In addition to spraying, the effect of inclosing the bunches of grapes in paper bags, picking off diseased leaves and berries, and the effect of fertilizers were investigated. The results of the different treatments are shown, together with the relative cost.

The experiments showed that ordinarily spraying with a 6:4:50 solution of Bordeaux mixture gave the best results, but in wet seasons, or during hot, wet, or muggy weather a stronger solution should be used. Bagging was found to protect the fruit from the fungus, but did not have the advantage possessed by the Bordeaux mixture of protecting the foliage and thus prolonging the growing season of the vines. The cost of spraying averaged $15.52 per acre.

The use of copper in combating gray rot of grapes, C. de James (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 46, p. 571*).—An account is given in which the author complains of the inefficiency of copper compounds as a means for the prevention of this disease. Applications were made of a mixture of triturated sulphur, sulphosteatite, and superphosphate, but after a brief period of rain the disease appeared with great destructiveness on both treated and untreated vines.

Powdery mildew and some grape hybrids, J. de Bouttes (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 45, pp. 547, 548*).—An account is given of the resistance of certain hybrids to powdery mildew. These hybrids have been produced at Flamarens, and represent the crosses of a number of different varieties. Some of the best hybrids are found to be the most resistant to the powdery mildew, as shown by their appearance at the close of the season. Where no fungicides had been used, one particular variety was found not only resistant to powdery mildew, but to the downy mildew as well.

The change in coloration of copper and sulphur fungicides after preparation, J. M. Guillon (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 24, pp. 1483, 1484*).—In a previous communication (E. S. R., 14, p. 669) the author called attention to the possibility of combating downy and powdery mildew of grape by applications of Bordeaux mixture and sulphur. This mixture simply holds the sulphur in suspension, and it is found that if not used immediately a decided change takes place in the color of the solution, which at length becomes nearly black. This change is the result of the formation of insoluble sulphur compounds. If this change does not take place it is an indication that the adherence of the compound has been diminished and that the solution should be used immediately after preparation.

A pepper vine disease, C. A. Barber (*Planting Opinion, 8 (1903), No. 35, pp. 618–621*).—The author describes some diseases to which pepper vines are subject, dividing them into 3 classes, one of which is called "canker," the second due to the attack of nematodes, while the third is caused by the presence of the mycelium of some fungus growing in the vessels of the plants to such an extent as to prevent their water conduction. Each of the diseases is briefly described and a suggestion is given for a possible prevention.

The dry-rot fungus, C. von Tubeuf (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), Nos. 3, pp. 89–104; 7, pp. 249–268, pls. 2, figs. 4*).—On account of its economic importance studies were made of *Merulius lacrymans*, the dry-rot fungus of timber. The occurrence and distribution of the fungus are commented upon, and investigations reported on the possibility of the fungus living parasitically in the living trees, its winter condition, spore formation, growth, and results of culture experiments.

A disease of plane trees, J. Beauverie (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 25, pp. 1586–1588*).—A description is given of a disease of plane trees caused by *Glœosporium nervisequum.* This fungus, which is usually supposed to confine its attack to the leaves, has been found to infest the extremities of young branches and sometimes even the larger ones and the trunks of the trees. When attacking the stems and branches of the trees the fungus destroys the cambium and phloem and survives from year to year as a mycelium in the tissues of the host, appearing in the spring to spread to other plants. From this form it spreads directly to the leaves, and so severe has been the attack in certain regions that it is feared the planting of plane trees will have to be abandoned.

The "stagheadedness" of spruce, C. von Tubeuf (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), No. 1, pp. 1–9, figs. 4*).—An examination was made of some of the causes of the frequent occurrence in spruce and other trees of "stagheadedness," by which is meant the death of one-third or more of the tops of the trees. This condition is of wide extent and has been attributed to various causes. The author seems inclined to the opinion that the preliminary injury is due to electric discharges through the trees, followed by attacks of bark beetles, fungi, etc.

The anatomical and pathological structure of stagheaded coniferous trees, C. von Tubeuf (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), Nos. 8, pp. 309–315; 9, pp. 367–372; 10, pp. 413–416, pls. 2, figs. 7*).—The anatomical and pathological structure of larch, spruce, pine, and other coniferous trees, as modified by the disease known as staghead, is described.

The leaf cast of Pinus cembra, H. C. Schellenberg (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), No. 8, pp. 306–309*).—A discussion is given of the leaf cast of *Pinus cembra*, which is attributed to *Lophodermium pinastri.*

A disease of Phœnix, W. H. Taplin (*Amer. Florist, 21 (1903), No. 806, p. 587*).—A brief account is given of an attack of palm leaves by the fungus *Peronospora phœnixæ.* This fungus is often found upon a number of species of Phœnix, and renders the leaves unsightly as well as interfering with their functional activity. When specimens are badly affected the author recommends as a means of checking the further spread of the disease burning, or thorough applications of Bordeaux mixture of moderate strength to the infected foliage.

ENTOMOLOGY.

Report of the entomologist, E. D. Sanderson (*Delaware Sta. Rpt. 1902, pp. 109–151, pls. 6, fig. 1*).—Experiments were made with remedies for codling moth.

Trees in various parts of the State were sprayed with different arsenical insecticides, and the results indicated that arsenate of lead applied at the rate of 1 lb. to 50 gal. of water gave a larger percentage of perfect fruit than the arsenites of lime or soda, or Paris green or green arsenoid. All these arsenicals, with the exception of the arsenate of lead, were of about the same value. It was found to be unnecessary to make 3 applications provided the first 2 were properly done and the addition of adhesives to the arsenical sprays proved to be of doubtful value. The addition of kerosene to arsenical applications was made without harm to the trees. The benefit from the most successful spraying for codling moth was estimated at from 25 to 75 per cent.

Notes are also given on insect parasites of the codling moth, and on banding trees. About 4 per cent of the larvæ were captured by banding. Spraying experiments with various contact insecticides and fumigation with hydrocyanic-acid gas, Aphis Punk, Nikoteen, tobacco leaves, and Nicoticide were made in the control of plant lice, including *Aphis pomi*, *A. sorbi*, and *A. fitchii.* The best results were obtained by hydrocyanic-acid gas. The San José scale was successfully controlled by the use of the California wash and by summer applications of crude petroleum or kerosene. The kerosene was not as effective as crude petroleum. A number of Asiatic ladybird

beetles were received from the Division of Entomology of this Department, but their value in Delaware has not yet been determined.

In controlling the strawberry root louse the best results were obtained by burning over infested patches and by fumigating with hydrocyanic-acid gas or dipping in tobacco water. Whale-oil soap and kerosene emulsion injured a large number of the plants which were dipped into these solutions. Notes are also presented on the periodical cicada, harlequin cabbage bug, white-marked tussock-moth, fall webworm, strawberry weevil, apple-tree tent caterpillar, plum curculio, etc.

First annual report on the noxious insects of the State of Illinois, B. D. WALSH (*Bloomington: Illinois State Hort. Soc., 1903, 2. ed., pp. 140, pl. 1*).—In a preface to this edition, written by S. A. Forbes, it is stated that the report has long been out of print and that this edition is issued on account of the value of the material contained in the report. The subjects treated include grape curculio, grape-leaf gall-louse, rose bug, grape-root borer, codling moth, apple maggot, oyster-shell bark-louse, woolly aphis, plum curculio, plum moth, locusts, etc.

Report of the State entomologist, W. M. SCHÖYEN (*Aarsber. Offent. Foranstalt. Landbr. Fremme, 1902, pt. 1, pp. 110–153, figs. 21*).—As usual in these reports the entomologist presents descriptive biological and economic notes on the insects which were of most importance during the year in Norway. Among the numerous species discussed mention may be made of the following: Crane flies, frit fly, pea weevil, cabbage-leaf maggot, flea-beetles, cabbage butterfly, carrot fly, tarnished plant bug, apple weevil, pear-leaf blister-mite, *Argyresthia ephippella*, currant sawfly, *Bombyx pini*, and various other species injurious to pine and other cultivated trees and plants.

First report on economic zoology, F. V. THEOBALD (*London: British Mus. Nat. Hist., 1903, pp. XXXIV+192, figs. 18*).—This volume includes a large number of miscellaneous articles on economic zoology and is intended for use by the Board of Agriculture of London. The introduction was prepared by E. R. Lankester and contains a classification of animals into groups, from the point of view of economic entomology. The various ways in which animals affect man are mentioned, with examples of species under each group.

A large number of miscellaneous insects and other noxious animals are discussed under groups according as they are injurious to field crops, horticulture, trees, domestic animals, household materials, etc. Copies are also given of reports to foreign and colonial offices on the subjects of tsetse fly, white ants, locust plagues, etc., and a list is presented of North African locusts and white ants.

Hessian fly reared in the laboratory, F. L. WASHBURN (*Canad. Ent., 35 (1903), No. 11, p. 316*).—The author presents data obtained from breeding experiments with the Hessian fly in the laboratory and also from observations in the field. The possibility of a second brood of Hessian fly is suggested by these observations.

Remigia latipes, A. HEMPEL (*Bol. Agr. São Paulo, 4. ser., 1903, No. 7, pp. 314–320.*)—The caterpillars of this species are injurious to corn, millet, and other cultivated plants. Notes are given on the appearance of this insect in its different stages, on the means of distribution, natural enemies, and artificial insecticide treatment.

Insect and fungus enemies of the peach, plum, cherry, fig, and persimmon, F. SHERMAN, Jr. (*North Carolina Sta. Bul. 186, pp. 5–22, figs. 7*).—Notes on fruit-tree bark-beetle, San José scale, plum curculio, fig eater, peach-tree borer, peach-twig borer, black peach aphis, twig girdler, fall webworm, etc.

Fighting the San José scale insect in 1903, W. E. BRITTON and B. H. WALDEN (*Connecticut State Sta. Bul. 144, pp. 26, pls. 3*).—During the season of 1903 spraying experiments were made on about 11,500 trees, including peach, pear, and apple. The insecticides used were lime, sulphur, and salt; lime, sulphur, and copper sulphate; lime and sulphur; lime and potassium sulphid; whitewash; strong Bordeaux mixture; and a 25 per cent mechanical mixture of crude oil, all being applied to dormant trees, while kerosene soap emulsion was used upon growing trees.

The California wash was used more extensively than any other insecticide, and the lime-sulphur mixture and the lime and potassium sulphid proved about equally efficacious. Whitewash and Bordeaux mixture proved unsatisfactory. The Oregon wash was also less effective than the California wash. Crude oil is regarded as a very effective insecticide, but is considered somewhat dangerous in the hands of the average orchardist. Throughout the State nearly 40,000 trees were sprayed by orchardists with the lime-sulphur mixture with satisfactory results. This remedy adhered longest to the trees when applied just before the appearance of the leaves. Kerosene emulsion proved rather unsatisfactory as a summer treatment.

The treatment of orchards infested with San José scale, W. Newell (*Georgia State Bd. Ent. Bul. 8, pp. 20, figs. 2*).—The author briefly discussed the insecticide work which has been done by the Georgia State Board of Entomology since 1898. During this period various materials, washes, and patent insecticides have been tested, but none has proved satisfactory except oil treatments and lime-sulphur-salt wash.

In the use of oils the best results were obtained when they were applied in the form of emulsions. In February, 1903, a large orchard was sprayed with regular strength of lime-sulphur-salt wash, all trees being thoroughly coated. The results of this application are presented in tabular form. It appears that the lime-sulphur-salt is not immediately destructive to adult insects, but has the power for a considerable time of preventing the larvæ from establishing themselves. This insecticide also destroys the scaly covering and exposes the mature insects to the action of the weather and predaceous enemies.

Further experiments with lime-sulphur-salt wash were conducted in a number of other orchards and with uniformly gratifying results. In no instance was any injury done to the trees except where the wash was applied after the buds were beginning to open. Further experiments showed that this remedy could be applied as a summer treatment provided care was exercised not to cover the foliage and undergrowth. The lime-sulphur-salt mixture was believed to be more effective and safer than any of the emulsions and mixtures of oils. It is recommended that this remedy be applied in December and again toward the end of February or first of March.

The codling moth, C. B. Simpson (*U. S. Dept. Agr., Division of Entomology Bul. 41, pp. 105, pls. 16, figs. 19*).—The present bulletin is the final report of the author on his investigation of the codling moth of the Northwest. Previous preliminary reports have already been noted (E. S. R., 14, pp. 468, 536).

The subject of the codling moth is discussed in a general manner, the following topics being included in the bulletin: Systematic position of the codling moth, varieties, geographical distribution, means of spread, depredations, food habits, life history, and means of combating the insect. The author concludes that there are but 2 broods of codling moth per year in the arid parts of the West, and that the existence of a third brood is not yet proved. In controlling the codling moth spraying with arsenicals is recommended at 2 periods corresponding to the 2 generations of the insect. At the early period 2 applications should be made, 1 a few days after the petals fall and the other about 2 weeks later. In Idaho the second generation of larvæ begin to enter the apples about the last week in July and the third spraying is required at this period.

In addition to spraying, banding the trees and the destruction of larvæ in windfalls are recommended. The author concludes that by the use of proper preventive measures, such as spraying and banding for a period of years, the injury from the codling moth may be reduced from nearly 100 per cent to from 5 to 10 per cent. A bibliography of literature on the codling moth is appended to the bulletin.

When to spray for codling moth, G. Quinn (*Jour. Agr. and Ind. South Australia, 7 (1903), No. 3, p. 140*).—The author recommends that the first spraying should be made when the young fruits are just formed, and the second 9 or 10 days later.

Other applications may be made at intervals of from 14 to 20 days. As an insecticide Kedzie's formula for arsenite of lime is recommended.

The peach-tree borer, C. L. Marlatt (*U. S. Dept. Agr., Division of Entomology Circ. 54, pp. 6, fig. 1*).—A revised form of Circular No. 17.

The depredations of Retinia turionana, together with notes on the life habits of members of this genus, J. Ritzema Bos (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 8, pp. 241–250, figs. 2*).—Economic and biological notes are presented on *Retinia resinella, R. duplana, R. buoliana,* and *R. turionana.* The last-named species is very injurious to pines in Holland and elsewhere in Europe and notes are given on its injurious effects, manifested in the malformations of growing twigs of pines.

In controlling this species in the nursery or in young trees the author recommends that the larvæ be crushed in the infested buds, and that badly infested trees be removed. It is desirable that deciduous trees be planted around areas of conifers.

A study of insect metamorphosis, C. Pérez (*Bul. Sci. France et Belg., 37 (1903), pp. 195–427, pls. 3, figs. 32*).—The author made an elaborate study of the metamorphosis of *Formica rufa.* Notes are given on various details of gross and microscopic anatomy as observed during the different developmental stages of this insect. The literature of the subject is critically discussed in connection with a bibliography.

The cocooning habit of spiders, T. H. Scheffer (*Industrialist, 30 (1903), No. 6, pp. 88–93*).—Notes are given on the habits and life history of various species of spiders with special reference to the purpose and method of constructing cocoons. Several species of spiders were studied, including *Araneus trifolium, Argiope aurantia,* etc.

Millipedes and centipedes (*Bd. Agr. and Fisheries [London], Leaflet 94, pp. 4, figs. 3*).—Notes are given on the habits and life history of these animals and on the means of combating them. Since they are usually distributed in leaf mold and similar substances, it is recommended that such material be mixed with lime or that infested soil be treated with bisulphid of carbon.

The Trichodectidæ, M. Morse (*Amer. Nat., 37 (1903), No. 441, pp. 609–624, figs. 18*).—Notes are given on the feeding habits of the genus Trichodectes and a key is presented to assist in the identification of the 18 species which are recognized as occurring in North America. A brief list of literature relating to this genus is also presented. Detailed descriptive notes are given for each of the species.

The Diplopoda, P. Silvestri (*Classis Diplopoda. Portici: E. Della Torre, 1903, vol. 1, pp. 272, pls. 4, figs. 346*).—In this first volume of the author's account of the Diplopoda the anatomical structure of species of this group is described in detail, and the most important features are illustrated. Especial attention is given to the anatomy of the integument, muscles, and body segments.

Certain new cercomonadines, little-known parasites in the intestines of insects, L. Léger (*Arch. Protistenkunde, 2 (1903), No. 1, pp. 180–189, figs. 4*).—Notes are given on a number of protozoan organisms parasitic in the intestines of common insects, such as the house fly and species of Tabanus, etc. The parasitic organisms include *Herpetomonas muscæ, H. gracilis, H. lesnei,* and species of Crithidia.

The monthly bulletin of the Division of Zoology, H. A. Surface (*Pennsylvania State Dept. Agr., Mo. Bul. Div. Zool., 1 (1903), No. 4, pp. 32, pls. 2*).—Brief notes on plant diseases and insect pests of the month of August, carpet beetle, grain weevil, game birds, and weeds.

Report of the economic zoologist, B. F. MacCartney (*Pennsylvania State Dept. Agr. Rpt. 1902, pt. 1, pp. 171–178*).—A brief account is presented of the nursery inspection in connection with a list of the nurserymen of Pennsylvania.

Canadian law relative to imports of nursery stock, F. S. S. Johnson (*U. S. Consular Rpts., 73 (1903), No. 279, pp. 637–639*).—The attention of nurserymen is called to the inspection law of Canada relative to trees, plants, cuttings, buds, etc., liable to infestation by San José scale. Such shipments will be fumigated by the

Canadian government officials at the risk of the shippers or consignees. A list of plants exempt from fumigation is also given.

The use of hydrocyanic-acid gas in the control of insects, H. FAES (*Bul. Soc. Vaud. Sci. Nat., 4. ser., 39 (1903), No. 146, pp. 65–82*).—Attention is called to the disadvantages in the use of carbon bisulphid as compared to hydrocyanic-acid gas.

A number of experiments were made by the author in fumigating greenhouses which contained a large variety of plants of different hardiness, infested with scale insects and plant lice. The amount of cyanid of potash used per cubic meter of space varied from 2 to 5.25 gm., while the sulphuric acid and water were used at the rate of 4.5 cc. and 6.75 cc., respectively, for each 3 gm. of cyanid. The period of fumigation varied from 25 to 35 minutes. It was found on ventilating the greenhouse after fumigation that the gas had entirely disappeared within 15 minutes.

A list is given of the plants in the various greenhouses in which experiments were made. The insects which it was specially desired to kill were *Dactylopius adonidum* and *Aphis dianthi*. When cyanid was used at the rate of 3.5 gm. per cubic meter and the greenhouse was fumigated for 30 minutes, all species of scale insects, including the one just mentioned, were killed. Equally satisfactory results were obtained in the destruction of plant lice.

Observations were also made to determine the effect of the gas upon other animals. When the cyanid was used at the rate of 3.5 gm. per cubic meter, white mice and guinea pigs were killed within 5 minutes, and cats succumbed after 15 minutes. Frogs and salamanders were destroyed during a fumigation period of ordinary length. No injury was done to plants except when a large quantity of cyanid was used. The author considers that 5.3 gm. per cubic meter is too much and recommends for the fumigation of greenhouses a charge of 4.25 gm. per cubic meter.

Insecticides, C. L. PENNY (*Delaware Sta. Rpt. 1902, pp. 84–87*).—An analysis of a sample of arsenite of lime as prepared by a fruit grower showed that only 6.77 per cent of arsenious acid was present and that probably some of the acid was lost in boiling. The addition of sodium arsenite to Bordeaux mixture at the rate of 2 oz. per barrel was found to leave about 2.75 per cent of the total arsenious acid in solution. This quantity, however, is considered harmless in Bordeaux mixture.

When Paris green, Bordeaux mixture, and crude petroleum were shaken together it was found that after being allowed to stand for some time a greenish blue scum formed on the surface, consisting of petroleum, while a clear middle layer consisting of the clear portion of the Bordeaux mixture was formed, and a blue precipitate, consisting of the sedimentary portion of the Bordeaux mixture and Paris green, collected at the bottom. In mixing whale-oil soap, Paris green, and Bordeaux mixture it was found that the clear solution of soap was completely precipitated by the Bordeaux mixture, and that an insoluble lime soap was thus formed. Neither copper hydroxid nor Paris green was found to have any perceptible chemical effect on whale-oil soap when the latter was mixed and agitated with either of the former.

Remedies for insect and fungus pests of the orchard and farm, A. M. LEA (*Tasmania: Dept. Agr., 1903, 2. ed., pp. 53, figs. 30*).—This is an enlarged and revised form of the original edition (E. S. R., 14, pp. 466, 467).

A monograph of the Culicidæ or mosquitoes, F. V. THEOBALD (*London: British Mus. Nat. Hist., 1903, vol. 3, pp. XVI + 359, pls. 17, figs. 193*).—This is a continuation of the author's monograph on mosquitoes (E. S. R., 13, p. 770), and was issued for the purpose of including descriptions of new species and other interesting material which has been examined since the publication of the 2 previous volumes. More than 100 additional collections have been received and from these collections 88 new species and 8 new varieties have been found and described. Notes are given on the biology and life history of the more important species.

Soil nitrification v. the incidence of malaria and other mosquito-borne diseases, A. R. WADDELL (*Lancet [London], 1903, I, No. 23, pp. 1589–1590; abs. in*

Agr. News [*Barbados*], *2* (*1903*), *No. 35*, *p. 270*).—"The author states that one part of strong liquor ammoniæ in 4,000 parts of water is fatal to the mature mosquito larva, and concludes that the addition of nitrogen compounds to surface waters, through the medium of actively nitrifying soils, should prove an effective means of checking the multiplication of mosquitoes and of preventing malaria."

Bees and bee keeping, H. PILLAR, Jr. (*Rpt. Supt. Farmers' Insts. British Columbia*, *4* (*1902*), *pp. 37–40*).—A brief outline is presented of the operations which are necessary in the successful management of bees, including notes on drones, hives, swarming, honey plants, etc.

The use of bee escapes, E. BERTRAND (*Rev. Internat. Apicult.*, *25* (*1903*), *No. 10*, *pp. 201–203*, *figs. 2*).—A brief description of the mechanism of these devices and on the advantages of using them in the management of bees.

Means of ridding combs of the larvæ of drones, N. BARTHÉLEMY (*Rev. Internat. Apicult.*, *25* (*1903*), *No. 10*, *pp. 207, 208*).—The author calls attention to the desirability of examining the combs for the presence of male larvæ, and gives brief notes on practical methods for removing them from the comb.

Experiments with the glossometer, J. MAISTRE (*Rev. Internat. Apicult.*, *25* (*1903*), *No. 10*, *pp. 198, 199*).—The author made a number of measurements of the tongues of bees for the purpose of determining the possible effect of crossing Italian and native bees upon the lengthening of the tongues. The results are encouraging, but not yet conclusive.

Silk industry of the United States and of France, J. C. COVERT (*U. S. Consular Rpts.*, *73* (*1903*), *No. 279*, *pp. 625–628*).—Statistics are given on the value of silk fabrics produced in the United States and France and on the general conditions of this industry.

FOODS—NUTRITION.

Foods; their composition and analysis, A. W. and M. W. BLYTH (*New York: D. Van Nostrand Co.*, *1903*, *5. ed.*, *pp. 616*).—The authors state that this volume has, to a great extent, been rewritten, much new material being added to the text, as well as new tables and diagrams. Chapters on the detection and estimation of arsenic, the composition and analysis of spices, and the bacteriology of water constitute a part of the new material.

The microscopical examination of food and drugs, H. G. GREENISH (*London: J. and A. Churchill*, *1903*, *pp. 321*, *pls. 168*; *rev. in Public Health*, *16* (*1903*), *No. 2*, *p. 99*).—"The book is divided into 12 sections, dealing respectively with starches, hairs and textile fibers, spores and glands, ergot, woods and stems, leaves, barks, seeds, fruits, rhizomes and roots, with 2 appendices, one on the preparation of reagents and the other on the varieties of cell wall and cell contents."

Directions are given for preparing and mounting specimens, and much information is included regarding the foods, etc., described.

The acid content of bread or similar bakers' goods, A. SCHMID (*Jahresber. Thurgau. Kanton. Lab.*, *7* (*1902*); *abs. in Ztschr. Untersuch. Nahr. u. Genussmtl.*, *6* (*1903*), *No. 21*, *p. 1008*).—As shown by the results of 26 analyses of goods from 4 bakeries the acid content varied from 2 to 9 degrees. The acid content of 9 samples of grits varied from 2.5 to 3.7 degrees.

Analyses of bakers' goods, BALLAND (*Jour. Pharm. et Chim.*, *6. ser.*, *16* (*1902*), *No. 11*, *pp. 533–535*; *abs. in Ztschr. Untersuch. Nahr. u. Genussmtl.*, *6* (*1903*), *No. 21*, *p. 1009*).—Analyses are reported of a number of biscuits, cakes, and similar goods.

Concerning tropical flours and starches used as foods, BALLAND (*Jour. Pharm. et Chim.*, *6. ser.*, *17* (*1903*), *No. 10*, *pp. 476–478*).—Analyses are reported of apé starch (*Arum macrorhizum*), conophallus meal from tubers of an Amorphophallus, tavolo starch (*Tacca pinnatifida*), mapé starch (*Inocarpus edulis*), nété meal (*Parkia [illegible]*), arrowroot (*Maranta arundinacea*), banana meal, caryot starch (*Caryota [illegible]*), sago

starch (*Sagus rumphii*), talipot starch or raw palmirah root flour (*Corypha umbraculifera*), and bread-fruit flour.

Food stuffs made from cassava, BALLAND (*Jour. Pharm. et Chim., 6. ser., 17 (1903), No. 7, pp. 316–319*).—The author reports the composition of cassava meal, starch, tapioca, cassava cakes, and other products.

The utilization of rice and rice by-products (*Bol. Agr. São Paulo, 4. ser., 1903, No. 6, pp. 269–271*).—A descriptive article quoting analyses.

Sorghum flour (*Bol. Agr. São Paulo, 4. ser., 1903, No. 6, pp. 272, 273*).—The manufacture and uses of sorghum flour are described.

Banana flour, E. LEUSCHER (*Jour. Agr. Trop., 3 (1903), No. 28, pp. 304–306*).—Information regarding banana flour is summarized and briefly discussed.

Leuscher's method of preparing banana flour, J. NEISH (*Jour. Jamaica Agr. Soc., 7 (1903), No. 11, pp. 439–441*).—The method referred to is essentially as follows: Selected green bananas are plunged into water at 80° C. to facilitate peeling and after remaining in the water from 4 to 5 minutes are removed, peeled, and introduced into a vacuum dryer having a pressure of 700 mm. While drying the bananas are kept in motion by means of stirrers which alternate and move between fixed knives. The drying is completed in about 2 hours, after which the mass is passed through sieves with 120 meshes to the square inch. Any material which may remain is passed through a simple mill and sifted afresh. A banana flour of good keeping quality, it is said, contains about 15 per cent water.

The determination of the baking quality and value of East Prussian wheat, E. REISCH (*Fühling's Landw. Ztg., 52 (1903), Nos. 15, pp. 545–552; 16, pp. 576–585; 17, pp. 605–624; 18, pp. 654–670, figs. 5; 19, pp. 700–712, figs. 2*).—In the author's opinion laboratory methods for determining the baking quality of flour are better fitted to give reliable results than practical tests in a bakery. Using such methods an extended investigation was made with flours ground from East Prussian wheats.

The results obtained showed that there was considerable variation between winter and spring wheat grown on the same land, and between the crops of different seasons, the amount of rainfall, for instance, having a marked effect on the composition of the crop, and that such considerations must be taken into account in judging of the quality of the wheat from any given region. Other conclusions have to do with details of the methods followed.

Milk in powdered form (*Breeders' Gaz., 44 (1903), No. 18, p. 724*).—The method of manufacturing a desiccated and powdered product from skim milk, which it is claimed can be used in many ways as an article of diet, is briefly described.

Studies of the more important milk preparations in Switzerland with special reference to the chemical composition, germ content, coagulability, and the digestibility in vitro, F. SIDLER (*Arch. Hyg., 47 (1903), No. 4, pp. 327–406*).—From investigations made with a large number of samples of pasteurized, sterilized, and condensed milks prepared in Switzerland on a commercial scale the following conclusions were drawn:

All the milk preparations examined conformed to the requirements of the Swiss Food Control. On account of the heat employed in manufacture the amount of so-called soluble protein in all the samples, with the exception of one brand, was about one-third less than in normal unheated milk. One of the sorts of modified milk did not agree with its purported composition, doubtless because the heat employed in sterilizing had changed the ratio of casein to dissolved proteids. As shown by cultures, 28 of the 109 samples of bottled and canned milk examined contained bacteria, although in most cases no change could be noted in the milk. In Switzerland as in Germany "sterilized" milk is not always free from microorganisms.

The effect of hydrochloric acid upon the milk was found to vary with the degree of heat which had been employed and the method of manufacture. Coagulation

with rennet also varied with the degree of heat employed. Generally speaking, the higher the temperature the slower the rate of coagulation.

As shown by artificial digestion experiments, the different milk preparations varied little in digestibility, condensed milks being somewhat less thoroughly digested than the bottled goods. It was noted that the amount of hydrochloric acid used had a marked effect upon the digestibility of the sample, much more being digested when 1 per cent was added than with either 0.5 or 0.25 per cent. A bibliography is appended.

Holland's export meat trade, T. A. L. BEEL (*Ztschr. Fleich- u. Milchhyg., 13 (1903), No. 9, pp. 278, 279*).—The official regulations governing the export meat trade are quoted.

The sorghum beer of the Matabeles, H. NEUVILLE (*Jour. Agr. Trop., 3 (1903), No. 28, pp. 296–298*).—A descriptive article quoting an analysis by S. A. Pingstone. Among other topics the author discusses the character of the fermentation which takes place in the manufacture of sorghum beer.

Means for the prolongation of life, H. WEBER (*British Med. Jour., 1903, No. 2240, pp. 1445–1451*).—In addition to other matters the author discusses food and diet in relation to longevity. Moderation in eating and drinking is recommended, especially as old age approaches.

Observations on the digestion of proteids with papain, L. B. MENDEL and F. P. UNDERHILL (*Trans. Connecticut Acad. Arts and Sci., 11 (1901–3), pt. 1, pp. 1–14*).—The data reported have been noted from another publication (E. S. R., 14, p. 680).

The value of calorimetric examination, A. SCHLOSSMANN (*Berlin. Klin. Wchnschr., 50 (1903), No. 12, pp. 264, 265; abs. in British Med. Jour., 1903, No. 2234, p. 61.*)—The importance of determining the fuel value of food and excretory products for clinical purposes is pointed out.

The employment of the Berthelot bomb calorimeter for determining the existence of arsenic in the body, G. BERTRAND (*Ann. Inst. Pasteur, 17 (1903), No. 9, pp. 581–586*).—On the basis of experiments which are reported, the author recommends the determination of arsenic in the residue remaining in the bomb after combustion is completed as a suitable method for estimating this element in materials of animal origin.

Phosphorus metabolism by adult man, R. EHRSTRÖM (*Versamml. Nord. Naturf. u. Aerzt., Verhandl. Sek. Anat., Physiol. u. Med. Chem., 1902, pp. 87, 88*).—A brief account of an investigation included in a report noted from another publication (E. S. R., 14, p. 1100).

ANIMAL PRODUCTION.

Concentrated feeds, C. BÖHMER (*Die Kraftfuttermittel. Berlin: Paul Parey, 1903, pp. XII+650, figs. 194*).—This volume, which is designed as a practical handbook, takes into account the sources from which concentrated feeds are derived, their method of preparation, composition, digestibility, and uses, special attention being paid to the detection of adulteration and to microscopical analysis. The sections into which the book is divided are cereals and milling processes; microscopical examinations of feeding stuffs for the detection of adulterants and determining age; cereal grains, milling products, and by-products of fermentation; leguminous seeds and their by-products; by-products of oil making; and meat meals and condimental feeds. Weed seeds and a number of other topics are treated of in an appendix.

The valuation of feeding stuffs, C. KROMPHARDT, G. FAYE, ET AL. (*Ugeskr. Landm., 48 (1903), No. 23, pp. 249–253*).—According to the authors, the value of a concentrated feed is represented by the protein multiplied by 1.5, plus the fat multiplied by 2.4, plus the nitrogen-free extract, plus 0.5 times the crude fiber, digestible nutrients being considered in every case. The factor 1.5 represents the cost of nitrog-

enous components when the nonnitrogenous substances, according to average prices of different feeding stuffs in common use in Denmark, are assumed to be equal to 1. Protein is taken as equivalent to nitrogen multiplied by 6.25.—F. W. WOLL.

The nutritive value of feeding stuffs, G. FAYE (*Ugeskr. Landm., 48 (1903), No. 28, pp. 302, 303*).—In continuation of the above, the author advocates the use of isodynamic units for the comparison of the value of feeding stuffs, as follows: Protein plus 2.4 times the fat, plus nitrogen-free extract, plus 0.5 times the crude fiber.—F. W. WOLL.

Concerning the nutritive value of cellulose, B. USTYANTSEV (*Zap. Novo-Alexandri Inst. Selsk. Khoz. i Lyesov, 15 (1902), No. 2, pp. 101–191*).—In view of the great differences of opinion regarding the nutritive value of cellulose, the author undertook a series of investigations on the subject, using 2 sheep and 3 rabbits, studying with the sheep the effect of the influence of crude fiber on the metabolism of nitrogen and with the rabbits taking into account the metabolism of carbon as well. The respiratory products were studied by the method elaborated by Pashutine and his associates. The principal conclusions follow:

In the case of sheep the digestible crude cellulose exercised little influence on the cleavage of protein. When pentosans and pure cellulose were considered, the effect of the cellulose was more marked. Digestible crude cellulose, as well as pure cellulose and pentosans had a much smaller protein-protecting power than starch and sugar with both sheep and rabbits. In the case of rabbits, the experiments showed that the addition of cellulose to a ration practically free from it decreased the outgo of nitrogen in the urine. However, this was largely compensated for by the larger proportion of nitrogen excreted in the feces. Cellulose was found to protect fat from cleavage to a certain extent and, therefore, the author believes, may justly be called a nutrient.—P. FIREMAN.

The feeding value of whale-flesh meal, S. HALS and A. KAVLI (*Norsk Landmandsblad, 22 (1903), No. 30, pp. 395–397*).—Analyses of 27 samples of whale-flesh meals of different origin are given, together with figures for the digestibility of protein as determined by the Stutzer method, and for the ammonia content. The following table shows average results, the material designated No. 1 being a pure product, and No. 2 a product containing considerable quantities of bone, which it is stated might be properly considered as a whale guano:

Composition of whale flesh and whale-flesh meal.

	Water.	Protein.	Fat.	Ash.	Coefficient of digestibility of protein.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Whale-flesh meal, No. 1 (pure product)	7.28	62.27	25.07	4.78	71.4
Whale-flesh meal, No. 2 (meal with bone)	5.60	51.11	21.87	19.18	72.8
Fresh whale flesh	81.58	10.37	.86	.39	98.3

The relatively low figures for the digestibility of the protein of whale-flesh meal was attributed to the high temperatures employed in drying it. A low water content was accompanied by low digestibility and a small percentage of ammonia. In the case of 7 samples, containing on an average 5.6 per cent water, the average coefficient of digestibility of protein was 62.8 per cent and the average ammonia content 0.15 per cent, as compared with a digestion coefficient for protein of 76.7 per cent and an ammonia content of 0.39 per cent in the case of 15 samples containing on an average 8.24 per cent water.—F. W. WOLL.

Molasses in the feeding of farm animals, P. DECHAMBRE (*Bul. Agr. Algérie et Tunisie, 9 (1903), No. 19, pp. 438–445*).—A summary and discussion of work in this line.

Stock and poultry powders or condimental foods, D. O. NOURSE and M. FERGUSON (*Virginia Sta. Bul. 144, pp. 10*).—Microscopical analyses are reported of 23 kinds of condition powders, stock foods, condimental poultry foods, and similar goods. Without exception they were found to contain small amounts of such materials as charcoal, sulphur, alum, fenugreek, epsom salts, gentian, common salt, cayenne, and ginger, the greater bulk consisting of ordinary feeding stuffs such as ground wheat feed, corn meal, linseed meal, cotton-seed meal, gluten, etc.

The authors point out that the actual cost of manufacture must be small, probably not exceeding $40 per ton, while the cost to the consumer varied from $140 to $1,600 per ton. The use of these condimental feeds is discouraged.

"Whenever the condition of an animal is such as to require tonics or medicines of any kind, it is far better and much less expensive to employ a veterinarian to prescribe a treatment peculiar to its ailment, or when a veterinarian can not be had, the family physician can often advise a treatment which will be infinitely more reliable than an indiscriminate mixture which may have absolutely no value as a medicine."

Colonial products of animal origin, H. J. DE CORDEMOY (*Les produits coloniaux d'origine animale. Paris: J. B. Baillière & Son, 1903, pp. VIII+391, figs. 94*).—In this volume, which is largely made up of descriptive and statistical matter, the author discusses food materials and industrial products. Under food materials are included preserved meats and meat products, fish and fish products, edible birds' nests, etc. The industrial products include silkworms, fur-bearing animals, ivory, sponges, feathers, etc.

The digestibility of dry and moist albumen with and without the addition of meat extract, M. VOIT (*Ztschr. Biol., 45 (1903), No. 1, pp. 79–103*).—In experiments with dogs the digestibility of the dry matter, organic matter, and nitrogen of dry meat meal was much less than in the case of freshly extracted meat. The addition of meat extractives did not improve the digestibility of the meat protein. The bearing of the experiments on general questions of digestibility is discussed at length.

Decomposition of vegetable feeding stuffs by bacteria, J. KÖNIG (*Fühling's Landw. Ztg., 52 (1903), No. 9, pp. 322–326*).—The investigations here summarized have been noted from another publication (E. S. R., 15, p. 65).

Products formed by rotting barley, J. K. LERMER (*Ztschr. Gesam. Brauw., 1902, No. 25, p. 165; abs. in Hyg. Rundschau, 13 (1903), No. 18, pp. 948, 949*).—The author studied and measured the gaseous products formed from barley at different stages of decomposition.

Disembittering lupines, B. SHIRYAYEV (*Zap. Novo-Alexandri Inst. Selsk. Khoz. i Lyesov, 15 (1902), No. 2, pp. 193–197*).—Good results were obtained in removing the bitter matter from lupines by boiling them for an hour and then washing for 24 hours in running water at 8° C. Detailed analyses of the lupines before and after treatment are reported. The total loss of dry matter varied from 16.5 to 18 per cent, the losses consisting largely of the less valuable constituents rather than albumen.—P. FIREMAN.

Meat production in Queensland, H. DEXLER (*Ztschr. Fleisch- u. Milchhyg., 13 (1902–3), Nos. 3, pp, 65–72; 4, pp. 97–105, figs. 4*).—A descriptive article.

Information concerning common goats, G. F. THOMPSON (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 42, pp. 14*).—The term "common goats" is used to include all mongrels, in order to distinguish them from Angora goats, which are a specific breed. Goat leather, according to the author, is always in demand, that of the common goats being useful for the manufacture of shoes and kid gloves, while that of the Angora is used for making morocco leather and to a considerable extent for the manufacture of heavy working gloves. In general, the longer the fleece the poorer the skin for leather making.

Statistics are quoted regarding the number of goats in the United States and imports of goat skins. The fact is emphasized that though the total number of goats kept in

the United States is large they are widely scattered and are seldom kept in large flocks, a fact which would render it difficult to secure any considerable number of common goats of desirable quality for breeding for leather.

The value of goat flesh, the use of these animals as destroyers of brushwood and as milk producers, as well as other topics connected with the industry, are discussed.

The high-bred sheep and swine industry of England and its importance for German breeders, E. A. Brödermann (*Schaf- und Schweine-hochzuchten in England und ihre Bedeutung für deutsche Züchter. Berlin: Deut. Landw. Gesell., 1903, pp. 20*).—Sheep and swine raising in England is discussed with special reference to its bearing upon similar industries in Germany.

Refrigeration as applied to bacon curing, L. M. Douglas (*Proc. Cold Storage and Ice Assoc., 4 (1903), No. 1, pp. 7–20, pls. 3*).—A brief paper with discussion.

Feeding stuffs for horses, P. Dechambre and E. Curot (*Les aliments du cheval. Paris: Asselin & Houzeau, 1903, pp. XVIII + 455, figs. 5*).—In this volume the authors discuss the composition of the body and the food requirements of horses, as well as the principal horse feeds and their nutritive and economic value, the whole constituting a useful summary of information on these topics. There are also chapters on poisonous feeding stuffs and veterinary medicine.

Cooperative records of the cost of producing eggs, H. H. Wing (*New York Cornell Sta. Bul. 212, pp. 48, fig. 1*).—In continuation of previous work (E. S. R., 14, p. 486) the station has cooperated with a number of practical poultry feeders for the purpose of obtaining data regarding the cost of the winter production of eggs under different conditions, the present investigation being in its essentials a duplicate of that reported earlier.

At the start the flocks included ranged in number from 43 to 700, exclusive of males. In every case some died or were removed during the test, which began December 1 and closed March 28, the time being divided into 4 periods, the second of 5 weeks and all the others of 4 weeks each.

"No restrictions were placed upon the owners as to how the fowls were to be fed, cared for, or managed. In brief, they were asked to produce, by their usual methods, the greatest possible number of eggs at the lowest possible cost and to report each week the kind and amount of food consumed and the number of eggs produced."

The average cost of feed per dozen eggs was 18.7 cts. and the average price of eggs 23.4 cts. per dozen. Considering this and the earlier test 29 flocks representing 10 owners and 5,200 fowls produced daily 22.8 eggs per 100 fowls, the average cost of feed per dozen eggs being 17.7 cts. The flocks which laid the most eggs during December and January also laid the most in March, and the hens which laid the most eggs produced them at the lowest cost per dozen regardless of the cost of the ration. The egg production of pullets was noticeably in excess of that of hens, particularly during the early part of the winter when the price of eggs was highest. The average cost of feed for 17 weeks was $35.33 per 100 fowls, and the average value of the product exceeded the cost of feed by $16.13 per 100 fowls.

A productive farmyard; ducks, swans, geese, and rabbits, L. Bréchemin (*La basse-cour productive: Palmipèdes et lapins. Paris, 1903, pp. 344, figs. 60; rev. in Jour. Agr. Prat., n. ser., 6 (1903), No. 44, p. 581*).—This volume, which is included in the *Librairie agricole de la maison rustique,* treats of the raising of ducks, swans, geese, and rabbits for profit.

Concerning the passage of fat from food to the egg, and concerning the fatty acids of lecithin, V. Henriques and C. Hansen (*Skand. Arch. Physiol., 14 (1903), No. 6, pp. 390–397*).—From some experiments with hens fed linseed products, and especially some in which hemp seed was fed, the conclusion was drawn that a considerable portion of the fat of food can pass into the egg unchanged. In this respect the egg fat is comparable in formation with body fat rather than milk fat.

Studies were made of lecithin from various animal sources and other fatty acids than stearic, palmitic, and oelic were identified, a fact which is not in accord with commonly accepted theories. The fat of the lecithin molecule, the authors believe, has a different structure from that found in other animal fats and is constant, being independent of the kind of animal or the character of the fat in the feed.

Concerning the formation and composition of chicken fat, A. ZAITSCHEK (*Arch. Physiol.* [*Pflüger*], *98* (*1903*), *No. 11–12, pp. 614–622*).—The effect of feeding milk on the composition of chicken fat was studied, one hen being given maize and milk and the other maize only. Cramming was resorted to in order that large amounts might be eaten. The conclusion was drawn that feeding whole milk induced the formation of a body fat which was similar to butter fat in composition except that no volatile fatty acids were formed. The nitrogen, phosphoric acid, and ash in the flesh of the 2 hens were determined in addition to the fat.

DAIRY FARMING—DAIRYING.

Dairying as a factor in the profitable utilization of farm lands, A. T. NEALE (*Delaware Sta. Rpt. 1902, pp. 7–39*).—A brief description is given of the dairy herd under observation and of its management.

During the calendar year 1902, 13 cows were in the herd. The total yield of 10 cows of the herd was 39,987 lbs. of milk, containing on an average 4.9 per cent of butter fat. At creamery prices for butter fat the income from this source amounted to $520.06.

Five calves were sold for veal for $47.20, and 4 heifers were reserved for breeding purposes, their value being placed at $41.25; 2 other calves died during an experiment with a calf food. The skim milk was fed to pigs, the detailed data from the experiment being given. An actual balance of $28.24 was credited to the skim milk. Considerable explanations are entered into concerning the small returns from this source, and the feeding of the pigs is discussed at some length. The avoidable losses and wastes in this experiment, amounting to $56.05, were attributed largely to the failure to combine rational feeding with practical care and attention.

The total income from the herd of 10 cows was therefore $636.82, the cost of purchased feed was $91.80, and the cost of the 68 tons of silage produced and used for this purpose was $101.75. Notes are given on the production of the silage. The allowance for pasturage of the cows was $53.62, and for labor and attendance $152.80. The total expense for food and labor was therefore $399.97, to which was added $32.23 interest at 6 per cent on the capital invested. The net profit from the herd during the year was $204.62, or $20.46 per head. The land used in pasturing the herd was estimated as returning a net profit of $11.34 per acre, and that upon which the silage crops were grown a net profit of $16.36 per acre. The nature of the capital involved is stated, the silo used is described, and the construction and value of silos in general is discussed (see p. 623).

Had the milk been sold to a condensed milk factory instead of to a creamery, the skim milk being fed to heifers and pigs, the total income as estimated would have been $622.93 in place of the $636.82 which was received. Furthermore, had the milk been sold to the wholesale market of Philadelphia, the income as estimated would have been $618.74; the conclusion being drawn that under the conditions of the experiment the creamery afforded the most satisfactory market.

Investigations on the cattle of "Cowland," E. FRANK (*Mitt. Landw. Inst. Univ. Breslau, 2* (*1903*), *No. 3, pp. 511–558*).—The region referred to is located in the northern part of Austria, and includes portions of Moravia and Silesia. A description is given of the region and of the cattle, together with considerable data relating to the different types of cows.

Feeding experiments with linseed cake, K. H. M. VAN DER ZANDE (*Verslag Ver. Exploit. Proefzuivelboerderij, Hoorn, 1902, pp. 14–22*).—Linseed cake having an

unusually high percentage of acid decreased slightly the amount of milk produced. For practical purposes the author believes that the factor of acidity may be neglected.—H. M. PIETERS.

The cow-protector "Simplex" (*Norsk Landmandsblad, 22 (1903), No. 19, pp. 240–242, fig. 1*).—A simple Swedish device for keeping cows clean in the stable. A broad piece of sail cloth is attached behind the cows and suspended so the droppings falling thereon do not come in contact with the animal or the bedding.—F. W. WOLL.

Methods of milking, with special reference to the manipulation method, F. W. WOLL (*Pennsylvania State Dept. Agr. Bul. 113, pp. 96, figs. 23*).—The author discusses the structure of the cow's udder and the secretion of milk; describes the various methods of milking, paying particular attention to the Hegelund method, and gives the results of tests previously noted from another source (E. S. R., 14, p. 694).

On the art of milking (*Landtm. Månadsbl., 1903, No. 7, pp. 107–110*).

The lime content of the udder, M. TOYONAGA (*Bul. Col. Agr. Tokyo Imp. Univ., 5 (1903), No. 4, pp. 455–457*).—In continuation of earlier work on the relation of lime to magnesia in animal tissues, the author determined the lime and magnesia in the udder of a cow. The water content of the specimen was 66.7 per cent. The lime content of the dry substance (as CaO) was 0.25 per cent and the magnesia was 0.06 per cent. The calcium content was higher than that reported by other investigators in the case of the spleen and muscle, while the content of magnesium was much lower than in these tissues.

Influence of stimulating substances upon milk secretion, G. FINGERLING (*Jour. Landw., 51 (1903), No. 3, pp. 287, 288*).—The influence of malt sprouts and fenugreek was studied with a sheep, and of hay extract and fennel with a goat. Some variations in the yield and quality of the milk were attributed to the different substances. Fennel in particular increased both the yield of milk and the percentages of fat, sugar, proteids, and ash.

The fat content of cows' milk, VANDERPLANCKEN and A. J. J. VANDEVELDE (*Repr. from Handel. Zesde Vlaamsch Natuur- en Geneesk. Cong., Kortrijk, 1902, pp. 8*).—Data obtained at a creamery during 3 years showed that the highest percentage of fat occurred during the months of December, January, and February.—H. M. PIETERS.

On variations in the fat content of cows' milk, L. FUNDER (*Tidsskr. Norske Landbr., 10 (1903), No. 4, pp. 168, 169*).—A discussion of the various factors that influence, or are believed to influence, the fat content of cows' milk.—F. W. WOLL.

The relation of temperature to the keeping property of milk, H. W. CONN (*Connecticut Storrs Sta. Bul. 26, pp. 16*).—This bulletin emphasizes the importance of low temperatures in keeping milk. In an experiment referred to in the discussion as an extreme case, the bacteria in milk multiplied 5-fold in 24 hours when the temperature was 50° F., and 750-fold in the same time when the temperature was 70°. Milk kept at 95° curdled in 18 hours, at 70° in 48 hours, and at 50° in 148 hours. So far as the keeping property of milk is concerned, low temperature is considered of more importance than cleanliness.

In milk kept at 95° the species developing most rapidly is the undesirable one known as *Bacillus lactis aerogenes*. At a temperature of 70° this species develops relatively less rapidly in the majority of cases than *B. lactis acidi*, which latter is very desirable in both cream and cheese ripening.

"The bacteria in milk kept at 50° increase slowly, and later consist of very few lactic organisms but of miscellaneous types, including many forms that render the milk unwholesome. These bacteria continue to grow slowly day after day, but the milk keeps sweet because the lactic organisms do not develop abundantly. Such milk in the course of time becomes far more unwholesome than sour milk, since it is filled with organisms that tend to produce putrefaction. . . .

"Although the temperature of 50° is to be emphatically recommended to the dairyman for the purpose of keeping his milk sweet and in proper condition for market, he must especially be on his guard against the feeling that milk which is several days

old is proper for market, even though it is still sweet and has not curdled. Quite the reverse is the case. Old milk is never wholesome, even though it has been kept at a temperature of 50° and still remains sweet and uncurdled. This very considerably modifies some of our previous ideas concerning milk, for it has been generally believed that so long as the milk remains sweet it is in good condition for use. Quite the contrary is the case, if it has been kept at a temperature of 50° or in this vicinity. It is not unlikely that it is this fact that leads to some of the cases of ice-cream poisoning so common in summer. The cream is kept at a low temperature for several days until a considerable quantity has accumulated or a demand has come for ice cream, and when made into ice cream it is filled with bacteria in great numbers and of a suspicious character."

The author also discusses briefly other means of improving the keeping property of milk, such as the proper care of cows and stables, the use of covered milk pails, the cleansing of dairy utensils, straining, and aeration.

The Casse pasteurizer, A. SJÖSTRÖM (*Nord. Mejeri Tidn., 18 (1903), No. 21, pp. 281, 282, fig. 1*).—Report of trials made at the station for trials of agricultural machinery at Alnarp, Sweden.—F. W. WOLL.

Trials of regenerative pasteurizers at Alnarp Dairy Institute, A. SJÖSTRÖM (*Nord. Mejeri Tidn., 18 (1903), No. 20, pp. 273–275, figs. 2*).—The following pasteurizers were tried: C. Holmberg, Paasch & Larsen, Petersen, and Rudelius & Boklund.—F. W. WOLL.

Bacteriology of milk, H. SWITHINBANK and G. NEWMAN (*London: John Murray, 1903, pp. 605, pls. 33, figs. 35, charts 3, map 1*).—A vast amount of information relating to dairy bacteriology is presented in this extended and excellent treatise. The opening chapter deals with some general considerations, such as the properties and composition of milk, milk secretion, and milk as a medium for bacteria; following which is a detailed discussion of technique.

A chapter treats of the examination of air and water in their relation to milk supply. Three chapters are devoted to the bacterial content of milk, fermentation in milk, and economic bacteria in milk and milk products. The tubercle bacillus is taken as a type of pathogenic bacteria in milk, and this subject is discussed at length. Other pathogenic bacteria in milk and the investigation and prevention of milk-borne epidemics are also fully considered. Descriptions are given of a large number of species of bacteria which have been claimed to have an important relation to milk, butter, or cheese. The species are arranged in alphabetical order, no attempt being made at classification. The concluding chapters are devoted to the control of the milk supply by the State, by private enterprise, and by the trade.

A series of appendixes contains milk regulations, forms of contract for supplying milk, etc. The footnotes throughout the volume serve as a valuable bibliography to the wide field of literature reviewed. American work is frequently cited. The book is well printed and illustrated, and will undoubtedly prove very useful to those interested in this subject, especially in its relation to preventive medicine.

Tallow-like butter due to the influence of light, A. LIDOW (*Vyestnik Shirov. Veshch., 4 (1903), p. 151; abs. in Chem. Ztg., 27 (1903), No. 81, Repert., p. 253*).—Butter subjected to the influence of artificial light was found to change in color from yellow to white and to develop the taste and smell of tallow. Analytical data are reported.

Influences affecting the content of fatty acids in butter, K. H. M. VAN DER ZANDE (*Verslag Ver. Exploit. Proefzuivelboerderij, Hoorn, 1902, pp. 45–72, dgms. 4*).—Reference is made to previous work along this line, and feeding experiments made during the fall and winter of 1902–3, are reported. Four lots of 5 cows each were used. Lot 1 was kept on plain pasture as long in the fall as possible. Lot 2 was also pastured late, but was fed in addition after October 7, a special food consisting of sirup mixed with finely ground cornstalks. Lot 3 was stabled early and fed freshly cut grass. Lot 4 was also stabled early, but was fed hay and linseed cake

The severe weather occurring while the cows were still on pasture decreased apparently the content of fatty acids. The author also concludes that the special food rich in sugar lessened but did not entirely overcome the bad effects of exposure. No decisive results were obtained as regards the feeding of grass as compared with hay and linseed cake. It is believed, however, that there is no advantage in stabling and feeding linseed cake over late pasturing, provided the pasturage is abundant and the weather not too severe.

The results of an experiment with parsnips are considered as indicating that these roots have a prompt and pronounced effect in increasing the content of fatty acids in butter.—H. M. PIETERS.

The "butterini" of Sorrento, C. A. NEUFELD (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 14, pp. 637–640, fig. 1*).—"Butterini" or "mantecchi," a peculiar product made in Sorrento, is described. This consists of a gourd-shaped yellow cheese of which the interior is filled with butter. The composition of the cheese and butter, fresh material, and that 3 months old, is reported.

Bacteriological examination of the "butterini" of Sorrento, W. RULLMANN (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 14, pp. 640, 641*).—A bacteriological study of the product mentioned above.

Cheese problems, J. MICHELS (*Michigan Sta. Spec. Bul. 21, pp. 10, figs. 2*).—Several series of experiments are briefly reported and discussed. Milk testing 3, 3.5, 4, 4.5, and 5 per cent of fat made respectively 8.24, 9.53, 10.35, 11.41, and 12.74 lbs. of cheese per 100 lbs. of milk; showing an increase in the yield of cheese corresponding closely to the increase in the fat content of the milk.

Coating cheese with paraffin gave results very favorable to this practice. The growth of mold was almost completely prevented, the loss due to shrinkage was greatly lessened, and the loss in rind was reduced from 11.56 to 3.14 per cent. The net economy in this treatment was estimated at 14 to 15 cts. per 100 lbs. of cheese. In paraffining cheese it was found desirable to heat the paraffin to 240–250° F. by means of a gasoline burner, and to omit the use of cloth as the paraffin adhered better to the cheese itself. It is stated that paraffin having a melting point of 130 to 135° is best suited for this purpose. About ¼ lb. of paraffin is required for a cheese weighing 44 lbs. Cheese should be coated within 12 hours after leaving the press. The apparatus used at the Michigan Station is illustrated.

Stirring the curd by hand for ½ to 1 hour and then salting was compared with matting, milling, and salting after 1 hour, according to the usual Cheddar process, the conditions in both cases being uniform until after the removal of the whey. One cheese in each case was cured in cold storage at 38° and 1 in an ordinary curing room at 60°. "More water can be incorporated in cheese when the curd mill is used and the curd matted than by the stirred process, but a water content of over 38 per cent is objectionable even in a quick-curing cheese. Cheese with a moderately high water content will cure better at 60 than 38°; but where the water content is excessively high or where the milk has a bad flavor, 38° is recommended as a ripening temperature rather than 60°."

In the manufacture of sage cheese satisfactory results were obtained by the addition of sage tea to the curd, 6 or 7 oz. of sage being required for the curd from 1,000 lbs. of milk. The most satisfactory method, however, was the addition of the finely powdered leaves to the curd just before salting; the amount of sage required being about one-half as much as when the extract is used.

Notes are given on the prevention of gassy curd by the use of starters.

Rennet enzym as a cause of chemical changes in the proteids of milk and cheese, L. L. VAN SLYKE, H. A. HARDING, and E. B. HART (*Jour. Amer. Chem. Soc., 25 (1903), No. 12, pp. 1243–1256*).—This article is essentially the same as Bulletin 233 of the New York State Station (E. S. R., 15, p. 399).

Report of the dairy instructor, G. S. THOMSON (*Rpt. Min. Agr. South Australia, 1902–3, pp. 26–37*).—This is an account of dairying in Europe as observed by the author

in a visit to the principal dairy countries, with suggestions for the improvement of the dairy industry in South Australia.

Modern dairying (*Quart. Rpt. Kansas State Bd. Agr., 22 (1903), No. 87, pp. 288, figs. 68*).—This is made up of a series of short popular articles reprinted from various sources. In the introduction brief statements are made concerning the present status of dairying in Kansas.

VETERINARY SCIENCE AND PRACTICE.

Infection and immunity with special reference to the prevention of infectious diseases, G. M. STERNBERG (*New York and London: G. P. Putnam's Sons, 1903, pp. XI+293*).—The purpose of this volume is to treat in a systematic way the main facts of infection and immunity, in so far as they may be made available in the control and eradication of infectious diseases. No attempt is made to discuss controversial matters relating to recent investigations and bearing upon the various theories of immunity. Special emphasis is laid upon the general proposition that infectious diseases are preventable and attention is called to the means of checking infection.

The subjects of disinfection by heat, sunlight, gases, and various chemicals is treated at some length. The discussion of specific diseases is confined largely to those which affect man, but special mention may be made of the chapters on tuberculosis, tetanus, and hydrophobia.

The theory of natural antibacterial immunity, P. T. MÜLLER (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), Nos. 5, pp. 458–463; 6, pp. 550–556; 7, pp. 700–713*).—The literature of this subject is critically reviewed in connection with experiments made by the author for the purpose of determining the basis of immunity in animals. Attention is called to the fact that the production of antibodies takes place very rapidly within a few hours after infection and that the tissues which are primarily affected by the disease are directly concerned in the production of these bodies. The antibodies arise first at the point of infection and later appear in other organs.

The author's experiments were made on pigeons which were artificially infected with a number of pathogenic organisms. Some of the pigeons were purposely starved and others were well fed during the progress of the experiments. It was shown by these experiments that defective nutrition and the consequent disturbance of metabolism exercises a pronounced influence upon the production of agglutinins. Different species of bacteria, however, did not react in the same way to the effect of nutrition on the infected birds. The typhoid bacillus and *B. pyocyaneus* uniformly developed a higher content of agglutinins in animals which had been partly starved than in those which were well fed, while *B. proteus*, *B. dysenteriæ*, and cholera vibrio behaved in the opposite manner. The withholding of food and other harmful interference with the normal course of animal metabolism have the power of influencing the production of antibodies which are associated with bacterial substances in a manner which is determined by the nature of the bacteria used in the experiment.

The study of the origin of alexins, U. LAMBOTTE (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), No. 5, pp. 453–457*).—The author's experiments were made on horses, dogs, and chickens. The blood plasma of all these animals acted in the same way toward the cholera vibrio, and the action of the serum and plasma was almost identical. The author believes that the bactericidal alexin, as well as the hemolytic alexin, comes from the organized elements of the blood.

Artificial immunity against staphylococci, PRÖSCHER (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), No. 5, pp. 437–445*).—Experiments carried on by the author indicated that normal goat serum has the power of agglutinating a portion of the staphylococci in a given culture, but does not affect the rest. Notes are given on methods of estimating the power of the immune serum of goats and horses with regard to the action of such serum upon staphylococci.

From the peritoneal cavity of animals treated with normal serum an exudate was taken 3 minutes after inoculation with staphylococci, and it was found that all of the micro-organisms had been surrounded by large mononuclear leucocytes; a few polynuclear cells had assisted in this process. It appears from these experiments that staphylococcus serum exercises a stimulating influence upon the multiplication of the leucocytes.

An attempt to explain the purpose and action of intermediary bodies, H. ZANGGER (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), No. 5, pp. 428–437*).—A study of toxins showed that these substances ordinarily react slowly in comparison with chemical reactions. Notes are given on toxins and various other substances obtained from the blood serum and various tissues. The author calls attention to the importance of the agglutinins and precipitins in the study of immunity. The similarity of intermediary bodies and ferments is shown by comparison of their various properties in detail.

On the question whether tetanolysin forms a nontoxic product in combination with the proteids of the serum of egg albumin, P. T. MÜLLER (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), No. 6, pp. 567–573*).—The experiments reported in this article were made with the serum of horses and steers. The results obtained indicate that precipitated and dissolved albumins, even in large doses, fail to exercise a pronounced check upon the development of tetanus. The alcoholic extract of the serum, however, showed a strong antihemolytic power. It appears, therefore, that the property antagonistic to tetanus is not precipitated in the albumins, but remains soluble in alcohol, and is therefore necessarily different from the serum proteids.

The author concludes, therefore, that the control of hemolysis and the apparent antitoxic action observed in the treatment of tetanus are not truly antitoxic, but pseudo-antitoxic phenomena due to physical and chemical processes brought about during the solution and distribution of the bodies concerned in the development and control of the disease.

A bacterial toxin with acute action, R. KRAUS (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), No. 6, pp. 488–496*).—Experiments were made with cholera vibrio obtained in 1899. The experimental animals were rabbits. It was found in experiments with this toxin that death was produced in rabbits within 24 hours after intravenous inoculation in moderate doses. The toxin exercised a hemolytic and other injurious actions which proved rapidly fatal in all cases.

It is concluded as a result of these experiments that evidence is thus obtained for the existence of a bacterial toxin which acts in a rapid manner without a period of incubation, and in that respect resembles snake virus. An antitoxin which operates in neutralizing this toxin exists in the normal blood serum of certain animals. This antitoxin, however, exercises its neutralizing action at a comparatively slow rate.

The action of bacteria upon the hemoglobin of the blood, M. LABBÉ (*Arch. Méd. Expér. et Anat. Path., Paris, 1. ser., 15 (1903), No. 3, pp. 364–378*).—A study was made of the changes produced in the blood of laboratory animals during infection with various organisms, such as anthrax bacillus, cholera bacillus, diphtheria bacillus, etc. The changes in the blood were studied by means of a spectroscope. The various micro-organisms with which the author experimented are classified in different groups according to the effect which they were found to exercise upon the hemoglobin.

It was found that the slight irritation and transformation of hemoglobin into methemoglobin are due to the action of bacterial secretions, and these phenomena should not be confused with the intense irritation of oxyhemoglobin, which is directly connected with the life of the micro-organisms.

An attempt at a new theory of bacteriology, A. P. FOKKER (*Versuch einer neuen Bakterienlehre. The Hague: Nederlandsche Boek- en Steendrukkerij, 1902, pp. 50,*

pls. 2).—The author presents a condensed summary of his various publications relating to the nature of bacteria, including an account of experiments with the anthrax bacillus undertaken for the purpose of determining the behavior of this bacillus on various culture media. When this organism was introduced into water containing various quantities of salt a considerable proportion of the bacilli were killed within a short period. Certain differences in resisting power were observed in colonies which had been cultivated on different media.

The author presents arguments of a general nature and based on his experiments, in favor of the proposition that bacteria are not necessarily the only cause of the infectious diseases in which they are found, and that the spontaneous generation of various species of bacteria, including the anthrax bacillus, is possible and is frequently observed.

Pathogenic molds and mucormycoses in animals and man, G. J. BARTHELAT (*Arch. Parasit.*, *7* (*1903*), *No. 1*, *pp. 5–116*, *figs. 63*).—A detailed critical review is given of the literature of this subject in connection with a bibliography. A considerable variety of species of molds have been found to be pathogenic to animals and man, and descriptive and biological notes are given on all these species. In the second part of the paper attention is given to the spontaneous and experimental occurrence of mucormycoses.

The author made numerous experiments for the purpose of ascertaining the pathogenic properties of species of molds, and as the result of his studies came to the following conclusions: Mycoses naturally fall into 2 groups according as they are produced by a species of Aspergillus or Mucor. The species of which the virulence for animals has been determined are *Mucor corymbifer*, *M. ramosus*, *M. truchisi*, *M. regnieri*, *M. pusillus*, *Rhizomucor parasiticus*, etc. Animal tissues attacked by pathogenic molds are modified in a characteristic manner. The infection by molds may be secondary and follow a primary infection by some species of bacteria.

The internal use of arsenic and iodid of potash was found useful in the treatment of nearly all forms of infection from pathogenic molds. When the spores of these molds were introduced into the veins of rabbits, guinea pigs, or chickens, the death of the animal was brought about within a short time, the duration of the disease depending upon the species of mold and the quantity of spores used. Not all internal organs are equally affected by pathogenic molds. These organisms seem to exhibit a decided preference for the kidneys, mesenteric ganglia, intestines, and striated musculature.

In acute cases the lesions in the kidneys are specially well marked in the convoluted tubules where the pathogenic mold is found in abundance. Subcutaneous inoculation of spores of these molds produced merely a reaction in the number of leucocytes, while intratracheal injection was without effect except in the case of birds. Ingestion of the spores was likewise without effect, the whole digestive tube remaining without any lesion. Diseases caused by pathogenic molds are not directly contagious.

The behavior of the pleuroperitoneal epithelium in surrounding foreign bodies during the process of healing, J. G. MÖNCKEBERG (*Beitr. Path. Anat. u. Allg. Path.*, *34* (*1903*), *No. 3*, *pp. 489–531*).—The experimental animals employed by the author were rabbits and guinea pigs. Intraperitoneal inoculations of lycopodium spores were made and the effect of these spores upon the peritoneal epithelium was studied. It appeared that during the process of healing the first demonstrable change consisted in the loss of the epithelial layers and the simultaneous appearance of a coagulable exudate and hematogenous wandering cells belonging to the type of polymorphous leucocytes. It was observed that during degenerative processes following inflammation the epithelial cells of the serous membranes undergo a process of proliferation and become motile more quickly than the connective tissue elements of the serous coats.

Report of the State veterinarian, L. PEARSON (*Pennsylvania State Dept. Agr. Rpt. 1902, pt. 1, pp. 99–170*).—During the year a diminution in the prevalence of tuberculosis, anthrax, and blackleg was noted, while a slight increase was observed in glanders, hog cholera, and rabies. A disease of cattle frequently referred to as "mountain disease," and popularly supposed to be due to poisonous plants, was shown to be hemorrhagic septicemia identical with that observed in Minnesota, Wisconsin, etc.

Notes are given on the methods of immunization of cattle against tuberculosis by the use of attenuated cultures. During the year about 60,000 doses of tuberculin, together with large quantities of mallein and anthrax vaccine were made and distributed. Papers on the intercommunicability of human and bovine tuberculosis, by M. P. Ravenel, and on the immunization of cattle against tuberculosis, by L. Pearson and S. H. Gilliland, are reprinted (E. S. R., 14, pp. 609, 610). Notes are also presented on anthrax, blackleg, hemorrhagic septicemia, abortion, ergotism, forage poisoning, glanders, Texas fever, rabies, hog cholera, and foot-and-mouth disease. A copy is also given of a law for the prevention of rabies, authorizing quarantine and muzzling of dogs.

Infectious diseases; their etiology, diagnosis, and treatment, G. H. ROGER, trans. by M. GABRIEL (*New York and Philadelphia: Lea Brothers & Co., 1903, pp. VI + 874, figs. 43*).—While this volume treats primarily of human diseases, a large proportion of the text is occupied with a discussion of the general characters of pathogenic bacteria, the etiology and pathogenesis of infections, the reactions of the organism to pathogenic bacteria, and the general subjects of immunity and predisposition to infectious diseases. An elaborate review is presented of the subject of tuberculosis in mammals, birds, and cold-blooded animals, and the relationship of tuberculosis in animals and man.

Infectious diseases of our farm animals, W. H. DALRYMPLE (*Proc. Nat. Live Stock Assoc., 6 (1903), pp. 220–230*).—Notes are given on the usual means by which various animal diseases are spread from place to place. The most important cattle diseases are mentioned and notes are given on methods which may be adopted for preventing their universal distribution. Attention is called to the importance of observing all possible sanitary precautions and applying disinfection after outbreaks of contagious diseases.

Certain diseases of animals and their relation to those of man, E. WIENER (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 9, pp. 653–723*).—The diseases to which the author devotes especial attention in this article are tuberculosis, anthrax, glanders, bubonic plague, and rabies. The agency of rats in carrying plague is briefly discussed. Statistics are given on a number of cases of anthrax in various domestic animals and man in the German Empire during the year 1900, and the literature relating to disinfection after the occurrence of anthrax is briefly discussed.

The author notes also the conditions under which glanders may be transmitted from animals to man and presents statistics on the prevalence of rabies in the German Empire. The greater portion of the article is occupied with an elaborate review of the tuberculosis question and the conclusion is reached that tuberculosis of man and animals is one and the same disease. Notes are also given on botulism and other forms of ptomaine poisoning.

Animal diseases, G. D'UTRA (*Bol. Agr. São Paulo, 4. ser., 1903, No. 8, pp. 351–374*).—The author describes the symptoms and pathological anatomy of nagana, surra, mal de caderas, and dourine. Notes are also given on the differential diagnosis of these diseases and on the insects which are concerned in their transmission.

Medico-veterinary observations for the province of Verona for the years 1898–1900, F. BRUNI (*Atti e Mem. Accad. Agr., Sci., Let., Arti e Com. Verona, 4. ser., 3 (1902–3), pp. 1–41*).—Notes are given on the more important diseases of man, especially tuberculosis, which prevailed during these 3 years, together with an

account of the chief animal diseases for the same period. The epizootics most prevalent during that period were foot-and-mouth disease, anthrax, hog cholera, rabies, and glanders. The distribution and prevalence of these diseases are shown in a series of tables.

Medico-veterinary observations in 1901, F. BRUNI (*Atti e Mem. Accad. Agr., Sci., Let., Arti e Com. Verona, 4. ser., 3 (1902–3), pp. 342–384*).—The important animal plagues are briefly discussed and their prevalence is shown in tabular form. These plagues include rabies, glanders, hog cholera, tuberculosis, anthrax, and foot-and-mouth disease.

Annual report on investigations in the field of veterinary medicine, ELLENBERGER ET AL. (*Jahresber. Leist. Geb. Vet. Med., 22 (1902), pp. 277*).—The authors present a list of the various periodicals which have been examined in the preparation of the abstracts of veterinary literature. Author and subject indexes are also given. The main body of the report is occupied with brief abstracts of the literature which appeared during 1902 on various veterinary subjects, including infectious diseases, tumors, parasites, sporadic diseases, anatomy, histology, zootechny, animal dietetics, etc.

The origin and comparative anatomy of malignant tumors, R. DISSELHORST (*Berlin. Tierärztl. Wchnschr., 1903, No. 5, pp. 61–65*).—A brief review is given of the various theories which have been held regarding the nature and origin of malignant tumors. The author believes that a special susceptibility toward certain tumors may be inherited. It appears also from the investigation of these tumors in animals that the older animals are considerably more susceptible than young animals. The frequency of the occurrence of various forms of tumors in horses, dogs, and cattle is shown in a tabular form.

The law of Darbot and modification of the laws relating to veterinary police officers, F. ROLLIN (*Jour. Agr. Prat., n. ser., 6 (1903), No. 41, pp. 472–474*).—In the author's opinion the present law regarding the control of animal diseases is too slow of operation and involves delays which frequently result in the unnecessary spread of highly infectious diseases, such as pleuro-pneumonia.

Experience in the use of Ichthargan, BERNHARDT (*Berlin. Tierärztl. Wchnschr., 1903, No. 6, pp. 77–79*).—According to the statements of the manufacturers of this product it contains 30 per cent of silver, it is readily soluble in glycerin, and in the author's experiments exhibited a bactericidal power considerably superior to that of nitrate of silver.

Ichthargan was used in the treatment of a number of diseases both externally and internally. It was found possible to administer the drug internally as a powder in milk. This use of Ichthargan proved beneficial in the treatment of mammitis in mares. The drug was also administered intravenously in cases of vaginitis with good results. In the treatment of vaginitis it was administered intravenously and also as a vaginal wash. The author believes that Ichthargan is superior to all other silver products with which he has experimented.

The first international conference on tuberculosis, PANNWITZ (*Berlin: Cent. Internat. Bureau for Prevention of Tuberculosis, 1903, pp. 461*).—A report of the proceedings of the international conference on tuberculosis held at Berlin October 22–26, 1902. The various papers which were presented and the discussions are reproduced in German, French, and English.

The proceedings of the conference included an inaugural meeting, at which general topics were discussed, and meetings of the general council, at which papers were presented relating to a review of measures for the prevention of tuberculosis and special reports on methods of repression as practiced in various countries. At this session also the means of furthering the propaganda for the suppression of tuberculosis were discussed. At the second meeting of the general council the following subjects were discussed: Obligatory notification, polyclinics and dispensaries, work-

shops, and means of collecting sputum. Attention was also devoted to the various methods of caring for human consumptives.

One meeting of the general council was devoted to a discussion of human and bovine tuberculosis (pp. 295, 296). At this meeting papers were presented by Köhler, Nocard, Arloing, De Schweinitz, Schroeder, and von Behring on the question of the unity of the various forms of tuberculosis. All of these speakers except Köhler came to the definite conclusion that tuberculosis of man and cattle is one and the same disease and may be transmitted from man to animals, or vice versa. Köhler expressed the opinion that the question of the unity or duality of tuberculosis was not yet satisfactorily determined.

The warfare against tuberculosis, M. P. Ravenel (*Proc. Amer. Phil. Soc., 42 (1903), No. 173, pp. 212–219*).—A discussion of the problem of tuberculosis from the viewpoint that the disease is transmissible, preventable, and curable in its early stages. The relationship between the human and bovine bacillus is discussed and notes are given on the most important method of repression of animal tuberculosis and on the recent methods for producing immunity by means of serum therapy and otherwise.

Modifications of the human tubercle bacillus, J. Auclair (*Arch. Méd. Expér. et Anat. Path., Paris, 1. ser., 15 (1903), No. 4, pp. 469–488*).—A series of experiments was undertaken by the author for the purpose of testing the possible modifications to which human tubercle bacillus was susceptible when cultivated on various nutrient media. Detailed descriptions are given of the appearance of this organism when cultivated on bouillon, agar, potato, gelatin, and other media. The morphological characters and staining reactions of bacilli treated by different methods are also compared.

Inoculation experiments were made on rabbits and guinea pigs by subcutaneous, peritoneal, intratracheal, and intravenous methods. For these experiments the homogeneous form of the bacillus was used. During these experiments it was found that by cultivation on various media and especially by the use of artificial devices, such as agitation, the tubercle bacillus could be transformed into a saprophyte. In this form the bacillus grows on ordinary media in the form of a homogeneous culture. Growth is rapid. The bacillus is motile, strictly aerobic, ferments lactose, liquefies gelatin, and takes ordinary stains.

When this form of the organism is inoculated into animals it is found to have lost its virulence and infectiousness, but is still slightly toxic. The toxin of the homogeneous form of the tubercle bacillus is quite different from the tuberculin of a virulent form of the bacillus and when inoculated into animals does not cause pneumonia, caseation, or sclerosis.

Notes on the article of Krompecher and Zimmermann concerning the virulence of tubercle bacilli, Vagedes (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), No. 6, pp. 507, 508*).—A controversial article occupied with a discussion of the possibility of variation in the virulence of the tubercle bacillus.

The action of the tubercle bacillus in experimental pulmonary tuberculosis, G. Herxheimer (*Beitr. Path. Anat. u. Allg. Path., 33 (1903), No. 3, pp. 363–408, pls. 2*).—The problems connected with a general study of tuberculosis are briefly outlined by the author. Experiments were made for the purpose of studying the behavior of the tubercle bacillus in cases of pulmonary infection. In these experiments the bacilli were injected directly into the lungs or by the intratracheal method. Fresh culture of tubercle bacilli in glycerin-bouillon were used.

The experimental animals were rabbits and guinea pigs. In some cases the bacilli were introduced in a dry form into the trachea. The experimental animals were killed at periods varying from ½ hour to 7 weeks after inoculation and microscopic preparations were made for further study. Detailed notes are given on the pathological findings of this investigation. According to the results obtained by the author

the tubercle bacillus passes down the trachea and arrives in the alveoli. During this passage it exercises considerable chemotactic action upon the polynuclear leucocytes in the walls of the bronchi.

As soon as the bacilli arrive in the alveoli they are surrounded by the alveolar epithelial cells and exercise a destructive influence upon the elastic fibers. The epithelial and connective tissue elements undergo considerable proliferation in the presence of the tubercle bacillus. Wherever the bacilli occur in large quantities the neighboring tissue is entirely destroyed and an accumulation of polynuclear leucocytes takes place. These in turn become destroyed, and round cells appear on the periphery of the tubercle.

Comparative investigations on tubercle bacilli of different origin, H. KOSSEL, A. WEBER, and HEUSS (*Tuberkulose-Arb. K. Gesundheitsamte, 1904, No. 1, pp. 1–82, pls. 4*).—The literature of this subject is discussed in connection with a bibliography of 194 titles. The plan of the experiments reported in the paper included the following features: The collection of the largest possible number of human tubercle cultures from different cases and from different tuberculous organs; inhalation experiments with virulent cultures of human tubercle bacilli in calves 3 to 6 months old; feeding experiments with similar cultures repeated daily for a period of 3 months in calves 3 to 6 months old and pigs 5 to 8 weeks old; one or repeated passages of slightly virulent human tubercle cultures through goats, and subsequent inoculation of calves 3 to 6 months of age with cultures thus treated; hypodermic inoculation of calves 3 to 6 months old with fresh cultures of bovine tubercle bacilli; inhalation experiments with similar cultures and with the same experimental animals; feeding experiments during which calves and pigs were fed daily for a period of 3 months milk containing bovine tubercle bacilli. Detailed notes are given concerning the cultures obtained for these experiments. Inoculation experiments with rabbits, cattle, and other experimental animals showed that hypodermic inoculations of cultures which came from tuberculous organs of cattle and hogs produced almost without exception c generalized tuberculosis in cattle and led to fatal results within 6 to 8 weeks in one-half of the cases. Experiments with tubercle bacilli from fowls indicated that this form of the bacillus was not capable of producing a progressive tuberculosis in the organs of cattle. In the majority of cases human tubercle bacilli were found to be distinguishable—from morphological, cultural, and pathological standpoints—from bovine tubercle bacilli. In a few cases, however, human and bovine tubercle bacilli appeared not to be distinguishable. The authors consider the bearing of these results upon the question of the treatment of tuberculous milk and meat, and conclude that the possibility of infection of man by tuberculous products must be admitted, but that this infection takes place with comparative infrequency.

Tuberculosis of fowls, A. WEBER and H. BOFINGER (*Tuberkulose-Arb. K. Gesundheitsamte, 1904, No. 1, pp. 83–158, pl. 1*).—The authors present a critical review of the literature of this subject, in connection with a bibliography of 183 titles. A series of experiments was made for the purpose of gaining additional information concerning the identity or nonidentity of mammalian and avian tubercle bacilli. The authors maintain that the identity of the organisms has not been shown in a single unexceptionable case. No indication was found from their own experiments, or from the literature of the subject that fowls suffer from tuberculosis of the ovaries, and it is therefore concluded that infection is not transmitted by means of the egg, but chiefly in the feces. The authors' experiments were made largely with 11 original cultures of avian tubercle bacilli. Detailed notes are given on the morphology and cultural characters of these organisms. Inoculation experiments were made with fowls, rabbits, guinea pigs, and mice, by the feeding, intravenous, hypodermic, and inhalation methods. The results of the authors' investigations may be summarized as follows: The avian tubercle bacillus, as a rule, shows morphological and cultural characters, which distinguish it clearly from the mammalian tubercle bacillus. Occasionally,

however, the organisms appear to be identical in these respects. It appears that under natural conditions tuberculous infection in fowls takes place through the alimentary tract. The avian tubercle bacillus is pathogenic to some extent for rabbits, mice, and guinea pigs. In guinea pigs, however, the progress of the disease is quite limited. The tubercle bacilli obtained from fowls retain their original pathogenic properties unchanged after passage through the body of mammals. In the authors' experiments these organisms could be recognized readily after being cultivated in guinea pigs and mice for a period of from 1 to 2 years. A typical culture of mammalian tubercle bacilli was obtained from the organs of a parrot affected with tuberculosis. The authors also succeeded in obtaining a typical culture of avian tubercle bacilli from the caseified mesenteric glands of a pig, which otherwise showed no symptoms of tuberculosis. Under natural conditions, therefore, the authors were unable to find any tendency of the mammalian tubercle bacilli to become modified into the avian form in the body of fowls, or of the avian bacillus to become modified into the mammalian form in the body of mammals.

Tuberculosis in cats, W. LELLMANN (*Berlin. Tierärztl. Wchnschr., 1903, No. 7, pp. 111, 112*).—The author presents details concerning the symptoms and pathological anatomy of 2 cases of tuberculosis in cats. An examination of the blood showed a great diminution in the number of red blood corpuscles, so that the ratio of red to white blood corpuscles was 50:1. The mesenteric glands were enlarged and innumerable small white tubercles were found in the spleen and liver. The bronchial and mediastinal glands were also tuberculous and enlarged.

Attenuation of the mammalian tubercle bacillus in cold-blooded animals, H. HERZOG (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), Nos. 6, pp. 535–539; 7, pp. 675–685, pl. 1*).—The literature of this subject is reviewed in connection with a brief bibliography. The author's experiments were made on frogs, fish, and other cold-blooded animals. Detailed notes are given on the methods of cultivation of the tubercle bacilli and the staining of affected tissue.

The inoculation of guinea pigs with mammalian tubercle bacilli after an extended sojourn in the organism of cold-blooded animals indicated that the mammalian tubercle bacillus preserves its virulence for at least 190 days when inoculated into cold-blooded animals. It was apparent during these experiments that the guinea pigs succumbed to reinfection by tubercle bacilli treated in this manner more slowly than by bacilli taken freshly from infected mammals. Distinct lesions were produced in cold-blooded animals by inoculation with bacilli of mammalian origin.

A supplemental series of experiments was carried out for the purpose of determining the effect of a sojourn in cold-blooded animals upon bacilli obtained from tuberculous calves. Inoculation of guinea pigs was made after the bacilli had been allowed to remain in frogs for periods of 62, 90, 140, and 191 days. These experiments also showed that the guinea pigs succumbed to infection more slowly, the longer the organism had been allowed to remain in frogs.

The tubercle bacillus of the turtle; its culture, biology, and pathogenic action, F. F. FRIEDMANN (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), Nos. 7, pp. 647–658; 8, pp. 793–804, pl. 1*).—Tubercle bacilli were isolated from cases of pulmonary tuberculosis in turtles and pure cultures were readily obtained. The growth and behavior of the organism on various culture media are described. The organism was found to grow luxuriantly at a temperature of 37° C., but some growth took place at various temperatures ranging from zero to 43°.

The bacillus obtained from turtles was readily distinguished from that obtained from other cold-blooded animals by the appearance of the cultures, and especially by its rapid growth at 37° C. Detailed notes are given on the morphology of this organism and on the changes of form which take place in cultures of different ages. A number of inoculation experiments were made on turtles of several species, snakes, blind worms, lizards, frogs, carp, chickens, doves, dogs, rats, white mice, rabbits,

and guinea pigs. The organism was found in all investigated species of cold-blooded animals, with the exception of carp, multiplied rapidly, and showed a wide distribution in these species.

Turtles died of miliary tuberculosis within periods ranging from a few weeks to a few months after intraperitoneal or intrapulmonary injections. Similar conditions were observed in other cold-blooded animals. Birds, dogs, rats, and white mice were resistant to the organism. Guinea pigs, however, when inoculated with large doses, died within 4 to 8 days and exhibited tuberculous formation in the peritoneal cavity, especially in the omentum. In cases in which guinea pigs lived for 12 to 14 days after inoculation true tubercles were formed. When small doses were used for inoculation of guinea pigs the tuberculous processes ultimately healed and entirely disappeared.

During these investigations it was found that cultures of tubercle bacilli obtained from turtles and grown at a temperature of 37° C. were absolutely indistinguishable from human tubercle bacilli.

The appearance of pseudo-tubercle bacilli in cattle, P. MOELLER (*Berlin. Tierärztl. Wchnschr., 1903, No. 10, pp. 156, 157, figs. 2*).—A study of a number of cases of tuberculosis in cattle showed that while the pseudo-tubercle bacilli may be present in the secretions and excretions, or even in the diseased organs of tuberculous cattle, they can not be considered as having any etiological connection with the disease.

The acid-resistant bacilli of butter, milk, and soil compared with the tubercle bacillus, P. COURMONT and M. POTET (*Arch. Méd. Expér. et Anat. Path., Paris, 1. ser., 15 (1903), No. 1, pp. 83–128, pl. 1*).—The subjects discussed in this article include a general history of acid-resistant bacteria, their habitat, cultures, morphology, staining characters, biological characters, and pathogenic action. A considerable variety of these organisms has been found in butter, milk, fertilizers, forage, soil, and elsewhere.

As a result of the authors' experiments, it is concluded that while under ordinary circumstances it is comparatively easy to differentiate between tubercle bacillus and other acid-resistant bacteria, none of the tests are universally applicable. Nearly all of the acid-resistant bacteria can be obtained in sufficient virulence to produce typical tubercles when inoculated into experimental animals. The pathogenic power of the tubercle bacilli, on the other hand, may be completely destroyed by cultivation under certain conditions. The possibility of relationship between the various forms of acid-resistant bacteria is suggested.

Lesions in the central nervous system produced by tetanus toxin, A. ZINNO (*Arch. Méd. Expér. et Anat. Path., Paris, 1. ser., 15 (1903), No. 3, pp. 335–363, fig. 1*).—The author conducted a double series of experiments, in the first of which portions of nervous tissue were prepared according to the methods of Courmont et al., and in the second of which greater care was exercised in preventing any contamination of the portions of the nervous system used in the experiment.

After animals were inoculated with tetanus toxin obtained from portions of the nervous system they were killed at various periods and a microscopic study was made of the nervous system. The experimental animals were dogs, guinea pigs, rabbits, and pigeons. These animals were inoculated with doses of different sizes, but always from a very virulent form of the bacillus.

As a result of these experiments it is concluded that the injection of tetanus toxin in ordinary experimental animals produces characteristic clinical symptoms which correspond with the nervous lesions. The lesions are observed in the chromatophilous cells, simultaneously in the centrosome and nucleolus. The neuroglia and nerve fibers are little affected except in advanced stages of the disease. In certain cases a secondary infection will spread rapidly to other organs and to other parts of the nervous system than those in which the primary attack appeared.

Meningo-encephalitis in rabbits, P. MISCH (*Arch. Path. Anat. u. Physiol. [Virchow], 172 (1903), No. 1, pp. 158–174*).—Detailed notes are presented on the course and outcome of a number of cases of this disease in rabbits. The scanty literature of the subject is critically reviewed. Abscesses were found in the cerebellum, with evidences of fresh suppuration. These lesions in the brain caused the various abnormal movements of affected animals. An exudation was observed upon the surface of the brain.

Cocci were isolated from the cerebro-spinal fluid and cultivated under artificial conditions. Rabbits inoculated intravenously with bouillon cultures of this organism died within from 1 to 3 weeks with symptoms identical with those observed in cases of spontaneous infection.

An attempt to explain the susceptibility of rabbits to anthrax, O. BAIL and A. PETTERSON (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), Nos. 5, pp. 445–452; 6, pp. 540–550*).—A detailed study was made of the blood of rabbits for the purpose of detecting the presence of any property in normal blood which could explain the known susceptibility of these animals to anthrax.

As the result of these experiments it is concluded that the marked destruction of anthrax bacilli by rabbit serum in vitro does not take place in the body at all, or at least only under special conditions. The reason for this difference in the action of the serum in and out of the body is that the intermediary body contained in the serum while the blood is in contact with the organs of the body is always united with the cell receptors in accordance with Ehrlich's theory.

The affinity of the intermediary body for the cell receptors is greater than that for the anthrax bacilli. As a result of the intermediary body, a complement of a bacteriolytic nature becomes associated with the cell receptors, so that the bactericidal complement contained in the serum is without effect, on account of the absence of a suitable intermediary body. In view of these facts it is readily understood why the anthrax bacillus is not checked in its development inside the body of rabbits.

The incineration of anthrax carcasses, L. FABRITIUS (*Berlin. Tierärztl. Wchnschr., 1903, No. 4, p. 50*).—Attention is called to the desirability of burning bodies of animals dead of anthrax in order to prevent the further spread of this disease. In burning such bodies the author recommends that the carcasses be dumped into ditches in such a manner that no material which may escape from the effect of the heat will be in a position where it is likely to cause reinfection of other animals with anthrax.

Contagious malignant vaginitis of cattle with special reference to the necrosis bacillus, ELLINGER (*Berlin. Tierärztl. Wchnschr., 1903, No. 2, pp. 25–29*).—The literature of this subject is critically reviewed. Contagious vaginitis, in the author's experience, is usually associated with inflammation of the udder, calf diarrhea, and abortion. The author observed a large number of cases in cows, all of which occurred soon after parturition. The cause of this disease, according to the author's investigations, is the necrosis bacillus, which is found in abundance in the vaginal secretions.

Notes are given on the pathological anatomy, differential diagnosis, and course of the disease. The treatment recommended by the author consists in thorough and repeated irrigation of the vagina with a 2 per cent solution of lysol or creolin, together with the use of tampons saturated with Lugol's solution. In preventing the disease attention should be given to strict quarantine and disinfectant measures. Incipient septicemia may be checked in many instances by intravenous injections of Collargol.

The treatment of parturient paresis by means of the air catheter, ZEHL (*Berlin. Tierärztl. Wchnschr., 1903, No. 1, pp. 5, 6*).—Notes are given on 15 cases of this disease which the author treated by forcing air into the udder. In all these cases recovery took place within a reasonable length of time, but in 13 out of the 15 cases a decided improvement or almost complete recovery was noted within 3 hours

after the administration of the air. In comparison with the results obtained by this method, the author states that in treating the same disease by the Schmidt method a mortality of 20 per cent was observed. The author believes, therefore, that the air treatment is in every way superior to the use of infusions of potassium iodid.

Notes on hemoglobinuria, SIMON (*Berlin. Tierärztl. Wchnschr., 1903, No. 4, pp. 51, 52*).—The author observed a number of cases of this disease during a general practice and describes the most common symptoms. As a rule a considerable anemia and emaciation were observed associated with an increase in temperature and a yellow coloration of the conjunctiva. In the majority of cases death took place within a few days. In controlling this disease the author recommends proper drainage of the soil in fields and corrals where cattle are allowed to run, and the free use of such well-drained pastures.

Ticks and African coast fever, C. P. LOUNSBURY (*Transvaal Agr. Jour., 2 (1903), No. 5, pp. 4–13*).—During the past season the author made a study of this disease in the Transvaal. The term African coast fever is preferred to Rhodesian cattle disease, Rhodesian tick fever, Rhodesian redwater, virulent redwater, etc., under which the same disease has been referred to by other writers. The disease is unquestionably different from ordinary Texas fever, but is transmitted by ticks, probably a species of Rhipicephalus commonly known as the brown tick. Notes are given by way of comparison showing the methods of transmission of other diseases by ticks and other animal parasites. It is of considerable importance to determine definitely just which species of ticks are concerned in the transmission of African coast fever. Experiments were made to determine the pathogenicity of *Rhipicephalus decoloratus*, *R. shipleyi*, *R. evertsi*, *R. simus*, *Hyalomma ægyptium*, and *Amblyomma hebræum*. Positive results were obtained only with *R. shipleyi*, commonly known as the brown tick, and this tick was found to be pathogenic only in its adult stage. Detailed notes are given on the habits and life history of the various species of ticks. In combating infestation with ticks the author recommends burning over infested fields wherever this method is possible, and the dipping and spraying of cattle with arsenical solutions. Carbolic dips are not recommended. Kerosene oil applied in various ways has given fairly satisfactory results. It is believed that 1 year is not too long a period of quarantine for infested fields.

Ringworm in cattle (*Bd. Agr. and Fisheries [London], Leaflet 95, pp. 2*).—Brief notes on the cause and treatment of this disease. A number of preparations are recommended for treating affected herds. Good results have been obtained from the use of a preparation containing 5 parts train oil and 1 part sulphur.

Warbles or grubs in cattle hides, R. C. JACOBSON (*Proc. Nat. Live Stock Assoc., 6 (1903), pp. 202–204*).—The author calls attention to the injury produced in cattle hides by the presence of the larvæ of the ox warble fly. It is stated that packers have agreed to classify cattle hides according to the number of warble holes in each hide. Class No. 1 includes only those hides which have not more than 4 warble holes. The author calls attention also to the irritation the presence of these grubs produces and of the consequent loss of flesh. The treatment for these parasites is comparatively simple and the author urges its prompt application.

Inspection of sheep on the range (*Proc. Nat. Wool Growers' Assoc., 38 (1903), pp. 75–84*).—This is a discussion by members of the association on the general subject of inspection of sheep on the public range, with special reference to its bearings upon the use of summer range, particularly in forest reserves. It was urged by some of the members that the general inspection of sheep for scab might result in some limitation of their privileges upon the public range.

Sheep pox and the epitheliomata of this disease, F. J. BOSC (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), Nos. 5, pp. 413–420, figs. 2; 6, pp. 517–526, figs. 6; 7, pp. 667–674, pls. 3*).—A detailed description is given of the lesions observed in cases of this disease in the skin, cornea, rumen, fourth stomach, lungs, liver, kidney, pan-

creas, and mammary glands. The disease attacks not only the epithelia of lining membranes, but also the various glandular epithelia. A number of products of cellular degeneration were observed in the foci of the disease. The author made a careful examination of this degenerated material and believes that he found sporozoa which may be considered as the parasitic organism of the disease. The various stages of transformation were observed in the cellular elements which were found in the diseased foci along with the supposed pathogenic organism.

The conditions of commerce in tanned sheepskins and its sanitary regulation in the Government of Moscow, M. L. Blumenfeld (*Arch. Vet. Nauk, St. Petersburg, 33 (1903), No. 9, pp. 980–991*).—The author discusses the dangers connected with the indiscriminate shipment and handling of the pelts of infected sheep and calls attention to the necessity of applying antiseptic treatment to these skins in order to prevent the development of infectious diseases.

A form of hog cholera not caused by hog-cholera bacillus, E. A. de Schweinitz and M. Dorset (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 41, pp. 4*).—An infectious disease of hogs was studied in southwestern Iowa and later in Washington in hogs which were imported from the original locality. Experiments and observations on this disease show that it is highly infectious, can not be distinguished clinically from hog cholera, but may be reproduced by inoculation with material which contains no hog-cholera bacilli. The period of incubation varies from 5 to 12 days.

The inoculation experiments made by the authors were on pigs which weighed from 15 to 40 lbs., and it was suggested that the period of incubation may be of longer duration in older hogs. Notes are given on the lesions observed in different parts of the body. Rabbits and guinea pigs were found to be refractory to the disease. The isolation of diseased animals and disinfection of infected premises has been found to be efficacious in controlling the disease.

Swine epizootics and means of repression, Röder (*Mitt. Oekon. Gesell. Sachsen, 1902–3, pp. 95–119*).—Statistics are given regarding the prevalence of swine erysipelas, swine plague, and hog cholera, together with a discussion of the remedies and means of prevention which have proved most successful in combating these plagues. The literature of the subject is briefly discussed. The author presents an account of various proprietary and commercial vaccines which have been manufactured for use in preventing the development of swine epizootics. The results obtained from the use of these vaccines by various investigators have differed considerably and further experiments are required to determine their value.

The bacterial flora of the intestines of hogs, E. Heinick (*Berlin. Tierärztl. Wchnschr., 1903, No. 9, pp. 141–143*).—The author's observations were carried out on a large number of hogs from which samples of the intestinal contents were taken for the purpose of comparing the bacterial content of this material. The results of these investigations are presented in the form of a table and indicate that a large number of known and unknown species of bacteria are commonly present in a hog's intestines. Culture experiments, together with the inoculation of experimental animals, failed to show the presence of pathogenic bacteria except in the rarest instances, and no bacilli of swine erysipelas were found in any case.

Experimental vaccination with Septicidin in Hungary, J. von Kukuljević (*Berlin. Tierärztl. Wchnschr., 1903, No. 6, pp. 79, 80*).—In the treatment of swine plague and hog cholera the author found that Septicidin applied at the right time and in the proper manner furnished a good means for preventing the further development of the disease and exercised a strong immunizing action in animals which were subsequently exposed to the disease. The details of the author's experiments are presented in tabular form.

Special report on diseases of the horse (*Washington: U. S. Dept. Agr., Bureau of Animal Industry, 1903, rev. ed., pp. 600, pls. 41, figs. 18*).—The first edition of this

report was issued in 1890 (E. S. R., 2, p. 518). The present edition has been revise and considerable new matter has been added, especially the article by L. Pearson o the examination of sick horses, and that on surra, by C. W. Stiles.

The following is a list of subjects treated in the volume: Examination of a sic horse, L. Pearson; methods of administering medicine, C. B. Michener; diseases o the digestive organs, C. B. Michener; diseases of the urinary organs, J. Law; disease of the respiratory organs, W. H. Harbaugh; diseases of the generative organs, J. Law diseases of the nervous system, M. R. Trumbower; diseases of the heart, blood ves sels, and lymphatics, M. R. Trumbower; diseases of the eye, J. Law; lameness A. Liautard; diseases of the fetlock, ankle, and foot, A. A. Holcombe; diseases of th skin, J. Law; wounds and their treatment, C. B. Michener; general diseases, R. S Huidekoper; surra, C. W. Stiles; shoeing, J. W. Adams.

The diseases of the army horse, G. JOLY (*Les maladies du cheval de troupe Paris: J. B. Baillière & Sons, 1904, pp. XII+456, figs. 39*).—The present volume i intended as a handbook on the diseases of the horse, with special reference to th diseases of greatest importance among army horses. The special subjects discusse by the author include glanders, contagious coryza, epizootic lymphangitis, horse pox intestinal diseases, overwork, skin diseases, broken knees, ruptures of tendons, bon diseases, wounds, important diseases observed in the French colonies, and the com mon diseases of camels.

Acute articular rheumatism in horses, ALTMANN (*Berlin. Tierärztl. Wchn schr., 1903, No. 4, pp. 50, 51*).—This disease has commonly been supposed to be o rare occurrence in horses and other domesticated animals. Undoubted cases wer observed by the author and notes are given on the symptoms and pathologica anatomy of this disease. The articular cartilages were found to have lost their glis tening appearance and the synovial secretion was considerably increased. In som instances pathological alterations of the heart were associated with the disease.

Articular inflammations in young colts, E. THIERRY (*Jour. Agr. Prat., n. ser. 6 (1903), No. 44, p. 574*).—The symptoms of this disease are briefly described. Th author believes that infection takes place through the navel and recommends anti septic treatment in preventing the disease.

The treatment of pneumonia with oxygen, TOEPPER (*Berlin. Tierärztl. Wchn schr., 1903, No. 3, pp. 37–42, figs. 2*).—A number of cases of this disease in horse were treated by inhalation of oxygen under pressure. A suitable apparatus for th administration of oxygen is described by the author. The effect of inhalation o oxygen upon the internal body temperature, pulse, respiration, and behavior of th animal is shown in a tabular form. No decided and uniform influence upon the rat and depth of the respiratory movements was observed. The discolored mucou membranes assumed a brighter red color.

The chief effect of oxygen when administered in cases of pneumonia is seen in th heart action. Oxygen appears to act as a heart stimulant and improves the genera condition of the animals. When administered during the earlier stages of the dis ease it is believed that many cases may be prevented from running a fatal course, an the expense is not prohibitive.

Experiments in the use of barium chlorid intravenously and per os in the treatment of colic in horses, MÜLLER (*Berlin. Tierärztl. Wchnschr., 1903, No. 7, pp. 109, 110*).—The author tested the value of this drug in about 40 cases of colic During these experiments it was found that when administered intravenously i a solution at the rate of 1:10, barium chlorid frequently gave rise to paralysis o the heart and sudden death of the horse. In some cases death resulted even whe administered in a solution at the rate of 1:40, and the author recommends that th drug be used in much more dilute solutions. When administered in solutions suffi ciently dilute to avoid any injurious effect upon the heart the general action of th drug was quite satisfactory.

Horseshoeing, J. W. ADAMS (*U. S. Dept. Agr., Farmers' Bul. 179, pp. 31, figs. 18*).—A systematic discussion of the problems of horseshoeing of most concern to the farmer and horse raiser. The subjects discussed include the anatomy of the foot and hoof, the physiological relations of these parts, the formation and various abnormal forms of the feet, the form and preparation of the shoe, the rubber pad, bar shoe, hot fitting, and various peculiarities in the form of the hoof as related to the requirements in the form and thickness of the shoe.

A monograph of the tsetse flies, E. E. AUSTEN (*London: British Mus., 1903, pp. IX+319, pls. 10, figs. 16*).—This volume contains an elaborate monograph of the genus Glossina, of which the following species are recognized: *G. pallidipes*, *G. longipennis*, *G. morsitans*, *G. longipalpis*, and *G. fusca*. This genus of flies is confined to Africa and its distribution is described in detail in connection with a map.

The author discusses the life history, habits, and systematic position of these flies, and presents bibliographies of literature relating to tsetse fly and the Trypanosoma of nagana, and kindred species. The mouth parts of Glossina and Stomoxys are described by H. J. Hansen. In appendices to the volume the author presents abstracts of some of the more important literature relating to tsetse flies, with notes on native methods of protecting animals against attacks of these flies, the geographical distribution of nagana and trypanosomiasis on the Upper Niger.

Spirillosis of fowls, E. MARCHOUX and A. SALIMBENI (*Ann. Inst. Pasteur, 17 (1903), No. 9, pp. 569–580*).—An outbreak of an infectious disease occurred in Rio Janeiro and caused the death of large numbers of chickens. This disease was found to be due to a spirillum which was also pathogenic to geese, ducks, guinea fowls, pigeons, turtle doves, and sparrows, but not to guinea pigs or monkeys. Affected fowls exhibit diarrhea, loss of appetite, a pale comb, and in acute cases die suddenly in convulsions. A certain percentage of chronic cases recover.

The pathogenic spirillum is found in the blood of affected birds, and the disease may be transmitted by inoculation with such blood. The disease is also produced by injection of the spirillum in cultures or of the excreta of affected birds. Under ordinary conditions *Argas persicus* is the carrier of the infection. The virulence of the spirillum is greatly diminished or lost after a period of about 48 hours. Successful vaccination may be produced by the use of blood and virulent serum preserved for from 48 hours to 4 days, or after heating for from 5 to 10 minutes at a temperature of 55°. The serum of animals which have recovered from the first attack possesses strong immunizing properties, and the same serum in vitro exercises a pronounced agglutinative action.

AGRICULTURAL ENGINEERING.

Report upon the administration of the public works department in Egypt for 1902, W. GARSTIN ET AL. (*Cairo: Public Works Ministry, 1903, pp. 476, pls. 15, dgms. 11*).—This includes a summary account and detailed reports of operations in the different departments of the Public Works Ministry during the year. The features of the report of the greatest agricultural interest are those dealing with the irrigation service.

The report of this service includes, among other topics, a discussion of the more efficient utilization of the Nile supply during the low water of 1902 by means of rotation in the use of water, the pumping of water for irrigation and drainage, the duty of water, drainage for removal of excess of water and alkali, and the filling and utilization of the water of the recently completed Nile reservoirs.

The report on the soil and water of the Wadi Tumilat lands under reclamation includes a discussion of situation, climate, geology, early history and present condition, nature and effect of the injurious salts present, cause of deterioration, and reclamation. Analyses of samples of the alkali efflorescences, the soil, and the drainage water of these lands show that the harmful salts present are sodium carbonate,

bicarbonate, chlorid, and sulphate. The accumulation of these salts in the soil is stated to be mainly due to seepage from the Ismailia Canal, which carries the water supply of this region. The method of reclamation which is being successfully employed consists of drainage and flooding to wash out the harmful salts.

Sanford system of irrigation (*Queensland Agr. Jour., 13 (1903), No. 4, pp. 308, 309*).—A combined system of subirrigation and drainage by means of glazed and unglazed tile, which is claimed to be in successful operation at Sanford, Fla., is briefly described. "The field is gridironed with a system of earthenware tile, about 18 in. below the surface, in squares of about 20 ft. The pipes running down the incline are of glazed tile, water-tight; these are the conducting pipes. The cross-pipes are of unglazed tile, not water-tight; these are used both for drainage and irrigation."

Irrigation in Tonkin (*Jour. Agr. Trop., 3 (1903), No. 29, p. 349*).—A brief note on Fesch's device used for raising water for irrigation in the uplands of Tonkin, based on an article in *Bul. Écon. Indo-Chine, Feb., 1903.*

Irrigation by means of artificial underground water, K. E. Widegren (*Agr. Jour. Cape Good Hope, 23 (1903), Nos. 4, pp. 456–461; 6, pp. 659–665, figs. 3*).—In this article the author discusses the feasibility of storing the water of streams in time of abundance by running them onto lands which present suitable infiltration areas, thus increasing the underground supply, which may be drawn on in time of scarcity, and explains in some detail the principles which underlie the suggested plan.

Pumping as an auxiliary to irrigation, F. Frank (*Agr. Jour. Cape Good Hope, 23 (1903), No. 5, pp. 554–557, pl. 1*).—The value of a pumping plant in case of a shortage of the usual supplies of irrigation water is explained and 7 designs of such plants are briefly described and illustrated.

Pumps and water-raising appliances for the farm, A. H. S. Baker (*Transvaal Agr. Jour., 2 (1903), No. 5, pp. 61, 62*).—Brief notes on various appliances suited to raising water for farm uses, especially irrigation.

Pumps, R. Masse (*Les pompes. Paris: Vve. Ch. Dunod, 1903, pp. 528, illus.*).

Irrigation engineering, H. M. Wilson (*New York: John Wiley & Sons, 1903, pp. XXIII+573, pls. 41, figs. 142*).—This is the fourth edition, enlarged and rewritten.

Device for flood gate and for clearing silt from before intake gate, F. Frank (*Agr. Jour. Cape Good Hope, 23 (1903), No. 5, p. 519, pl. 1*).—Drawings and a brief description are given of a gate which automatically closes when a flood reaches a given height, and causes an acceleration of the current past the intake gate so that accumulations of silt are removed.

Report on trials of agricultural machinery at Alnarp, 1902, A. Sjöström, N. Engström, et al. (*Meddel. Styr. Maskin-och Redsk. Profningsanst.* [*Stockholm*], *1903, No. 8, pp. 107, figs. 49*).—The report gives the results of trials of feed grinders, cake crushers, root cutters, plows, self-binders, and a number of smaller machines, and of dairy machinery, regenerative pasteurizers, milk forewarmers, the hand-separator "Perfect," Casse pasteurization regulator, Ulander milk strainer, etc.—F. W. WOLL.

Report on trials of agricultural machinery at Ultuna, 1902, G. Timberg, O. Nycander, et al. (*Meddel. Styr. Maskin-och Redsk. Profningsanst.* [*Stockholm*], *1903, No. 7, pp. 126, pls. 4, figs. 75*).—The report includes trials and critical examinations of feed cutters, steam locomobiles, scythes, harrows, manure spreaders, mowing machines, etc.—F. W. WOLL.

Trials with wagons with broad and narrow tires, F. Bokelman and E. Jorgensen (*Tidsskr. Landökon., 1903, No. 3, pp. 113–138*).

Trials with small thrashing machines for horse power (2–3 horses), C. V. Birk (*Tidsskr. Landökon., 1903, No. 3, pp. 139–200*).

Experiments with electrical plow installations, M. SCHILLER (*Arb. Deut. Landw. Gesell., 1903, No. 85, pp. 70, figs. 46*).—Three series of field trials of double-motor systems are reported, the apparatus and machines used being described in detail. The power was supplied from a central plant and the tests included deep plowing (30 to 36 cm.) on heavy soils and shallow plowing (14 to 18 cm.) on light soils, the object being to secure data on rapidity of work, amount of soil moved, loss of power, cost, and time required to move from field to field. The results are not considered conclusive and further tests are recommended.

The Scott motor cultivator (*Queensland Agr. Jour., 13 (1903), No. 4, pp. 316, 317, fig. 1*).—A petroleum motor adapted to a variety of farm operations is described and a comparison is made of the efficiency of motor and horse cultivation.

Agricultural implements and vehicles in foreign countries (*U. S. Consular Rpts., 73 (1903), No. 279, pp. 729–742*).—This is a series of reports in continuation of those already noted in the Record (E. S. R., 15, p. 416). The countries reported on in this article are Denmark, British India, Uruguay, and Honduras.

Roads; their construction and maintenance, with special reference to road materials, A. GREENWELL and J. V. ELSDEN (*London: D. Fourdrinier, 1901, pp. 280, figs. 48*).—An elementary treatise suited especially to English conditions.

An essay on the history of rural engineering, M. RINGELMANN (*Ann. Inst. Nat. Agron., 2. ser., 2 (1903), No. 2, pp. 181–212, figs. 22*).—The development of rural engineering during the prehistoric period is briefly traced in this article.

[The octagonal silo], A. T. NEALE (*Delaware Sta. Rpt. 1902, pp. 30–35*).—The methods and cost of construction as well as the practical advantages of octagonal silos are discussed.

"The octagonal silo may be regarded as a compromise between the old style square shaped, heavily framed or thick walled stone form and the modern lightly constructed stave silo, circular in shape and bound by iron hoops." The experience on a number of farms in Delaware with silos of this type constructed upon plans and specifications furnished by the station is cited to show that such silos have proven very satisfactory in practice, and as regards cost, availability of material, ease of construction, durability, and efficiency possess many decided advantages.

The construction of such a silo 13 ft. from face to face and 22 ft. deep, having a capacity of 68 tons when properly filled with settled corn and cowpea silage, is thus briefly described:

"If eight pieces of seasoned white oak, each 3 in. thick, 6 in. wide, and 6 ft. long, are so placed as to form a regular eight-sided figure with the corners bolted together, the sill of the silo will have been formed, and this drawn down into soft cement by the corner bolts which extend into the masonary foundation 10 in. will make an air-tight base. Posts of black or red oak, each 3 in. thick, 6 in. wide, and 18 in. tall are set upright at each of the eight corners of this sill and firmly spiked to it; upon the top of said posts a second eight-cornered hoop of black or red oak, but in all other respects similar to the sill, is built. Seven similar hoops are in turn built one upon the other, upon posts which increase in length as the height of the structure increases, until the posts which bear the plate are reached and these may safely measure 3 ft. in length. These hoops may be compared with those which bind together the staves of a barrel.

"In the silo the staves are of inch boards, 1 ft. wide, firmly nailed both to plate and sill, as well as to all of the intermediate hoops. These boards may be of hemlock, or poplar and of second or third rate quality, for their province is simply to hold plastering lath, which in turn supports a coating of good cement. If after this cement has hardened and dried thoroughly it is treated to a coat of gas tar thickened with slate ground to flour, an enduring and perfectly impervious lining will result, examples of which after 16 years in constant use may be cited in this State.

"Just as boards used as staves are nailed upon the inner surface of the hoops, so weather boarding is nailed to their outer edges. When roofed to suit the owner's taste the silo is completed."

The cost of construction of such a silo is estimated to be $150.10.

"Octagonal silos without cemented linings are in use, and one in particular has been filled three times at least with satisfaction. . . . The lining is made of two thicknesses of chestnut boards with tarred paper between them. . . . The wastes have been moderate and the lining shows few if any signs of decay. The owner is, however, inclined to feel that losses of silage would have been smaller had he . . . used the lath and cement construction."

The utilization of town refuse in agriculture, Von Kahlden (*Mitt. Oekon. Gesell. Sachsen, 1902–3, pp. 1–31, dgm. 1*).—A general discussion of the subject with descriptions of methods followed by different municipalities, but especially in Dresden.

Artificial refrigeration and its industrial, commercial, and agricultural applications, J. De Loverdo (*Le froid artificiel et ses applications industrielles, commerciales et agricoles. Paris: Vve. Ch. Dunod, 1903, pp. VII+652, figs. 156*).—Different chapters treat of the machines and equipment for mechanical refrigeration; refrigeration plants; applications of artificial refrigeration in the management of foods, fruits, vegetables, and miscellaneous materials, in storage and in transport; and the development of the refrigeration industry.

Cheap power for cold stores and ice factories, G. D. Hunt (*Proc. Cold Storage and Ice Assoc., 4 (1903), No. 1, pp. 35–41*).—A brief paper followed by general discussion.

MISCELLANEOUS.

Fourteenth Annual Report of Delaware Station, 1902 (*Delaware Sta. Rpt. 1902, pp. 163*).—This includes a financial statement for the fiscal year ended June 30, 1902; the organization list of the station; and reports of the agriculturist, mycologist, chemist, horticulturist, entomologist, and meteorologist, abstracted elsewhere.

Sixteenth Annual Report of Illinois Station, 1903 (*Illinois Sta. Rpt. 1903, pp. 13*).—This consists of a list of the publications of the station during the year, mention of the principal lines of work, a subject list of Bulletins 1–88, of the station, and a detailed financial statement for the fiscal year ended June 30, 1903.

Sixteenth Annual Report of Maryland Station, 1903 (*Maryland Sta. Rpt. 1903, pp. XXXII+200*).—The report of the director includes a brief history of the station; statements concerning the organization, equipment, and work of the station; a discussion of some of the results of station work with special reference to their practical application; a subject list of station publications; financial statements for each year from 1888 to 1903, inclusive; and a summary of observations on temperature and rainfall. Appended to the report are reprints of Bulletins 85–89 of the station on the following subjects: Alfalfa for Maryland (E. S. R., 14, p. 433); the influence of preservatives upon the food value of milk (E. S. R., 14, p. 679); the periodical cicada, and its appearance in Maryland in 1902 (E. S. R., 14, p. 988); economical methods for improving the keeping qualities of milk (E. S. R., 15, p. 293); experiments upon the use of potash as a fertilizer (E. S. R., 15, p. 461).

Twenty-First Annual Report of Ohio Station, 1902 (*Ohio Sta. Rpt. 1902, pp. XXIV*).—This includes the organization list of the station; a report of the Board of control; a financial statement for the fiscal year ended June 30, 1902; and a report of the director containing a review of the work of the station during the year, and a list of acknowledgments.

Report of the agricultural chemical experiment station at Vienna for 1902 (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 3, pp. 213–268*).

Report of the chemical physiological experiment station for grape and fruit growing at Klosterneuburg for 1902 (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 3, pp. 269–284*).

Report of the agricultural chemical station at Göritz for 1902 (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 3, pp. 285–313, pl. 1*).

Report of the agricultural experiment station at Spalato for 1902 (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 3, pp. 314–337*).

Eighth annual report of the Pennsylvania department of agriculture, 1902 (*Pennsylvania State Dept. Agr. Rpt. 1902, pt. 1, pp. 1029*).—This includes reports of the State secretary of agriculture, director of farmers' institutes, dairy and food commissioner, veterinarian, and economic zoologist. The last 2 reports are noted elsewhere. The papers read at the annual meeting of the State board of agriculture dealing with dairy hygiene, food adulteration, pollution of wells, and preparation for farm work are included.

The following articles included in the report have been noted from other sources: Methods of steer feeding (E. S. R., 13, p. 880; 14, p. 684), treatment for San José scale in orchard and nursery (E. S. R., 14, p. 169), canning of fruits and vegetables (E. S. R., 14, p. 147), bacteria of the soil in their relation to agriculture (E. S. R., 14, p. 749), some common insect pests of the farmer (E. S. R., 14, p. 780), the varieties of fruit that can be profitably grown in Pennsylvania (E. S. R., 14, p. 965), the natural improvement of soils (E. S. R., 14, p. 849), the fundamentals of spraying (E. S. R., 13, p. 876; 14, p. 592), insects injurious to cucurbitaceous plants (E. S. R., 14, p. 886), modern dairy science and practice (E. S. R., 14, p. 1014), cocoa and chocolate (E. S. R., 11, p. 970), potato culture (E. S. R., 14, p. 960), the management of greenhouses (E. S. R., 14, p. 763), and phosphates (E. S. R., 12, p. 930; 14, p. 556).

Press bulletins (*Ohio Sta. Bul. 135, pp. 117–135*).—This consists of reprints of press bulletins issued during the year. The subjects discussed are as follows: Fighting the chinch bug, soil analysis as a guide to the use of fertilizers, the Hessian fly, lime as a fertilizer, how much seed wheat to the acre, can we afford to omit nitrogen and potash from our fertilizers, oat smut and how to prevent it, sweet clover as a soil ameliorant, spraying for the San José scale, bitter rot of apples, grape rot and its prevention, and special spraying instructions.

Agricultural statistics (*Ontario Bureau Ind. Rpt. 1902, pp. 5–46*).—This includes meteorological observations; notes on the condition of crops; and statistics on field crops, fruits, live stock, valuation of farm property, cheese factories, etc.

Agricultural statistics of Belgium for 1902 (*Statistique de la Belgique, recensement agricole de 1902. Brussels: Min. Agr., 1903, pp. 261.*)—These statistics include the distribution and yield of field crops; the quantities of fertilizing material and feeding stuffs used in 1902; the number of horses, cattle, and swine on Belgian farms; together with the losses and natural increase during the year and the number of farms in the different provinces, classified according to their area.

Agricultural imports of Germany, 1897–1901, F. H. Hitchcock (*U. S. Dept. Agr., Division of Foreign Markets Bul. 30, pp. 323*).—This is a detailed statistical report upon this subject. The total imports during the 5 years averaged annually $1,258,129,280, of which the agricultural imports constituted 59.23 per cent. Of the agricultural imports during 1901, 21.86 per cent came from the United States, 16.26 per cent from Russia, and 10.60 per cent from Austria-Hungary. Raw materials constituted 45 per cent of the agricultural imports. The leading items were grain and grain products, vegetable fibers, animal fibers, meat and meat products, live animals, seeds, hides and skins, fruits and nuts, coffee, and tobacco.

Yearbook of agriculture and agricultural societies, C. Silvester (*Annuaire de l'agriculture et des associations agricoles. Paris: Author, 1903, pp. XII+2052*).—This book outlines the history of agricultural societies in France and gives the text of the laws enacted for their establishment and regulation, together with the text of the most important legislation bearing on agriculture. The agricultural administration in the national government as well as in the government of each territorial department is described, and in each case agricultural statistics are given. The

agricultural shows and markets together with agricultural industries, breeders of various kinds of farm animals, producers of special crops, manufacturers of and dealers in articles used by the farmer and his family, and dealers in agricultural products, etc., are listed.

Agricultural geography of France and the world, J. Du Plessis de Grenédan (*Géographie agricole de la France et du monde. Paris: Masson & Co., 1903, pp. 424, maps 85, dgms. 33*).—This book is divided into 3 parts, treating of France, the French Colonies, and the world in general. The chapters devoted to France discuss the geographical location, area, and topography of the country, the natural and artificial conditions affecting agriculture, the distribution of crops, and the nation's agricultural wealth, in addition to considering the culture of different crops and the raising of various kinds of live stock.

The French Colonies are divided into 2 groups, according to their location in temperate and tropical regions, and each colony is described separately. The third part, which has reference to the world in general, treats of soil, water, climate, agricultural regions, population, commerce, plant and animal production, and the different nations engaged in agriculture.

Farming, W. M. Tod (*London: J. M. Dent & Co., 1903, pp. 268, pls. 8*).—This book devotes a chapter to each of the following agricultural topics: Fertility, the improvement of soils, manuring, cereal crops, roots, green crops, clovers and grasses, live stock, farm horses, and cattle. In addition, the interesting features and the pleasures connected with farm life and the profitableness of the pursuit under the changed conditions in Great Britain are discussed.

Rural economy, E. Jouzier (*Économie rurale. Paris: J. B. Baillière & Son, 1903, pp. XV+476, figs. 10*).—This is one volume of the *Encyclopédie agricole* published under the direction of G. Werry.

The principles and aims of modern agriculture, Wölfer (*Grundsätze und Ziele neuzeitlicher Landwirtschaft. Berlin: Paul Parey, 1903, pp. VIII+281, figs. 5*).—This book on rural economics treats of the increase and cheapening of production of crops and animals, credit, organization and cooperation, farm accounts, and the promotion of technical education.

New elementary agriculture, C. E. Bessey, L. Bruner, and G. D. Swezey (*Lincoln, Nebr.: The University Pub. Co., 1903, pp. 194, figs. 62*).—An elementary text-book designed for rural and graded schools.

NOTES.

California Station.—J. H. Barber, formerly in charge of the Foothills Substation at Jackson, recently closed, has been transferred to the Southern California Substation at Ontario.

Hawaii Station.—The station has received a donation of $500 from the Hawaiian Stock Breeders' Association for experiments in range improvement.

Florida University and Station.—Foster Hall, the young women's dormitory, was totally destroyed by fire, together with most of its contents, during the holidays. The building was a 2-story frame structure. It will be replaced by a new brick dormitory to be erected on the old site. H. H. Hume, horticulturist in the university and station, has accepted a similar position under the North Carolina Board of Agriculture.

Iowa College and Station.—Among the legislative appropriations asked for by the board of trustees are the following items for experiment station work: Soils, $6,000; corn investigations, $6,000; horticulture, $5,000; experiments with beef cattle, $10,000; with swine, $3,000; with sheep, $2,000; dairy and creamery investigations, $5,000; poultry work, $3,000; agricultural extension work, $5,000; and good-roads experimentation, $5,000. An appropriation of $15,000 is asked for the establishment of an engineering experiment station, $75,000 for a new dairy building, $25,000 for dairy farm land, and $25,000 for furnishing and equipping the dairy farm and poultry department. Plans are being made for a new agricultural hall to cost $250,000.

Massachusetts College.—The trustees at their annual meeting voted to ask the State legislature for an appropriation of $38,000 for a horticultural building, and $1,000 annually for its maintenance. A bill looking to this is now before that body. As a result of negotiations with Simmons College, at Boston, the trustees approved an agreement whereby not over twenty students from Simmons College may take horticulture, entomology, and botany for the third year of their course in horticulture, on the payment of from $2,500 to $3,000 to the agricultural college. The plan can not be carried out for two years.

Montana College and Station.—V. K. Chesnut, of this Department, entered upon his duties as chemist to the college and station January 20.

Nevada College and Station.—J. N. Evans, president of the board of regents and board of control, recently met with a fatal accident while at work on his ranch. The funeral was held in the university gymnasium under the auspices of the institution, and with military escort. Mr. Evans' large business experience and ability made him a most useful and efficient regent. John E. Bray, of Reno, a man of long experience in educational work, has been appointed to fill out the unexpired term. The station has recently purchased new horses and is now stocking with types of dairy cattle, sheep, and hogs.

Cornell University and Station.—A bill has been introduced in the State Assembly appropriating $250,000 for a hall of agriculture. Governor Odell in his annual message called attention to the needs of the agricultural college and to the fact that there had been many applications from the agricultural interests for such recognition. He said: "Without making any specific recommendations as to the line which you should follow, I do desire to impress upon you the necessity for complying with these demands, which I believe to be reasonable and in the interest of New York." Speaker

Nixon, in his opening remarks to the Assembly, also gave considerable attention to the need of more adequate provision for agricultural instruction, citing the example of other States in this respect. In conclusion he said: "We should maintain a State agricultural college equal to the best in the Union. It is for our interest to do so, and our large agricultural population and the amount of capital invested in their industry, which is the basis of all prosperity, constitute a claim that should no longer be ignored." Referring to the Cornell School of Forestry, the governor expressed the belief that the school should not be discontinued, "because with the lapse of years a proper understanding of scientific forestry will become more and more a necessity. This is particularly true of farm forestry, which will form an important part of the future of agriculture within the State. That our people do not desire, however, that public lands shall be denuded is beyond question." He recommends immediate legislation to recover the property to the State, embracing about 30,000 acres, and suggests an adjustment of the contracts made with the Brooklyn Cooperage Co. either by the executive or the courts, relieving Cornell University of any burden in the matter. The university has acquiesced in this plan.

Ohio Station.—George M. Lummis has resigned as assistant botanist on account of ill health.

Oregon College and Station.—Hon. William W. Cotton, of Portland, Oreg., has been appointed regent, vice Benton Killin.

Pennsylvania Station.—John Foster has been appointed assistant chemist.

Porto Rico Station.—Hendrick C. Hendricksen, of the subtropical laboratory conducted by this Department at Miami, has been appointed assistant horticulturist to the station. During the year prominence has been given to the investigations with coffee, tobacco, and tropical fruits. Experiments with reference to improving the old coffee groves were commenced immediately after the crop of 1902 was harvested, and record was made of the yield of each of ten plats before the treatment began. Several acres of virgin forest have been cleared and planted with coffee trees from the nurseries. A number of foreign varieties have been planted, and the plantation of Porto Rican varieties will be used for studying the best distances for growing the trees, making experiments with shade, manures, and pruning. The tobacco investigations consist of a preliminary survey of the principal tobacco districts, and experiments with methods of cultivation, manuring, curing, and fermenting. The cultural work is being carried on in cooperation with a farmer at Aguas Burnas. The work with tropical fruits has been confined mainly to the assembling of plant material and the propagation of nursery stock. The station nurseries contain all of the citrus varieties to be found on the island, most of the stock being large enough to bud. The orchards now contain 45 varieties of bananas, 24 of budded oranges, lemons and grape fruit, 12 of cacao, and about 65 varieties of miscellaneous tropical fruits. Experimental plantings have been made of cassava, yautia, malangas, yams, and other tropical tubers, as well as vegetables from Northern-grown seeds.

Vermont Station.—The station has recently added to its farm buildings a hennery, 16 by 80 ft. in size. The building is constructed of novelty siding and paper, with slate roof, and is sealed inside with pine. A feed and tool room, 8 by 12 ft., is provided at one end, and the remainder of the space is divided into 4 general sections for separate flocks, each having a scratching shed, 12 by 12 feet, with southern exposure, protected by long glass windows hung with hinges at the top and balanced with weights. One section has oiled cloth in place of windows to test this protection in comparison with glass. Adjoining each scratching shed is a laying and roosting room, 6 by 12 ft., and a yard on the south side 56 ft. deep. Each section is intended to accommodate 40 fowls. At present only three breeds—Barred Plymouth Rocks, Rhode Island Reds, and White Wyandottes—are being kept.

Referees of Official Agricultural Chemists.—The appointments of the referees and associate referees of this association for the year 1904 had not been made at the

time the account of the annual meeting of the association was published. These have just been received from the secretary, Dr. H. W. Wiley.

The list of referees is as follows: *Phosphoric acid*, C. B. Williams, Raleigh, N. C.; *nitrogen determination*, C. H. Jones, Burlington, Vt.; *separation of nitrogenous bodies*, E. B. Hart, Geneva, N. Y. (milk and cheese proteids); *potash*, F. B. Carpenter, Richmond, Va.; *soils*, C. G. Hopkins, Urbana, Ill.; *dairy products*, G. E. Patrick, Washington, D. C.; *foods and feeding stuffs*, J. O. LaBach, Lexington, Ky.; *food adulteration*, W. D. Bigelow, Washington, D. C.; *sugar*, L. S. Munson, Washington, D. C.; *tannin*, G. A. Kerr, Damascus, Va.; *insecticides*, B. H. Smith, Washington, D. C.; *ash*, R. W. Thatcher, Pullman, Wash.; *medicinal plants and drugs*, L. F. Kebler, Washington, D. C.

Following are the associate referees: *Phosphoric acid*, F. P. Veitch, Washington, D. C.; *nitrogen determination*, F. A. Urner, Geneva, N. Y.; *separation of nitrogenous bodies*—meat proteids, W. D. Bigelow, Washington, D. C., and vegetable proteids, J. S. Chamberlain, Washington, D. C.; *potash*, G. S. Fraps, College Station, Tex.; *soils*, R. H. Loughridge, Berkeley, Cal.; *dairy products*, F. W. Woll, Madison, Wis.; *foods and feeding stuffs*, J. K. Haywood, Washington, D. C.; *food adulteration*—colors, W. G. Berry, Appraiser's Office, New York, N. Y.; saccharine products (including confectionery), E. B. Kenrick, Winnipeg, Manitoba, Canada; fruit products, E. M. Chace, Washington, D. C.; wine, G. E. Colby, Berkeley, Cal.; beer, H. E. Barnard, Concord, N. H.; distilled liquors, C. A. Crampton, Washington, D. C.; vinegar, R. Fischer, Madison, Wis.; flavoring extracts, R. E. Doolittle, Lansing, Mich.; spices, A. L. Winton, New Haven, Conn.; baking powder and baking chemicals, R. O. Brooks, Trenton, N. J.; meat, M. E. Jaffa, Berkeley, Cal.; fats and oils, L. M. Tolman, Washington, D. C.; dairy products, A. E. Leach, Boston, Mass.; cereal products, A. McGill, Ottawa, Canada; infants and invalids' foods, H. W. Wiley, Washington, D. C.; vegetables, F. W. Bedford, St. Paul, Minn.; condiments other than spices, J. D. Hird, Washington, D. C.; cocoa and cocoa products, E. N. Eaton, Chicago, Ill.; tea and coffee, H. C. Lythgoe, Boston, Mass.; and preservatives, W. D. Bigelow, Washington, D. C.; *sugar*—molasses methods, H. E. Sawyer, Boston, Mass.; special analytical methods, C. A. Browne, jr., Audubon Park, New Orleans, La.; *tannin*, H. C. Reed, Stamford, Conn.; *insecticides*, S. Avery, Lincoln, Nebr.; *ash*, F. T. Shutt, Ottawa, Canada.

Diversification Farms.—The Department of Agriculture has arranged for conducting during the coming season 30 farms in the Southern States to serve as demonstrations in farm management. These farms will be of from 40 to 50 acres each and are located as follows: Texas, 14; Louisiana, 5; Mississippi, 3; Alabama, 3; Georgia, 2; South Carolina, 2; Florida, 1. These farms will be located on private farms and will be under the direction of officers of the Bureau of Plant Industry, who will visit them frequently during the season. The Department will furnish the seed and one-half of the fertilizer, and the expense of carrying on the farms will be borne by the owners, who will enter into an agreement to carry on the areas set aside according to plans prescribed by the Bureau of Plant Industry. General farm crops will be grown with reference to demonstrating the practicability and the methods of diversified agriculture. The immediate charge of this will be in the hands of W. J. Spillman, the agrostologist.

Challenger.—The December-January number of *Agriculture*, the publication issued by the agricultural students of the University of Nebraska, gives an account of the raising and feeding of Challenger, the champion steer of the International Live Stock Exhibition. Challenger was raised by a farmer in Nebraska, his dam being a Shorthorn cow with enough Holstein blood to give her a blue-white color and quite ordinary in appearance, while his sire was a registered Hereford bull of unusual individual merit. He was selected by Prof. H. R. Smith, of the department of animal husbandry, from a bunch of 2-year-old steers last May. At that time he weighed 1,300 lbs. and was purchased for 5 cts. a pound, or a total of $65. The breeder, who was

also his feeder until May 1, showed him no preference, for, as he says, "we noticed nothing in him to give him a preference." He was fed by the university from May until the time he was shipped to Chicago, and during the latter part of the period "was under extremely high-pressure feeding, consuming 25 lbs. of grain per day besides a few pounds of sugar beets and about 8 lbs. of alfalfa and prairie hay." He gained 200 lbs. in the last two months and weighed 1,760 lbs. when he was shipped to the show. His total cost to the college, not including freight and labor, was $105.72. He won $430 in prize money and sold for 26 cts. per pound, or approximately $450. Challenger dressed 1,135 lbs. of meat, or 65 per cent of his live weight. It was reported at the place where he was slaughtered that "he made a magnificent carcass of beef, by far the best our cattlemen had ever seen." Challenger is being mounted for the St. Louis Exposition, after which he will be returned to the University of Nebraska for class-room illustration.

Farmers' Institutes in Georgia.—The past year a very successful series of farmers' institutes was held in the State, which aroused much interest. This was the first systematic attempt to introduce the farmers' institutes, and was supported by the University of Georgia, the trustees of which set aside $1,000 for the purpose. During the year 44 institutes were held, one in each senatorial district of the State. One of the objects of the first year's work was to organize the institute system thoroughly, and with this end in view a president and secretary were elected for each district, and a vice-president from each county in the district. One-day sessions were held, with an average attendance of between 150 and 200. The faculty of the agricultural college and the staff of the experiment station took part in these institutes, presenting papers at a considerable number of meetings, but neither organization was made responsible for the management of the institutes, which was placed in the hands of Hon. Harvie Jordan, of Monticello, as director of institutes. It is hoped that provision will be made for carrying on the institutes another year so that at least one meeting may be held in each county and the sessions continued for two days in each place.

Hawaiian Sugar Chemists' Association.—An association of chemists who are or have been engaged in sugar work, either in sugar factories or in experiment station laboratories in Hawaii, has been formed with a membership of over thirty. The object of the association is the study of sugar chemistry and the methods of analysis used in the chemical control of sugar-house work, with a view to arriving at uniformity both in methods and statement of results. A meeting was held October 26 and 27, 1903, at which provisional methods were adopted and these, together with specimen blanks for the rendering of reports, have been issued in pamphlet form. The president of the association is P. A. G. Messchaert, of Waipahu, Oahu, and the secretary-treasurer is E. C. Shorey, chemist to the Federal experiment station at Honolulu.

School of Practical Gardening for Girls.—A recent issue of the *British Medical Journal* describes the women's branch of the Practical Gardening School of the Royal Botanic Society. The pupils in this school are for the most part young women who have obtained scholarships from the London school board, and who intend to adopt gardening as a profession. They are nominated by the technical education board of the London County Council. The students are allowed to work in a portion of the grounds of the botanical gardens in Regent's Park, and also learn practical hothouse work in the conservatories.

"The longest course is three years. The first-year students are taught ground operations, flower and vegetable gardening, and everything connected with the operations. During the second year the subjects taught are outdoor work, indoor work, and theoretical work. The third year is devoted to pruning, mowing, care of conservatory, plant houses, frames and pits, etc., and to theoretical work, such as keeping accounts, elementary meteorology, landscape gardening, sprays and washes for insect pests, and to classes and laboratory work in botany and horticultural chemistry.

"A new laboratory has been built for the use of students, and theoretical lectures followed by practical teaching are given on botany, elementary and advanced general histology, morphology, and physiology. Those students who wish to learn gardening as a pastime are allowed to attend on special days. The course of study in the botanical and horticultural laboratory is under the direction of Prof. E. J. Schwarz. Owing to the satisfactory report of the progress made by the scholars, the board has doubled its grant to the Royal Botanic Society, and now offers twenty scholarships instead of ten. Students readily find situations, and it is interesting to note how many people now employ lady gardeners in preference to men."

Bills before Congress.—A bill introduced into the Senate calls for an appropriation of $250,000, to be expended at the rate of $50,000 a year, to enable the Department of Agriculture to carry on, in conjunction with the experiment stations in the noncorn-growing States, experiments in the breeding, rearing, and finishing of live stock for market, the introduction and development of horses, cattle, sheep, and swine suitable for such regions and conditions, and the introduction and cultivation of suitable crops and forage plants.

The agricultural appropriation bill was reported in the House of Representatives February 4, and passed the following day. It carries a total appropriation of $5,711,240, an increase of $233,080 over that for the present year. The chairman, in presenting the bill, stated it to be the judgment of the committee that "although the estimates have not in all cases been allowed, the several amounts recommended will be ample to keep all branches of the Department of Agriculture in progressive motion, and will fully meet all the proper and justifiable demands of the country upon the Department." In reply to the assertion of some that the United States is not spending money enough toward the promotion of agriculture, statistics collected by the Census Bureau were presented showing that as nearly as could be ascertained the aggregate yearly expenditure for agriculture by the States and Territories amounts to something over $4,500,000, "which added to the $6,250,000 spent annually by the United States Government for the same cause makes a total of $10,750,000 spent annually for the promotion of agriculture. Certainly this is a most liberal figure, and much more than is being expended by any other Government in the world for the same purpose." The bill contains a new clause relating to the experiment stations, which authorizes and directs the Secretary of Agriculture "to coordinate the work of the several stations and the work of the stations with the Department of Agriculture, to the end of preventing unnecessary duplication of work, of increasing the efficiency of the stations and the Department of Agriculture, and to unify and systematize agricultural investigations in the United States." This is in line with the trend of discussion in the hearings of the Committee on Agriculture. An amendment to the bill, offered by Hon. H. C. Adams, providing for an increase in the appropriation to the stations along the lines of the bill previously introduced by him, was ruled out on a point of order.

A joint resolution has been introduced in Congress authorizing the printing of 4,000 additional copies of the Report of Irrigation Investigations in Utah, which was issued in a limited edition last summer as a bulletin of this Office.

Several bills have been introduced in both branches of Congress for the construction and improvement of roads and the establishment of a Bureau of Public Highways in the Department of Agriculture. Four of these call for an appropriation of $24,000,000 for road building in cooperation with the various States and Territories, to cover a period of 3 years. Another appropriates $50,000,000, and provides for the issuing of bonds for this purpose if necessary.

Personal Mention.—F. H. King, Chief of the Division of Soil Management of the Bureau of Soils, has resigned to take effect June 30. He was relieved from charge of the laboratory February 1, and will prepare a report upon his investigations. Professor King entered the Bureau of Soils in November, 1901.

E. E. Ewell, for several years connected with the Bureau of Chemistry of th Department, and for the past year in charge of the Atlanta office of the Germa Kali Works, died in New Orleans February 7.

Director E. B. Voorhees, of the New Jersey Stations, has been appointed presider of the New Jersey State Board of Agriculture.

W. B. Madison, of the National Farm School at Doylestown, Pa., goes March 1 t the Mount Hermon School, near Northfield, Mass., as horticulturist.

Prof. Pierre Mouillefert, professor of horticulture and forestry at the Nationa Agricultural School of Grignon, France, died December 26, 1903. He had been con nected with the institution since 1864, as student and assistant, and subsequently a professor. He published a book on the vineyards and wines of France, and a brie treatise on the culture of truffles, and wrote largely for French agricultural journals A treatise on sylviculture, consisting of four volumes, of which two have appeare and the others are in press, is also from his pen. In 1874 he was commissioned by th French Government to investigate the destruction of vineyards by the Phylloxera

Miscellaneous.—Wellesley College announces a course in general horticultur and elementary landscape gardening. The course includes lectures on the prepara tion of soils, the propagation, cultivation, and pruning of plants, school gardens and planting designs; and a brief consideration of the plants used in practical plant ing. The lectures will be supplemented by reading, work in the greenhouse, prac tice in making planting plans, practical work in the field, and visits to gardens, nurseries, and estates in the vicinity. The course covers one year and includes 3 hours a week for that period. It is in charge of Henry S. Adams, instructor in botany. The college has also offered for a couple of years past a course in trees and forestry, covering one year and including forest botany and sylviculture, the forests of the world, value and uses of their products, and the protection of wood lands.

Simmons College, Boston, offers a course in theoretical and practical horticulture designed to aid young women who wish to undertake the cultivation of flowers, fruits, and vegetables for commercial or other purposes. The course serves also as a practical basis for landscape gardening. It will extend over either three or four years, the first two years to be spent in Boston studying the underlying sciences and theoretical elements of horticulture, and the third year at the Massachusetts Agricultural College, as mentioned elsewhere.

The Girls' Industrial College, at Denton, Texas, which was opened to students the latter part of last September, will give considerable attention to the teaching of horticulture and ornamental gardening. This is provided for in the department of rural arts, in charge of A. J. Seiders, which will embrace floriculture, horticulture, truck and berry growing, dairying, bee keeping, and poultry keeping. Three new greenhouses 18 by 40 ft. have been completed and a small nursery has been established. The campus of about 70 acres will be devoted largely to landscape gardening and forestry.

The department of economics and sociology recently established by the Carnegie Institution, in charge of Carroll D. Wright, Commissioner of Labor, has undertaken the preparation of an economic history of the United States, embracing eleven subjects. The second of these subjects, relating to agriculture and forestry, including public land and irrigation interests, has been assigned to President K. L. Butterfield, of the Rhode Island College. This part of the work, it is understood, will be carried on with the collaboration of experts in various branches of agriculture.

According to press reports, George C. Creelman, superintendent of farmers' institutes in Ontario, has been appointed president of the Ontario Agricultural College at Guelph, to succeed Dr. James Mills, who has retired after twenty-five years of service to become a member of the railway commission newly appointed by the Dominion government. Mr. Creelman entered upon his duties February 1.

O

EXPERIMENT STATION RECORD.

VOL. XV. MARCH, 1904. No. 7.

The progress which has been made in organizing agricultural work in the Philippine Islands appears to be most gratifying and encouraging when the island conditions and the short period of operation are taken into account. The prime importance of agriculture in the development of the islands, the diversity of this industry, and its crude and crippled condition combine to make the field one of unusual opportunity and attractiveness to the agricultural expert and experimenter. The introduction into the islands of American methods for the improvement and promotion of agriculture has been full of interest to those who have watched its progress from afar.

Something of the present organization of the Bureau of Agriculture and the lines of work which have been inaugurated is learned from the second annual report of its chief, Prof. F. Lamson-Scribner. Professor Scribner entered upon the work of organizing the bureau about two years ago, and at the time the above report was concluded (last August) had been in the islands only about eighteen months. The difficulties of securing a competent staff of employees, the natural conditions of the islands, ravages of disease among the domestic animals, and the distance from the base of supplies have presented many obstacles and inevitably impeded progress, but in spite of this the bureau has been placed upon a substantial working basis and work undertaken in the leading branches of agriculture in the islands.

The organization now includes a central office at Manila, with experts in charge of seed and plant introduction, fiber investigations, soil studies, and animal industry; an experiment station and testing grounds near Manila, and six other stations and farms located at various points in the islands. At most of these outlying stations and farms buildings have been erected for the officers in charge and for laborers and animals, and a large amount of preliminary work has been performed in the direction of securing draft animals and farm machinery, getting the land into condition, establishing plantations, constructing the necessary roads, and other pioneer work. The total number of employees in the bureau last August was 205, 29 of whom were Americans and 176 natives. Most of the latter were laborers, although several natives were satisfactorily filling positions of considerable responsibility.

During the year seven farmers' bulletins and four regular bulletins were issued, mostly in both English and Spanish. The editions of these varied from 2,000 to 3,500, and it is noted that the first editions of several of the farmers' bulletins have been exhausted, necessitating reprints. On the basis of replies to a circular of inquiry sent out by the bureau regarding the agricultural products of the islands, an annotated list of the principal agricultural plants and products, exclusive of fibers, has been prepared for publication. Information has also been gathered regarding the cost of land, conditions of labor, the cost of establishing and maintaining plantations of abacá, cocoanut, tobacco, and other leading crops, as many inquiries came to the bureau from prospective planters. This gives an interesting insight into the prevailing conditions and methods, and should prove very useful.

Nearly 22,000 packages of assorted seeds have been distributed, reaching almost every province in the archipelago. These have included 137 varieties of American-grown field and garden seeds, and it is pointed out that the requests have come very largely from native farmers. It has been clearly demonstrated that many garden vegetables of American origin may be grown to perfection in the islands. A number of native fruits and vegetables are thought to be very promising and worthy of experiment to determine the cost of culture, possibility of improvement by selection, etc.

A variety of the most modern agricultural implements and farm machinery have been introduced by the bureau and put in use. It is interesting to learn that the natives take readily to these and soon get to use them skillfully. Native teamsters employed on the experimental grounds have learned to operate disk and sulky plows, cultivators, and similar implements very satisfactorily. A machine for thrashing rice which the bureau imported for use on its rice farm has attracted much attention, and there has been considerable demand for its services from native rice growers, who were willing to pay a good toll for having their rice thrashed out by machinery, in preference to hand labor, which otherwise prevails.

The experiment stations and farms in the Philippines are spread over a wide area of country, and embrace a diversity of agricultural interests. The experiment stations proper include those at Malate, just out of Manila; at Batangas, in Batangas Province; at Trinidad, in Benguet Province; and at La Carlota, in Western Negros, where an agricultural college has also been located. The farms include the government farm at San Ramón, in Zamboanga; a rice farm at Murcia, Tarlac Province; and a live stock farm on the Island of Culion. The farms at La Carlota and San Ramón were inherited from the Spanish régime, and were in a generally dilapidated condition when the bureau took hold of them. The San Ramón farm is only 7 degrees removed

from the equator, and is in the midst of tropical surroundings, while the work in Benguet Province has been carried on at a high elevation in a climate so cold that difficulty has been experienced in growing American vegetables. An unusually wide range of climatic conditions is therefore represented by the experiment farms.

The experiment station at Malate, upon which work was begun in October, 1902, comprises about 12 acres of land. It is used largely as a testing ground and for growing improved seeds for distribution. An adequate water supply has been provided and a water tower built, with the necessary pumping and distributing outfits for irrigating during the dry season. Special mention may be made of the experiments at this place with teosinte and Sumatra tobacco. The teosinte was a great success, as will be noted later; and the experiments in growing Sumatra tobacco gave most satisfactory results. The yield of two crops was at the rate of 1,470 pounds to the acre. Plants grown under shade had very thin, elastic, and delicately veined leaves, with a fine silky luster. The great superiority of the shade-grown tobacco was clearly demonstrated.

In Benguet Province the experiments in growing American vegetables and field crops at Baguio have been transferred to Trinidad, four and a half miles distant, and about 900 ft. lower in elevation. The establishment of an experiment station at this point is well under way. In Batangas Province the work at the Batangas Station is devoted chiefly to the growing of forage plants and American vegetables; and at Lipa, in the same province, which lies about 1,000 ft. higher, experiments in the rehabilitation of the coffee industry have been undertaken. A coffee plantation has been established on a tract of about 10 acres, in cooperation with a planter and under the immediate supervision of an expert of the bureau.

Prior to 1891 there were extensive coffee plantations in Batangas Province covering thousands of acres of land, which yielded large incomes to their owners. Since that time the plantations have been almost totally destroyed by attacks of leaf blight and borers, accompanied by almost absolute neglect of the trees and their cultivation. The bureau has imported seed and reared a large number of plants of the Liberian and Maragogype hybrid, which have been successfully transplanted to the thoroughly prepared ground. Experiments will be made in securing resistance to disease and insect injuries by the selection of vigorous-growing varieties and the adoption of the best system of cultivation and treatment.

The agricultural college and experiment station at La Carlota, in Western Negros, was transferred to the Bureau of Agriculture from the Bureau of Education in November, 1902, and a director appointed the following March. This estate, which comprises at present about 2,000 acres, is located in a province where the chief industry is sugar

making. It will be made essentially a sugar station, and devoted mainly to problems connected with the culture and improvement of sugar cane. An appropriation of $15,000 was made for beginning improvements on the farm, and $25,000 has been appropriated for the erection of a main building of brick, to be made on the grounds, which will serve for laboratories, class rooms, offices, and dormitories.

The government farm at San Ramón, in Zamboanga, includes about 5,000 acres, and was formerly used as a penal colony by the Spanish Government. It will be used principally for studying the problems in the management of cocoanut plantations, the preparation of copra, and the culture of abacá (Manila hemp). The farm already has a large number of cocoanut trees in bearing, which have improved in condition since the bureau took charge, and 2,000 additional trees were planted during the year, making a total of 10,700 on the farm. Ground for 8,000 hemp plants was broken during the year, which are reported to be in a thrifty condition. The advantages of cultivation to lessen the damage of drought were abundantly demonstrated on this tract during the season.

The revenues from hemp and copra on this farm amounted during the year to nearly $9,000, and it is thought that by further planting it could be easily made a source of considerable revenue.

The prospects for stock raising as a lucrative industry in the islands are believed to be good, but this will require the exercise of greater care in the prevention of contagious diseases and more attention to the cultivation of forage crops. The industry is at present at a low ebb and there continue to be heavy losses from disease. The stock found in the islands is for the most part of an inferior quality, owing principally to injudicious and careless breeding, lack of care during development, and inattention to feeding.

To aid in developing the industry a stock farm was established on the Island of Culion in January, 1903, after exploring several regions for a suitable location. The farm lies in a large, well-watered valley which affords excellent grazing, and although the island is rather isolated the location is thought to be well suited in all respects for a stock farm. Buildings have been erected for the foreman and laborers, and a stable 24 by 132 ft.; and improved stock of horses, cattle, hogs, milch goats, milch buffalo, and a number of varieties of fowls are being imported to place upon the farm, together with some native stock. The effort of the bureau will be to ascertain the breeds and crosses best adapted to existing conditions, to introduce new breeds of animals for breeding purposes, and to study questions relating to the improvement of the forage supply.

The forage problem is an acute one, and experiments in that line are closely connected with the development of animal industry. The

chief forage for cattle and horses in the cities and towns is grass cut fresh each day, and sold by local dealers to supply the daily needs. The most common kind of grass grown for this purpose, called zacate, is extensively cultivated in the vicinity of Manila, being grown in shallow water in paddies very similar to those prepared for rice culture. Nowhere in the Philippines is any attempt made to produce hay, although it is thought that hay farms in the vicinity of Manila would be both successful and profitable.

Teosinte has proved very productive and profitable as a forage crop, and is thought to give great promise for that country. From experiments at the Malate Station it is estimated that on well-fertilized land with frequent irrigation, ten cuttings could be obtained in a year, yielding over 100 tons of green fodder or approximately 30 tons of dry fodder per acre. The crops grown by the bureau were sold green in Manila at $10 (gold) per ton. Where the seed was allowed to mature an abundant crop was produced, yielding at the rate of 800 pounds of cleaned seed per acre during a dry season; and it is thought that two and probably three crops of seed could be grown annually, which would give a return for seed alone of over $1,400 an acre.

Several varieties of Indian corn have been grown in the islands for many years, but little attention is paid to its culture and care, and the returns are light. It is used mostly as a human food, but nothing is known of the many methods of preparing it for food in the United States. American varieties have shown a tendency to dwarf and ear out close to the ground. Promising results, however, have been secured from the second generation of seed in Batangas, the crop being in considerable contrast to that grown from native seed. The indications are that the use of acclimated American seed will increase the yield one-fourth or more, and that proper cultivation will bring about an increase of an additional one-fourth, thus adding fully 50 per cent to the present output without increase of either acreage or farm labor.

The consumption of rice—the staple article of food for the Filipinos—is estimated at approximately 5,000 tons a day, which is far in excess of the amount produced in the islands. Last year ten million dollars' worth were imported. The Bureau of Agriculture believes that with more extensive culture of rice and the use of modern methods of cultivation the islands are capable of producing not only their own supply but a large surplus for exportation. Steps were taken during the year to secure land and establish a rice farm for the introduction of machinery and better methods. The farm is located at Murcia, Tarlac Province, on the line of the Manila and Dagupan railroad, and embraces about 1,800 acres. About 1,000 acres were put in shape for planting and for irrigation, and were seeded with an American drill. The crop was cut with a reaper and binder, similar to the methods followed in Louisiana and Texas, and was thrashed out

with a rice thrasher of the latest American make. The most approved methods of rice culture will be followed on this farm, which is expected to serve not only as a demonstration farm, but to yield considerable revenue also.

Professor Scribner points out some of the opportunities and some of the needs of agriculture in the Philippine Islands. Manila hemp, the product of abacá, is known the world over, and is the most important source of revenue and the leading industry of the archipelago. The reasons for its prominence are found in the existing natural and industrial conditions. With the development of other forms of agriculture it is believed that the crude methods in practice will have to be improved upon. A more careful selection of the species of hemp grown and better methods of culture would greatly increase the yield of merchantable fiber. In the extraction, drying, baling, and transportation of the fiber there is also opportunity for great improvement, and it is believed that the perfection of a machine for stripping and cleaning the hemp fiber would aid more than any other one thing in developing the industry. Up to the present time no practical machine has been devised for this purpose, and the work continues to be done by hand, resulting in great variation in the quality, color, length, and texture of the fiber, as well as difficulty in securing the necessary labor.

Sisal hemp forms an article of considerable commercial importance in some sections, and will grow in regions entirely unsuited to abacá and upon soils otherwise of little value. The opportunity for extending the industry and for importing suitable machinery for extracting the fiber is thought to be unusually good.

The preparation of copra from the meat of the cocoanut, which is a staple article for export, is carried on in many places by exceedingly crude methods, the drying being done over pits or ovens dug in the ground which are little less than smokehouses. The method is thought to be in urgent need of improvement, and it has been suggested that desiccators or ovens especially constructed for this purpose could be introduced to great advantage.

From this brief outline it will be seen that in the short period of its existence the Bureau of Agriculture has accomplished a very creditable amount of work in agricultural exploration, experimentation, and investigation. It has been somewhat restricted by the limitations of its organization, since all work of a scientific character requiring laboratory equipment is assigned to the Bureau of Government Laboratories. Under this provision the studies of diseases of plants and animals, the composition of crops and agricultural products, and similar problems which require laboratory investigation are without the domain of the Bureau of Agriculture. The botanical work, which was in its charge

during the first year, was transferred to the Bureau of Government Laboratories last summer. The work on rubber production appears also to be assigned to that bureau.

This division of the work into the practical and the scientific, or that of the field and the laboratory, will call for the most cordial cooperation between the two bureaus. Such cooperation will be essential to the rounding out of the work in agriculture, and the efficient investigation of the various scientific phases which are sure to develop as the work progresses.

Some time ago it was mentioned that the Department Library had undertaken the preparation of a card index of the articles contained in the more important scientific periodicals devoted to agriculture. This undertaking is in line with the suggestion of the Committee on Indexing Agricultural Literature and is intended as an aid in looking up the investigation on a given subject.

Considerable progress has been made in this work and the Library is now ready to begin issuing the cards. A circular has been distributed explaining the scope and cost of the index and as soon as returns are received showing the number of subscribers the printing of the cards will begin.

Subscriptions will be received for complete sets, including author and subject cards, for author sets alone, or for the cards relating to any particular subject, as soils or horticulture, or animal production or entomology; and furthermore, a single card or a set of cards for any particular article may be purchased. The "author entry set" will include one card only for each article listed. As the articles are frequently quite broad in their scope and might be classified under several subject headings, and as the index is analytical, additional cards will be required to make up the complete set. The cards in the author set will be sold at one cent each, and the additional cards for making the complete set at one-half cent each.

For the cards subscribed for in a particular class, as soils or entomology, a charge of two cents will be made for the first card and one-half cent for each duplicate card, as considerable more work will be involved in making up such sets. The scheme of subjects from which selection may be made follows in general the classification of the card index issued by this Office, although some changes have been made to better suit it to this particular purpose. Single cards or a set of cards for any article can be purchased at the regular price of two and one-half cents for the first card and one-half cent each for duplicates.

In beginning the preparation of these cards three prominent journals devoted to agricultural science were selected, and the work in analyzing them has progressed to a point where a considerable number of volumes have already been covered and an estimate secured of the

number of entries which will be involved. For the set of *Annales de la Science Agronomique*, from 1884 to 1903, the author set will include 328 cards, costing \$3.28, and the complete set (with author set) will include 844 cards, costing \$5.92. The 31 volumes of *Landwirtschaftliche Jahrbücher*, covering the period from 1872 to 1903, will require 838 cards for the author set, costing \$8.38, and 2,500 cards for the complete set, costing \$17. Similarly, for *Die landwirtschaftlichen Versuchs-Stationen* from 1859 to 1903, 1,378 cards will be required for the author set, costing \$13.78, and 4,100 cards for the complete set, costing \$27.

The form adopted for the printed card leaves the classification to the individual, so that the scheme is very elastic both in the matter of classification and of purchasing the cards. The card for a particular article will contain the name of the author, the exact title of the article in the original language, the reference to the page and number of the journal, and in small type at the bottom, the principal subject or subjects covered by the article. The latter is merely suggestive and is intended as an additional guide to the contents of the article, as the title is frequently not sufficiently definite.

No free sets will be distributed either to libraries or individuals. The price charged is barely sufficient to cover the cost of printing and distribution. If a sufficient number of sets are subscribed for in advance, this mechanical work will be undertaken by the Library of Congress as a part of its card distribution work, although the preparation of the index will remain in the Department. Prospective subscribers are requested to communicate promptly with the Department Librarian in order to hasten the printing of the cards, and notice will be sent out when they are ready for delivery regarding the proper method of payment.

While the cost for the complete sets of cards is considerable, it should be borne in mind that the labor of preparing these cards is contributed by the Department Library, and that no private concern would be warranted in attempting the work. The cost of complete sets of cards for the three serial publications noted above is approximately \$50, but these sets cover 108 volumes with over 2,500 articles, and include nearly 7,500 cards. Other periodicals are to be taken up later as the work progresses, beginning in each case with the earlier volumes. The value of this index to the investigator will be readily appreciated. It constitutes one of those bibliographic helps which no experiment station or large well-equipped agricultural library can afford to be without.

The issuing of a list of current experiment station publications has been commenced by this Office, and the first number has brought many expressions of approval and commendation. The list will be

issued bimonthly in future, and will contain brief synoptical notes regarding each publication listed. It will be in the form of the monthly list of publications of this Department, which it will supplement so far as the station reports and bulletins are concerned. The latter are now so numerous that few people can expect to receive them all, and moreover the widespread distribution of complete files would result in the waste of many bulletins. The new list will enable farmers' institute workers, agricultural editors, various specialists, and others interested in the work of the stations to select such bulletins as are of particular interest and value to them.

In order that the list may be issued promptly and may be complete, it is very desirable that the experiment stations should send copies of their publications to this Office as soon as issued. The plan at present followed at some stations of sending out several bulletins together frequently results in considerable delay. The adoption of a uniform plan of mailing the separate bulletins to the Office as soon as they are received from the printer, would materially facilitate not only the preparation of the new list, but the review of the station work in general.

NEW DAIRY BARN AT THE KENTUCKY STATION.

D. W. May.

Kentucky Experiment Station.

The new dairy barn at the Kentucky Experiment Station is an adaptation of the Swiss style of architecture of deep, overhanging eaves (Pl. II). The building consists of a main portion of two stories and a basement, 68 ft. long by 37 ft. wide, two ells each 60 ft. long, and a milk room 14 by 22 ft. (fig. 8).

The basement underlying the entire main portion of the barn has a natural limestone bottom. This space is used for the heating plant, the storage of ice, etc. The barn is lighted by electricity, and a motor is to be installed for power. The first floor of the main portion contains two offices, a dairyman's room, bathroom, and feed room. This floor is ceiled throughout with hard pine, natural finish. The second story is used for the storage of hay and grain feeds, the grain bins being connected with the feed room below by chutes.

The cow stable, in one of the wings, is 60 by 39 ft., with a loft above for the storage of hay and bedding. The floor is cemented with cement plaster extended on the walls to a height of 4 ft. all around. The remainder of the walls and ceiling are finished in hard pine and varnished. Stalls (Pl. II) are fitted up to accommodate 30 cows. These are constructed of gas pipe embedded in the cement floor, and the upper spaces being fitted with 2-inch netting made of No. 9 wire. The objects in view in the stall construction were to have as little material as possible for necessary protection of the animals, and at the same time to economize the available space. The animals are fed from galvanized iron troughs 14 in. wide and extending across the front of the stalls. A drop 18 in. wide runs the length of the stalls in the rear. The manure is handled with a Cherry carrier running on an overhead track behind the stalls. It is taken directly to the fields and spread at once or as soon as the ground may be traversed. The cows are tied with a single rope.

The second ell is 60 by 27 ft., with a clay floor, and is ceiled throughout. It is divided into box stalls built of oak. Two are solid and high, to be used for bulls or sick animals. The remainder are made of oak palings 4 ft. high, fitted with stanchions for holding calves

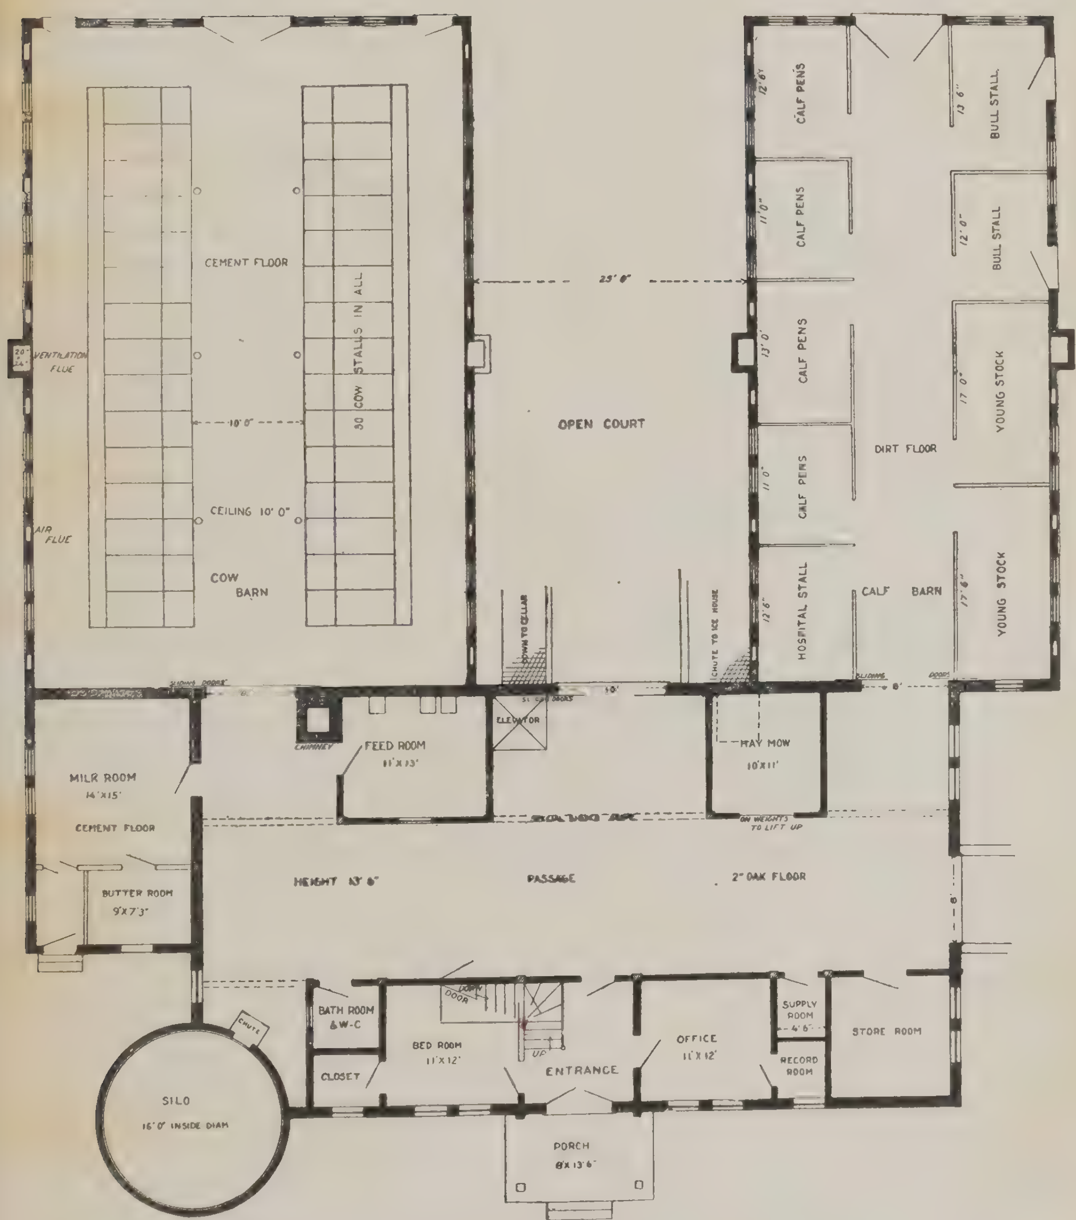

FIG. 8.—Ground plan of Kentucky Station dairy barn.

while they are being fed. A system of ventilation is provided for both wings, illustrated in figure 9.

The milk room is cemented throughout on steel lath. It is fitted with slate shelving, porcelain basins, and nickeled trimmings, so that it may be sterilized readily with hot water or steam.

The silo at one corner of the building is 38½ ft. high by 16 ft. in

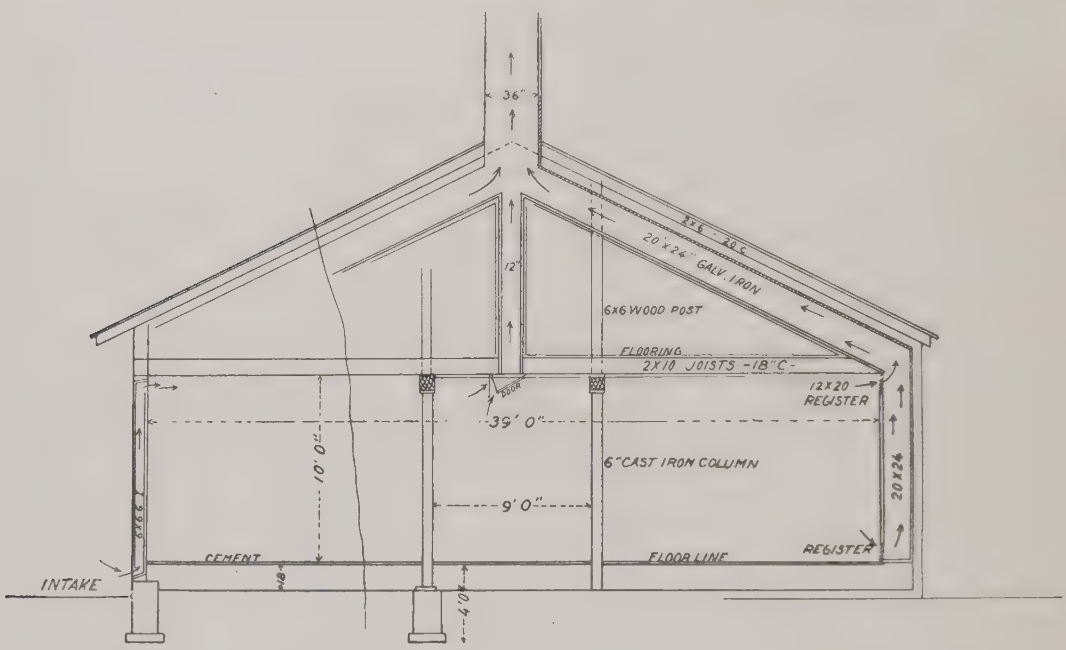

FIG. 9.—Ventilation system of Kentucky Station dairy barn.

diameter. The outside is weather boarded like the barn, and the interior lining is constructed of two sheathings of seven-eighths in. shiplap siding, with two layers of tarred paper between.

The cost of the barn complete, including stalls and plumbing, was approximately $8,500.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The determination of citric-acid soluble phosphoric acid in Thomas slag, P. Wagner et al. (*Die Bestimmung der zitronensäurelöslichen Phosphorsäure in Thomasmehlen. Berlin: Paul Parey, 1903, pp. VII + 112*).—This is the first of a series of contributions from the Association of German Agricultural Experiment Stations, which are designed to summarize in concise form lines of investigation by the German stations which have led to conclusive results of practical value. This number reviews the history of the development of the German official method of determining the solubility of the phosphoric acid of Thomas slag in citric acid, explains in detail the sources of error and the precautions to be observed in using the method, and gives a full description of the method and of the preparation of the reagents required.

Investigations on phosphorus and phosphoric acids, H. Giran (*Ann. Chim. et Phys., 7. ser., 30 (1903), Oct., pp. 203–288, figs. 6*).—This article deals in a somewhat exhaustive manner with the different forms, heat of combustion, and solubility in bromin of phosphorus; forms and properties of phosphoric anhydrid; and preparation and properties of metaphosphoric and pyrophosphoric acids and the rapidity of their transformation in solution.

Solubility of magnesium ammonium phosphate in ammonium citrate, A. Bolis (*Chem. Ztg., 27 (1903), No. 94, p. 1151*).—By treating 2 gm. of freshly precipitated magnesium ammonium phosphate with 100 cc. of neutral ammonium citrate containing 400 gm. of citric acid per liter for 24 hours in the cold, it was found that the average solubility of the phosphate was 0.457 per cent. When the solution was kept warm during the treatment the solubility was somewhat higher, approximately 0.6 per cent.

The influence of ammonium salts in preventing the precipitation of magnesium by means of ammonia, F. P. Treadwell (*Ztschr. Anorgan. Chem., 37 (1903), No. 2, pp. 326–331; abs. in Chem. Ztg., 27 (1903), No. 93, Repert. 21, p. 299*).—The author's investigations confirm Lovén's conclusion that the action of ammonium salts in preventing the precipitation of magnesium by means of ammonia is due not to the formation of complex salts, but solely to the prevention of dissociation of ammonium hydroxid by ammonium chlorid according to the law of mass action.

On the quantitative separation of lime and magnesium by the indirect method, A. C. Christomanos (*Ztschr. Analyt. Chem., 42 (1903), pp. 606–612; abs. in Chem. Centbl., 1903, II, No. 20, p. 1145*).—Methods applicable to mineral waters and magnesite are described. These are based upon the conversion of the calcium and the magnesium after the removal of silica, iron, and alumina from the solution, first into carbonate and then into sulphate. A method of estimating the lime and magnesia from the weights of carbonate and sulphate obtained, with proper factors to use, is explained, and results of analyses of a number of samples of magnesite are reported.

A contribution to the knowledge of calcium carbonate, W. Meigen (*Ber. Naturf. Gesell. Freiburg, 13 (1903), July, pp. 40–94, figs. 9*).—A detailed and technical chemical study.

Detection and estimation of ammonia by means of sodium picrate, C. Reichard (*Chem. Ztg., 27 (1903), Nos. 80, pp. 979, 980; 82, pp. 1007, 1008; abs. in Jour. Chem. Soc. [London], 84 (1903), No. 493, II, p. 754*). In the method proposed

the ammonium salt (chlorid or sulphate) is dissolved in the smallest possible quantity of cold water. The solution is then heated to boiling and mixed with an excess of boiling 10 per cent solution of sodium picrate. The liquid is allowed to cool gradually, and when quite cold is decanted, the portion adhering to the crystals being removed by means of filter paper. The crystals are then dried at 60 to 70° C. and weighed. Carbonates, cyanids, and compounds of potassium, rubidium, and caesium (but not of lithium) interfere with this reaction.

A method for the determination of ammonia, A. SCHITTENHELM (*Ztschr. Physiol. Chem., 39 (1903), p. 73; abs. in Chem. Ztg., 27 (1903), No. 81, Repert. 18, p. 251*).—A modification of the Krüger-Reichs method, adapted to clinical purposes, is described.

Estimation of nitrates in waters by the Schultze-Schloesing method, L. L. DE KONINCK (*Bul. Assoc. Belge Chim., 17 (1903), pp. 117–120; abs. in Chem. Centbl., 1903, II, No. 7, pp. 461, 462; Jour. Chem. Soc. [London], 84 (1903), No. 493, II, p. 754*).—In this method the gas evolved by the action of hydrochloric acid and ferrous chlorid is collected over potassium hydroxid and the resulting nitric oxid is finally measured over water. The author, however, prefers to first decompose the carbonates. It was found that bromids do not interfere with the reaction. In estimating silica in water containing nitrates the author prefers to acidify with sulphuric acid instead of hydrochloric acid, especially when a platinum dish is used.

On the determination of nitrate nitrogen in presence of organic nitrogen, T. PFEIFFER (*Ztschr. Analyt. Chem., 42 (1903), No. 9–10, pp. 612–617; abs. in Chem. Centbl., 1903, II, No. 20, p. 1145*).—Referring to a recent article by Liechti and Ritter (E. S. R., 15, p. 121), the author reports further studies of the accuracy of Schloesing's method, which bear out his conclusions drawn from previous investigations, that the presence of ammonium salts and organic compounds of nitrogen seriously interfere with the accuracy of this method, causing the results to be too low.

The determination of nitrogen by the Kjeldahl method, R. B. GIBSON (*Jour. Amer. Chem. Soc., 26 (1904), No. 1, pp. 105–110*).—Owing to the recent discussion of the reliability of the Kjeldahl method for the determination of nitrogen in organic compounds, the author made control determinations of nitrogen in uric acid, hippuric acid, tyrosin, leucin, urethane, thiourea, phenylmethyloxypyrimidin, aminobenzoic acid, and caseinogen by the Kjeldahl-Gunning method.

The results are believed to afford no occasion to question the usefulness or accuracy of the the Kjeldahl method as applied to physiological-chemical work. It is stated that "when due care is exercised to procure a proper decomposition and oxidation of the substances analyzed, uniformly satisfactory determinations can readily be obtained. For substances of unknown structure, however, the results furnished by the Kjeldahl process should not be accepted without verification by other methods."

The results of recent investigations in proteid chemistry, P. A. LEVENE (*Science, n. ser., 19 (1904), No. 472, p. 106*).—A brief note on a paper presented by the author at a meeting of the Society for Experimental Biology and Medicine, calling attention to the results of some of the more recent work on the chemistry of proteids, which is of especial interest as explaining biological phenomena.

On vegetable protein, O. NAGEL (*Jour. Soc. Chem. Ind., 22 (1903), No. 24, pp. 1337, 1338*).—Notes are given on the preparation of vegetable albumin from certain oil cakes, of which sesame and rape seed are preferred, and of vegetable casein from soy beans.

A new Kjeldahl apparatus, M. VOGTHERR (*Chem. Ztg., 27 (1903), No. 80, pp. 988, 989; abs. in Chem. Centbl., 1903, II, No. 20, p. 1141*).

Phosphomolybdic acid as a reagent for the detection of the amino group, F. SEILER and A. VERDA (*Chem. Ztg., 27 (1903), No. 91, pp. 1121–1125*).

Provisional methods of the Hawaiian Sugar Chemists' Association (*Honolulu: Hawaiian Gazette Co., Ltd., 1903, pp. 10*).—This contains the provisional methods of the association for the analysis of sugar cane, bagasse, waste molasses, and press

cake, compiled and edited by the executive committee. Forms for analytical reports are appended.

On the polyrotation of sugars, E. ROUX (*Ann. Chim. et Phys., 7. ser., 30 (1903), Nov., pp. 422–432*).

Notes on the hydrolysis of starch by acids, G. W. ROLFE and H. W. GEROMANOS (*Jour. Amer. Chem. Soc., 25 (1903), No. 10, pp. 1003–1014, dgm. 1*).—The conclusion was reached by Rolfe and Defren in work published in 1896 (E. S. R., 9, p. 22), that a constant relation exists between optical rotation and copper reduction; or, in other words, that products of hydrolysis of the same rotation have the same reducing power. The results of this work as recalculated, and additional data obtained in an investigation of hydrolyzed products of several commercial starches, are reported. The results are believed to show conclusively the presence of another reducing body than dextrose in acid-hydrolyzed starch products.

The presence of maltose in acid-hydrolyzed starch products, G. W. ROLFE and I. T. HADDOCK (*Jour. Amer. Chem. Soc., 25 (1903), No. 10, pp. 1015–1019, pls. 6*).—Maltosazone was separated from alcoholic fractions of commercial glucose solutions. The method used is to be further investigated. Incidentally the relation of optical rotation to cupric reduction as applied to alcoholic fractions was tested, the relation being found to agree in general with that for homogeneous acid-hydrolyzed products.

A study in raffinose determinations, D. L. DAVOLL, Jr. (*Jour. Amer. Chem. Soc., 25 (1903), No. 10, pp. 1019–1028*).—Several methods of determining raffinose in the presence of saccharose were tested. A modification of Clerget's method proposed by the author is believed to give satisfactory results with dark-colored products. The modification consists in the addition of 1 gm. of powdered zinc for 3 to 4 minutes at 69° C. after the completion of inversion by the method of Clerget.

Butter and butter substitutes, P. SCHWEITZER (*Columbia, Mo.: pp. 28*).—In this investigation into the chemical properties of fats used as articles of food, 31 samples were examined. Notes are given on the methods of analysis used, and the results are discussed in detail. The data are summarized in the following table and the author's conclusions are quoted below:

Analyses of fats and oils.

	Hübl number.	Reichert-Meissl number.	Köttstorfer number.	Hehner number.	Index of refraction.	Fuel value.
						Calories.
Butter	27.8	32.0	229.9	87.02	1.4587	9,287

Corn oil	....	....	....	95.50	1.4727	....

"As this study was undertaken chiefly to answer the question whether certain fats used as food by man could be distinguished one from the other, I would say that butter, oleo oil, neutral lard, cotton-seed oil, beef stearin, lard oil, and any of their mixtures, whether called butterine or by any other name, can be distinguished one from the other with perfect certainty, and that in mixtures, even those containing a certain proportion of butter, the nature of the components can be ascertained with a reasonable degree of accuracy."

The iodin number of cotton-seed oil, peanut oil, and some other oils and fats, J. J. A. Wijs (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 15, pp. 692–697*).—Determinations made by the author's method of the iodin absorption of a number of samples of oils and fats are reported.

Readings on the Zeiss butyro-refractometer of edible oils and fats, H. C. Lythgoe (*Tech. Quart., 16 (1903), No. 3, pp. 222–226*).—The author reports actual readings of cocoanut oil, beef stearin, cacao butter, beef tallow, mutton tallow, lard stearin, beef oleo, lard oil, peanut oil, rape-seed oil, yellow and black mustard oils, sunflower oil, and poppy-seed oil, most of the samples being of known purity. A table is given, in which the calculated readings of these oils and fats at different temperatures are incorporated with the butter readings of Zeiss, the lard readings of Hefelmann, and the olive oil and cotton-seed oil readings of Leach. The iodin number and specific gravity of beef stearin, lard stearin, beef oleo, and lard oil are also reported.

Acido-butyrometric analyses of whey, P. Wieske (*Rev. Gén. Lait, 3 (1903), No. 2, pp. 30–34, fig. 1*).—The Adams, Gottlieb, and Gerber methods of determining fat were compared on 16 samples of whey. Duplicate determinations by the Gerber method showed no greater variations than by the gravimetric methods. The results of the 3 methods agreed closely.

The determination of fat in skim milk, C. Barthel (*Rev. Gén. Lait, 3 (1903), No. 2, pp. 25–29*).—The Adams and Gottlieb methods were compared on whole and skim milk. The Adams method gave too low results in the case of skim milk obtained from milk subjected to considerable agitation before separation, while the Gottlieb method was believed to give reliable results under all circumstances.

Determination of fat in milk by the Adams, Gottlieb, and Gerber methods, M. Siegfeld (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 6, pp. 259–271*).—A large number of duplicate determinations by each of these methods, extending over a number of years, are reported. No more accurate results are believed to be obtained by one of the methods than by another. The possible sources of error in each method are pointed out.

Investigations on the Gottlieb-Rose method of fat determination, M. Popp (*Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 1, pp. 6–12*).—According to the author's experience the Gottlieb-Rose method is simpler, shorter, and more accurate than other gravimetric methods of determining fat in milk. In one series of experiments a study was made of the effect of allowing the sample to stand for varying periods, from ½ to 6 hours, after the addition of the ammonia, alcohol, ether, and petroleum ether. About 1 hour is recommended.

In another series of experiments comparison was made of ammonia of different concentrations (sp. gr. 0.98 to 0.91, corresponding to NH_3 4.8 to 24.99 per cent). The result showed no greater variations than with the use of the concentration (sp. gr. 0.96) recommended by Gottlieb. Practically the same figures were obtained by the weakest ammonia and double the usual amount of the strongest ammonia used.

Qualitative reactions of hydrogen peroxid and their use in the examination of milk, C. Arnold and C. Mentzel (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 7, pp. 305–309*).—The different tests for hydrogen peroxid are mentioned and their application to the detection of this substance in raw and heated milk is briefly described.

New reactions for distinguishing raw and heated milk, as well as for the detection of hydrogen peroxid in milk, C. ARNOLD and C. MENTSEL (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 12, pp. 548, 549*).—Characteristic color reactions are reported as obtained by 2 aromatic amins, p-diethyl-p-phenylenediamin and p-diamido-diphenylaminhydrochlorid.

The examination of milk samples containing unduly large quantities of preservatives, M. SIEGFELD (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 9, pp. 397–408*).—Fat was determined by the Gerber method in milk containing various quantities of formalin and potassium bichromate. The results were materially influenced by large quantities of these preservatives.

A comparative study of methods of determining formaldehyde, B. H. SMITH (*Jour. Amer. Chem. Soc., 25 (1903), No. 10, pp. 1028–1035*).—The Blank and Finkenbeiner method of determining formaldehyde was found very satisfactory for strong solutions. The Legler method gave lower results but was fairly satisfactory. The gravimetric hexamethylenetetramin method was considered practically worthless. The iodiometric and potassium cyanid methods gave good results on dilute solutions. It was considered possible to determine with accuracy 1 part of formaldehyde in 100,000 by the potassium cyanid method. In the anilin volumetric method the author found it impossible to ascertain the end point.

The estimation of formaldehyde in milk, B. H. SMITH (*Jour. Amer. Chem. Soc., 25 (1903), No. 10, pp. 1036–1038, dgm. 1*).—Several experiments are reported, the results of which are summarized by the author as follows:

"It may be said that considerable time and trouble may be saved by using a Kjeldahl flask and a round, flat evaporating burner in the distillation of milk; that the quantity of sulphuric acid added has a decided effect upon the amount of formaldehyde obtained in the first part of the distillation; that, if the treated milk is kept in a cool place, the percentage of formaldehyde found will remain practically constant for at least 48 hours; and that where 100 cc. of milk are treated with 1 cc. of sulphuric acid of a dilution 1:3 and distilled, the first 20 cc. of the distillate will contain very close to $33\frac{1}{3}$ per cent of the total formaldehyde present."

A chemical method for detecting and measuring the addition of low-grade flour to wheat flour, G. VOLPINO (*Gior. Farm e Chim., 52 (1903), pp. 337–346; abs. in Chem. Centbl., 1903, II, No. 15, p. 844*).—Contrary to the opinion of other investigators the author maintains that when a mixture of wheat flour and barley, rye, maize, or rice meal is washed out with water by means of a water pump, only gluten possessing the qualities of wheat gluten will remain, and in about the proportion in which wheat gluten is present in the original mixture. The insoluble proteids of barley, rye, maize, and rice meal are found in the water used for washing the gluten, and are removed from the water by filtration. The estimation by the Kjeldahl method of these insoluble proteids obtained after the removal of gluten furnishes information regarding the quality of the flour and the kind and amount of adulteration.

Flour is regarded as adulterated which contains, after the removal of the gluten, more than 0.02 gm. of proteid insoluble in water. The kind of adulteration can be determined usually with a microscope. Spoiled wheat flour shows an increase in the insoluble proteids remaining after removing gluten which is proportional to the degree of change. These insoluble bodies do not equal the amount found in other sorts of flour besides wheat.

Volumetric determinations, A. WOHL (*Ber. Deut. Chem. Gesell., 36 (1903), pp. 1417–1422; abs. in Bul. Soc. Chim. Paris, 3. ser., 30 (1903), No. 22, p. 1230*).—The author explains the application of his method, previously described (E. S. R., 14, p. 1043), to the determination of ammonia and carbon dioxid.

Potassium tetroxalate as a titrating reagent, O. KÜHLING (*Ztschr. Angew. Chem., 16, (1903), pp. 1030–1033; abs. in Chem. Centbl., 1903, II, No. 25, pp. 1390,*

1391).—The author claims that potassium tetroxalate of constant composition can be prepared from oxalic acid which has been carefully purified by crystallization (from hot hydrochloric acid and boiling water), by recrystallizing the tetroxalate obtained on adding potash solution to the oxalic acid, pressing between sheets of hardened filter paper, and allowing to air-dry until the crystals no longer adhere to the sides of a glass vessel. It is pointed out that the difficulty which has often been encountered with this reagent was probably due to the fact that the tetroxalate was prepared by desiccation over sulphuric acid.

On the titration of sulphuric acid with benzidine hydrochlorate, W. J. MÜLLER and H. DÜRKES (*Ztschr. Analyt. Chem., 42 (1903), pp. 477–492; abs. in Chem. Centbl., 1903, II, No. 17, pp. 964, 965*).—The investigations reported are a continuation of previous work (E. S. R., 15, p. 337) and relate to conditions of accuracy and applications of the method to various compounds.

On the impurities in compressed oxygen and their rôle in combustion by means of the bomb calorimeter, M. BERTHELOT (*Ann. Chim. et Phys., 7. ser., 30 (1903), Aug., pp. 433–440, fig. 1*).

The determination of carbon dioxid, A. WOHL (*Ber. Deut. Chem. Gesell., 36 (1903), pp. 1412–1417; abs. in Bul. Soc. Chim. Paris, 3. ser., 30 (1903), No. 22, p. 1230*).—The method described is based upon the loss of weight due to the expulsion of carbon dioxid, aqueous vapor generated within the flask being used for the latter purpose. The apparatus employed and the precautions observed to prevent inaccurate results due to absorption of carbon dioxid by condensed aqueous vapor are described.

The determination of argon in atmospheric air, H. MOISSAN (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 16, pp. 600–606*).

On the determination of the composition of chemical compounds without the aid of analysis, G. TAMMANN (*Ztschr. Anorgan. Chem., 37 (1903), No. 2, pp. 303–313, figs. 5*).—The method described is based upon the melting or fusing point and the relation of the properties of the crystallized fusion to chemical composition.

The general principles of physical science, A. A. NOYES (*New York: Henry Holt & Co., 1902, pp. VII+172; rev. in Science, n. ser., 19 (1904), No. 472, p. 102*).

The progress in agricultural chemistry, 1902, A. HILGER, T. DIETRICH, ET AL. (*Jahresber. Agr. Chem., 3. ser., 5 (1902), pp. XXXVI+580*).—This contains abstracts of the more important articles in agricultural chemistry published in 1902, and titles of articles of less importance. The subjects are classified, as usual, under plant production, animal production, agricultural technology, and methods of investigation.

BOTANY.

Acidity of plants, A. ASTRUC (*Ann. Sci. Nat. Bot., 8. ser., 17 (1903), pp. 1–108; abs. in Jour. Roy. Hort. Soc. [London], 28 (1903), No. 1–2, pp. 229, 230*).—An account is given of investigations on the occurrence of free or partially combined acids in different plants, and in different parts of the same plant under varying conditions.

In the case of nonsucculent plants the chief conclusions drawn are that vegetable acids are present in greater quantity in young leaves and diminish as the leaves become older, and that the younger parts of the leaf contain more acid than the more mature parts of the same leaf. The organic acids are gradually fixed by saturation or etherification and disappear as free acids. The production of organic acids is intimately associated with the processes of respiration and assimilation. In the green parts of variegated leaves the acids are more abundant than in the paler parts, and in etiolated plants the acids increase on exposure to light. In the stem the greatest acidity is found in the young growing parts. The acidity of the flowers decreases as development goes on, but begins to increase as the flowers begin to fade. This change is said to be due to the commencement of the growth of the ovary into fruit.

In the second part of the report the investigations are confined to succulent plants. These have long been known to be peculiar in their absorption and excretion of oxygen and carbon dioxid gas, as well as in their acidity. The author has shown that the acidity of these plants, which is chiefly due to malic acid, increases considerably during darkness. In a leaf partly exposed to full sunlight the acid content is distinctly greater in the shaded parts and less in the exposed parts. This disappearance of acids in succulent plants is said to be due not to their fixation, but to the processes of respiration and assimilation. The transpiration of the succulents studied was influenced more by the salts present in the different organs of the plants than by their acid content.

The significance of ethereal oils in xerophytes, C. Detto (*Flora, 92 (1903), pp. 147-199, figs. 7; abs. in Jour. Roy. Hort. Soc.* [*London*], *28* (*1903*), *No. 1–2, pp. 250, 251*).—The author has examined the functions of ethereal oils in their significance toward desert plants. The theory of Tyndall that they serve to check excessive heating by the opacity of their vapor to ultra-red rays is held to be improbable. Dixon's theory that the function of essential oils is to check transpiration was examined and found to depend on the presence of these oils in the vapor. The author regards the function as protective against many animals, such as mollusks, herbivorous mammals, etc., and justifies his view by a careful series of experiments.

Carbonic acid assimilation in submerged plants, O. Treboux (*Flora, 92* (*1903*), *pp. 77–97; abs. in Jour. Roy. Hort. Soc.* [*London*], *28* (*1903*), *No. 1–2, p. 239*).—Experiments are reported on Elodea in a dark room illuminated by an incandescent lamp. Various substances were added to the water and the rate of assimilation estimated by counting the gas bubbles given off in 5 minutes.

Assimilation was found to be reduced by the addition of neutral salts, while salts of the heavy metals, alkaloids, and anæsthetics, which in minute proportions increase respiration, had no effect on assimilation. Chloroform was found to arrest assimilation temporarily. All acids when sufficiently dilute not to be harmful increased assimilation. Sufficiently dilute formaldehyde was indifferent to the rate of assimilation, and neither in the presence of light nor in darkness was there any additional starch formed from it. In stronger solutions formaldehyde was found to be injurious.

Growth without oxygen, A. J. Nabokich (*Bot. Centbl., Beihefte, 13* (*1902*), *No. 3, pp. 272–332; abs. in Jour. Roy. Hort. Soc.* [*London*], *28* (*1903*), *No. 1–2, p. 264*).—A report is given of experiments in growing sunflower hypocotyls in flasks which had been exhausted by an air pump and then sealed. The investigations showed that a distinct elongation is perceptible in the absence of oxygen, and that practically no effect is produced by traces of oxygen where the amount present is less than 0.06 per cent.

The effects of temperature on the individuality and character of the mother plant, of the duration of the experiments, and of the use of sugar solutions or water in the experiments were investigated. It was found that when seeds were germinated in an atmosphere deprived of oxygen there was a reduction of nitric acid, although bacteria were absent from the substrata and from the seeds. The point of interest in the paper is that the anaerobic life followed by many bacteria can be adopted by the cells of higher plants under certain conditions.

The effect of the temperature of the soil on the growth of roots, P. Kossovich (*Zhur. Opuitn. Agron.* [*Jour. Expt. Landw.*], *4* (*1903*), *No. 4, pp. 389–399*).—The experiments reported upon were carried out in vessels having 3 zinc walls and 1 of glass, permitting the examination of the root systems from time to time. Each vessel received the same amount of soil and fertilizer, and the humidity was maintained at 27.3 per cent of the dry soil.

The plants used in the experiments were oats, mustard, and flax; and the different vessels were kept throughout the growing season at different temperatures by placing the vessels in zinc boxes sunk in the ground and the temperature regulated

by warm or cool water. In one series a temperature of 6 to 8° C. was maintained; in the second 12 to 17° C., and in the third 26 to 30° C. The development of the plants proceeded normally. All the vessels were kept in the open air from May 29 to the end of September.

A tabulated report is given of the growth of the different plants, in which it appears that the mustard made the greatest growth at the highest soil temperature, the oats at the medium temperature, and flax at the lowest. The smallest production of the different plants was in the inverse order of the maximum. In regard to the underground development, the weight of the roots of all the plants was found to be greatest in the coolest soil. This was particularly noticeable in the case of the oats. The weight of the roots of the oats in the cooled soil was 21.87 gm., as compared with 14.98 gm. in the warmest, and 17.27 gm. in the medium temperature. From this it is concluded that a soil temperature of from 6 to 9° is the best for the development of the roots of oats.—P. FIREMAN.

The influence of colored glass on the red and yellow pigments in plants, E. LAURENT (*Rev. Hort. Belge, 28 (1902), No. 11, p. 243; abs. in Jour. Roy. Hort. Soc. [London], 28 (1903), No. 1–2, p. 244*).—Experiments are reported with *Telanthera versicolor* of a pronounced red foliage in frames with red and blue glass. None of the glasses was monochromatic. Under the red and blue glass the leaves all became green, and after a month's interval the leaves produced were smaller than normal. A variety of Coleus, with large leaves, green at the base and reddish-violet toward the tips, bore normal leaves under clear glass, but under the red and blue glass the leaves were diminished and the colored parts became more and more reduced, while the flowers were green. Similar results were obtained with a number of other plants. A zonal pelargonium became entirely green under the red and blue glass.

The results of the experiments show that a brilliant light favors high coloration of foliage, as can be shown in purple-leaved trees, the coloring matter of the leaves being dependent upon their assimilation. Trees and shrubs with golden leaves when poorly illuminated became green. Red glass induced etiolation in some species, and under the blue glass the stems of many were decidedly shortened. These experiments are said to show that the yellow pigment of the foliage is a product of assimilation.

The influence of Aspergillus niger on the transformation of the albuminoids in peas, I. S. KOSYACHENKO (*Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 4, pp. 439–449*).—Since 1896 the hygienic laboratory of the Kharkov Veterinary Institute has conducted investigations relative to the transformation of the nitrogenous substances in various fodder products which were infested with molds. These investigations have shown that, in the development of molds on grain products containing in their composition more than 10 per cent proteid substances, simultaneously with the decrease of the total quantity of nitrogenous substances there is a decrease of the true albuminoid substances.

A quantitative analysis of the products of decomposition under the influence of molds was made, the studies being carried on with ground peas subjected for 64 days to cultures of *Aspergillus niger*. The products of the decomposition of the proteid substance of the peas under the influence of pure cultures of the fungus were found to be tyrosin and leucin, and various hexose bases such as arginin, lysin, etc.—P. FIREMAN.

The physiological principles of plant culture, C. KRAUS (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), Nos. 5, pp. 180–200; 6, pp. 220–236; 7, pp. 268–279; 9, pp. 342–367*).—A discussion is given of the principles of plant growth, breeding, and improvement as illustrated with beets.

Poisoning by Lepiota morgani, F. L. STEVENS (*Jour. Mycol., 9 (1903), No. 68, pp. 220–222*).—An account is given of the injurious effect on the author of this mushroom, which is frequently considered as edible. The symptoms produced by the

eating of a small portion of a freshly picked specimen are described at some length.

The conservation and cultivation of medicinal plants, H. KRAEMER (*Amer. Jour. Pharm., 75 (1903), No. 12, pp. 553–569*).—Classifications are given of plants yielding drugs and it is shown that about three-fourths of all the medicinal plants are either growing wild or in cultivation in this country. Of the remaining one-fourth probably one-half could be grown in this country, leaving but a comparatively small number of plants that could not be economically grown.

METEOROLOGY—CLIMATOLOGY.

Meteorological observations, J. E. OSTRANDER and F. F. HENSHAW (*Massachusetts Sta. Met. Buls. 178, 179, 180, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during October, November, and December, 1903. The general character of the weather of each month is briefly discussed and the December bulletin gives a summary for the year. The principal data in this summary are as follows:

Pressure [a] (inches).—Maximum, 30.70, November 21; minimum, 28.93, February 17; mean, 29.996. *Air temperature* [b] (degrees F.).—Maximum, 97, July 9; minimum, −12, January 20; mean, 46.7; mean sensible (wet bulb), 43; maximum daily range, 45, February 21, March 14, May 12; minimum daily range, 3.5, June 15, October 11; mean daily range, 21.7. *Humidity.*—Mean dewpoint, 37.6; mean relative humidity, 73.5. *Precipitation.*—Total rainfall or melted snow, 45.45 in.; number of days on which 0.01 in. or more rain or melted snow fell, 116; total snowfall, 33.5 in. *Weather.*—Total cloudiness recorded by sun thermometer, 2,328 hours, or 52 per cent; number of clear days, 119; number of fair days, 98; number of cloudy days, 148. *Bright sunshine.*—Number of hours recorded, 2,126, or 48 per cent. *Wind.*—Prevailing direction, west southwest; total movement, 46,256 miles; maximum daily movement, 402 miles, April 17; minimum daily movement, 4 miles, August 27; mean daily movement, 126.7 miles; maximum pressure per square foot, 22 lbs., February 12, W. *Dates of frost.*—Last, May 2; first, September 25. *Dates of snow.*—Last, April 4; first, October 26.

Central meteorological observatory of Mexico, M. E. PASTRANA (*Bol. Sec. Fomento [Mexico], 2. ser., 3 (1903), No. 6, IV, pp. 99–126, pls. 3, dgm. 1*).—A report on meteorological observations during the months of July, August, and September, 1902.

Meteorology of Tunis, G. GINESTOUS (*Bul. Dir. Agr. et Com. [Tunis], 8 (1903), No. 29, pp. 519–532*).—A detailed summary is given of observations during the summer (June, July, and August) of 1903 at 42 different places in Tunis on pressure, temperature, rainfall, humidity, cloudiness, direction of the wind, and miscellaneous phenomena. The average temperature for the summer of 1903 is compared with that of previous years, in some cases extending as far back as 1885.

Meteorology of British Guiana, J. B. HARRISON (*Rpt. Agr. Work Bot. Gard. [British Guiana], 1902–3, pp. 3–5*).—A record is given of the rainfall and duration of sunshine at the government laboratory, Georgetown, during the 18 months ended June 30, 1903. The record includes not only measurements of the rainfall, but its contents of chlorin and of nitrogen in the form of ammonia and nitric acid. The rain which fell during the period referred to contained 244 lbs. of chlorin, equal to 402 lbs. of common salt per acre, and 4.67 lbs. of combined nitrogen, equivalent to 22 lbs. of ammonium sulphate. For the year ended June 30, 1903, the figures were 3.1 lbs. combined nitrogen and chlorin, equivalent to 205 lbs. of common salt per acre. The total rainfall for the same period was 98.9 in.

Meteorological observations in Rhodesia, G. DUTHIE (*Rpts. Administr. Rhodesia, 1900–1902, App., pp. 103–124*).—A summary is given of observations on atmos-

[a] Reduced to freezing and sea level. [b] In ground shelter.

pheric pressure, temperature, rainfall, and direction of the wind during 1900–1902 at a number of places in different parts of Rhodesia.

Weather conditions of South Australia, A. J. PERKINS (*Rpt. Min. Agr. South Australia, 1903, pp. 5, 6*).—A tabular summary is given which shows the distribution of rainfall over the agricultural districts of South Australia during 1902 as compared with previously recorded means.

Normals of the air pressure reduced to 32° F. and constant gravity, latitude 45, J. ELIOT (*Indian Met. Memoirs, 16 (1903), pt. 1; rev. in Science, n. ser., 19 (1904), No. 472, pp. 115, 116*).—"The memoir includes the monthly and annual means of the barometric observations at all observatories in India which have been in operation at least 20 years. At most of the observatories the observations date from 1875, when the department was 'imperialized.'

"In June, 1878, the government of India sanctioned arrangements for the publication of a daily weather report, which included observations made at 10 a. m. at about 100 stations. The hour was later changed to 8 a. m. It is to be noted that certain persistent discrepancies appear when the observations, after reduction to sea level, are compared, the most noteworthy cases being those of stations which are more or less completely shut in by hills of considerable elevation. The result of this condition is to check somewhat the horizontal movement of the air and to give too high a pressure during the morning. At the three stations where this topographic effect is most marked the excess of pressure averages about 0.02 in. at 8 a. m."

Studies on the meteorological effects in the United States of the solar and terrestrial physical processes, F. H. BIGELOW (*U. S. Dept. Agr., Weather Bureau Doc. 290, pp. 37, figs. 13, charts 24*).—This includes the following papers reprinted from Monthly Weather Review for December, 1902, and January and February, 1903: The semidiurnal periods in the earth's atmosphere, synchronous changes in the solar and terrestrial atmosphere, the structure of cyclones and anticyclones on the 3,500-foot and 10,000-foot planes for the United States, and the mechanism of counter currents of different temperatures in cyclones and anticyclones.

Hurricanes: Especially those of Porto Rico and St. Kitts, W. H. ALEXANDER (*U. S. Dept. Agr., Weather Bureau Bul. 32, pp. 79, figs. 7*).

Weather changes and the appearance of scum on ponds, H. R. MILL, W. RAMSDEN, and F. J. HILLIG (*Nature [London], 69 (1903), Nos. 1775, p. 7; 1779, p. 104; 1780, p. 127*).—These articles note the occurrence of scum on ponds preceding any decided change of weather and offer various explanations of this phenomenon, the most plausible being that the formation of the scum is due to the rise of marsh gas from the ooze at the bottom of the ponds following a sudden fall in barometric pressure, the gas carrying along with it some of the solid matter of the ooze and thus forming the scum.

Influence of cultural operations on the production of white frost, A. PETIT (*Jour. Soc. Nat. Hort. France, 4. ser., 4 (1903), May, pp. 300–305*).—Observations on the effect of watering (irrigation), pulverizing and compacting the soil, and the application of compost and manure on the temperature of the soil are reported.

It was observed that saturating the soil with water retarded the radiation of heat, saturated soil being 2.6° C. warmer at a depth of 1 cm. and 1.1° to 2.2° warmer at the surface than dry soil the morning after the water was applied. Soil which had been pulverized was about 2° warmer than that which was left in a cloddy condition, and soil which had been first pulverized and then compacted was 4.2° warmer than cloddy soil. Soils with which compost had been incorporated showed at first a higher temperature in the surface soil, but practically the same temperature at a depth of 15 cm. as soil not so treated. The surface temperature, however, was apparently maintained at the expense of that of the lower layers of the soil, and in time the manured soil became colder than the unmanured. It is suggested that if large amounts of fresh and fermenting manure had been used instead of compost the results might have been different.

The influence of coverings of various kinds, including a layer of sand 10 to 12 cm. deep, as proposed by Rimpau, mulches, and living plants is discussed; and observations are reported which show that mulched soil has a lower temperature than unmulched, thus indicating that mulching increases the danger of frost.

Measurement of precipitation, C. F. Marvin (*U. S. Dept. Agr., Weather Bureau Circ. E, Instrument Division, pp. 27, figs. 10*).—The second edition of this pamphlet of instruction for the measurement and registration of precipitation by means of the standard instruments of the U. S. Weather Bureau.

The new cosmical meteorology, F. H. Bigelow (*Science, n. ser., 19 (1904), No. 470, pp. 30–34, figs. 3*).—In this article the attempt is made to present in orderly form the sequence between sun spots and meteorological conditions on the earth.

Weather folklore and local weather signs, E. B. Garriott (*U. S. Dept. Agr., Weather Bureau Bul. 33, pp. 153, charts 21*).—In this bulletin proverbs and sayings relating to wind, clouds, atmospheric pressure, temperature, and moisture, the habits and actions of animals and birds, and to plant life applicable to the United States are briefly quoted and discussed. Finally, a summary illustrated by charts is given of local weather signs as observed at regular stations of the Weather Bureau.

Proceedings of the second convention of Weather Bureau officials held at Milwaukee, Wis., August 27-29, 1901, edited by J. Berry and W. F. R. Phillips (*U. S. Dept. Agr., Weather Bureau Bul. 31, pp. 246, pls. 37, figs. 9*).

WATER—SOILS.

Irrigation experiments in 1901, J. A. Widtsoe et al. (*Utah Sta. Bul. 80, pp. 65–199, pls. 9, figs. 5*).—The experiments here reported represent the cooperative work of three departments of the station, and "deal wholly with the proper use of water by the farmer."

The experiments were made on 90 plats 2 by 4 rods and 8 plats 2 by 5 rods in size on the deepest and best land of the college farm, which is situated on typical "bench" land formed by former Lake Bonneville. The soil is underlaid at a variable but usually shallow depth by coarse limestone gravel, which secures perfect drainage, but increases the difficulty of thorough irrigation. Physical and chemical analyses of the first, second, and third feet of the soil are reported, and the specific gravity and water-holding capacity were determined. Data relating to temperature, sunshine, humidity, rainfall, and evaporation during the irrigating season are also given, as well as the temperature and composition of the irrigation water used.

The water was very constant in composition during the irrigating season. "Nitrogen was absent; phosphoric acid and potash were present only in small quantities. The fertilizing value of the water was therefore very small." The temperature varied from 54° F. in June and September to 60° in July and 62° in August. "All the water used on the plats was measured by means of a very carefully constructed Cippoletti weir" and a self-recording water meter. "The water was distributed entirely in small wooden flumes. One main flume passes across the whole system of plats, and lateral branches supply the different belts on either side of the main line." The construction of these flumes and their use in distributing the water are described in detail.

In the experiments reported an attempt was made to follow in considerable detail the downward and lateral movement of the water applied to the soil, by means of moisture determinations in samples of soil from different locations and depths and at different times; and to study the influence of irrigation on the growth, yield, and composition of crops, including, corn, oats, wheat, potatoes, sugar beets, alfalfa, red clover, timothy, and English rye grass. The results, which it is pointed out apply primarily to shallow bench lands, are summarized as follows:

"At the time of the first irrigation wheat and oats had drained the soil more completely of its moisture than had corn, potatoes, or sugar beets. Perennials use less water in early spring than do annuals.

"The amount of water held by the soil decreases with the depth.

"Only about 60 per cent to 75 per cent of the maximum water capacity of the soil is utilized one day after irrigation.

"The lateral movement of water in the soil of the college farm is about $4\frac{1}{2}$ ft. for the first foot; 6 ft. for the second foot. On soils like those of the college farm the lateral movement of the soil water is of little consequence to the farmer.

"The loss of the soil moisture is greatest from soil which has received most water, and is in direct proportion to the percentage of moisture in the soil immediately after irrigation. Of 2 soils having the same percentage of moisture, the deeper soil loses most moisture. The longer the time that elapses after an irrigation the more water is lost. About one-half of the water added in an irrigation is evaporated during the first week. All tillage, having in view the conservation of soil moisture, should [therefore] be put into operation as soon as possible after irrigation.

"The effect on the soil moisture in changing the relative humidity a few degrees is very slight. Sunshine is a strong factor in causing a loss of soil moisture. Of the 3 factors, relative humidity, sunshine, and temperature, the last is most potent in causing a loss of soil moisture. Winds cause a large loss of soil moisture.

"The rate of loss of soil moisture depends upon the kind of crop. The order, beginning with the most wasteful, is the following: Potatoes, oats, wheat, corn, sugar beets, old lucern, red clover, timothy, and English rye grass.

"The soil moisture is taken nearly at the same rate from the different depths, though the upper soil layer dries out first. The extent to which soils can dry out was 2.13 per cent for the first 3 in., 3.72 per cent for the first foot, and 4.63 per cent for the second. More water is lost from the furrow than from the row, though the soil under the row is quite moist.

"The percentage of water in plants and in the ripe seeds increases slightly with increase in irrigation. Heavy irrigations increase the percentage weight of the heads of plants; light irrigations increase the relative weight of leaves. Irrigation modifies definitely the composition of plants and plant parts; the seeds are affected more than any other plant part. The percentage of protein in corn kernels was increased from 12.05 to 15.08 as the amount of irrigation decreased, in oat kernels from 14.07 to 20.79, in wheat kernels from 15.26 to 26.72. In all these seeds the fat and nitrogen-free extracts were increased by liberal waterings. Increased irrigation increased the starch content and decreased the protein content of potatoes. The composition of sugar beets seemed to be less strongly affected by irrigation than were other crops. Between 20 and 25 in. of water yielded beets with the highest sugar content. The water in plants is somewhat dependent on the water in the soil.

"With a given amount of water, better yields of corn were obtained by flooding than by furrowing. Late irrigation did not affect unfavorably the growth and yield of corn. The proportion of ear corn to stover increased regularly with the increased application of water. The best amount of water for corn lies between 20 and 25 in.

"Late irrigations were found very beneficial in transferring nutritive materials from oat stalks to the heads. Not less than 15 in. of water should be used for oats, and not more than 30.

"Late irrigation was beneficial for the wheat crop. The percentage of grain in the wheat crop increased with increased irrigations. The yield of wheat increased up to 30 in. of water.

"Frequent small irrigations of potatoes produced the best yields. The percentage of marketable potatoes increased with irrigation.

"The best amount of water for sugar beets is about 20 in.

"Crops in an arid district require a greater number of pounds of water for 1 lb. of dry matter than in humid climates.

"Water has a varying value. The first few inches possess a much higher value than the later ones; and the value continues to decrease as the amount of water increases. By following the indications of the varying value of water it is possible that the irrigated area may be increased one-third or more with the amount of water now used."

The influence of soil moisture upon the chemical composition of certain plant parts, J. A. Widtsoe (*Jour. Amer. Chem. Soc., 25 (1903), No. 12, pp. 1234–1243*).—This is a brief discussion based on data reported in a recent bulletin of the Utah Station (see above) of results of a series of experiments with amounts of water varying from 5 to 40 in., applied to corn, oats, wheat, potatoes, and sugar beets on a shallow bench soil underlaid with coarse gravel. Chemical and physical analyses of the soil and analyses of the grains and tubers produced are reported, and the relation of the composition of the latter to the amounts of water used in irrigating the crops is discussed.

It is shown that the chemical composition of plants and plant parts is strongly influenced by the amount of soil moisture, the protein and nitrogen-free extract being affected to a greater extent than the other constituents. Withholding water from the plant increased the percentage of protein and diminished the percentages of nitrogen-free extract and fat, and vice versa. The variations in composition of crop brought about by varying amounts of water applied is shown in the following table:

Difference between highest and lowest percentages due to varying soil moisture.

Substance.	Protein.	Fat.	Nitrogen-free extract.	Starch.
Corn kernels	2.56	0.90	2.33	....
Oat kernels	5.31	.68	1.69	....
Wheat kernels	11.46	1.78	12.43	....
Potatoes	4.24	....	5.70	6.93
Sugar beets	4.88	....	5.05	....

Irrigation waters and their effects, W. P. Headden (*Colorado Sta. Bul. 83, pp. 16*).—A brief popular bulletin presenting some of the conclusions drawn from investigations reported in detail in a previous bulletin of the station (E. S. R., 15, p. 454).

Water used for drinking and similar purposes (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 22, pp. 1040–1059*).—This is a series of brief abstracts of and references to 60 recent articles relating to this subject.

The judging of drinking water from the standpoint of the physiology and hygiene of domestic animals, T. Kasparek (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 11, pp. 753–764*).—A general discussion of this subject is given, with some observations on the behavior of various pathogenic germs under different culture conditions.

The present status of soil investigation, C. G. Hopkins (*Illinois Sta. Circ. 72, pp. 21, figs. 6*).—This is the address of the chairman of the section on agriculture and chemistry of the Association of American Agricultural Colleges and Experiment Stations, at Washington, D. C., November 17, 1903 (E. S. R., 15, p. 329), with an introductory statement by E. Davenport and an added note by the author on methods. The paper calls attention to the discrepancies in the conclusions drawn by prominent investigators from studies in soil fertility, dealing more particularly with the methods and conclusions presented in Bulletin 22 of the Bureau of Soils of this Department. Basing his statements mainly upon his own work on soil fertility, the author dissents from many of the conclusions stated in this bulletin.

Field operations of the Bureau of Soils, 1902 (fourth report), M. WHITNEY ET AL. (*U. S. Dept. Agr., Field Operations of the Bureau of Soils, 1902, pp. 842, pls. 60, figs. 25, maps 44*).—This report contains a general review of the work of the Bureau of Soils during 1902 by the Chief of the Bureau, together with the following accounts of surveys: Soil Survey of the Bigflats Area, New York, by L. Mesmer and W. E. Hearn; Soil Survey of the Lyons Area, New York, by W. E. Hearn; Soil Survey of the Trenton Area, New Jersey, by R. T. A. Burke and H. J. Wilder; Soil Survey of the Albemarle Area, Virginia, by C. N. Mooney and F. E. Bonsteel; Soil Survey of the Hickory Area, North Carolina, by T. A. Caine; Soil Survey of the Mount Mitchell Area, North Carolina, by T. A. Caine and A. W. Mangum; Soil Survey of the Abbeville Area, South Carolina, by F. W. Taylor and T. D. Rice; Soil Survey of the Darlington Area, South Carolina, by T. D. Rice and F. W. Taylor; Soil Survey of Perry County, Alabama, by R. T. A. Burke et al.; Soil Survey of the Smedes Area, Mississippi, by W. G. Smith and W. T. Carter, jr.; Soil Survey of the Brazoria Area, Texas, by F. Bennett, jr., and G. B. Jones; Soil Survey of the Vernon Area, Texas, by J. E. Lapham et al.; Soil Survey of the Toledo Area, Ohio, by W. G. Smith; Soil Survey of the Columbus Area, Ohio, by W. G. Smith; Soil Survey of Union County, Kentucky, by H. W. Marean; Soil Survey of Posey County, Indiana, by H. W. Marean; Soil Survey of Tazewell County, Illinois, by J. A. Bonsteel et al.; Soil Survey of Clinton County, Illinois, by J. A. Bonsteel et al.; Soil Survey of St. Clair County, Illinois, by G. N. Coffey et al.; Soil Survey of Clay County, Illinois, by G. N. Coffey et al.; Soil Survey of the Janesville Area, Wisconsin, by J. A. Bonsteel; Soil Survey of the Dubuque Area, Iowa, by E. O. Fippin; Soil Survey of Howell County, Missouri, by E. O. Fippin and J. L. Burgess; Soil Survey of the Stuttgart Area, Arkansas, by J. E. Lapham; Soil Survey of the Wichita Area, Kansas, by J. E. Lapham and B. A. Olshausen; Soil Survey of the Grand Forks Area, North Dakota, by C. A. Jensen and N. P. Neill; Soil Survey of the Billings Area, Montana, by C. A. Jensen and N. P. Neill; Soil Survey of the Lewiston Area, Idaho, by L. Mesmer; Soil Survey of the Walla Walla Area, Washington, by J. G. Holmes; Soil Survey of the Lower Arkansas Valley, Colorado, by M. H. Lapham et al.; Soil Survey of the Yuma Area, Arizona, by J. G. Holmes; Soil Survey from Arecibo to Ponce, Porto Rico, by C. W. Dorsey, L. Mesmer, and T. A. Caine.

During the field season of 1902, 17,996 square miles or 11,517,440 acres were surveyed and mapped on a scale of 1 in. to the mile. Prior to that year the total area surveyed and mapped was 15,871 square miles or 10,157,440 acres. The average cost of the work in 1902 was $1.93 per square mile. The accounts of the individual surveys include, as heretofore, data relating to the location, history, topography, physiography, geology, climate, agricultural conditions, type soils, and crop adaptations.

Soil survey from Arecibo to Ponce, Porto Rico, C. W. DORSEY, L. MESMER, and T. A. CAINE (*Porto Rico Sta. Bul. 3, pp. 53, pls. 4, fig. 1, map 1*).—This bulletin, of which there are both English and Spanish editions, is a reprint from Report of Field Operations of the Bureau of Soils of this Department for 1902 (see above). The area reported upon extends 5 miles each side of the proposed government road from Arecibo to Ponce, and embraces many types of soil which are represented in other parts of the island. The report deals with location and boundaries of the area, history of settlement and agricultural development, climate, physiography and geology, water supply for irrigation, underground water and drainage, alkali in soils, and agricultural methods and conditions, and maps, and gives results of detailed surveys, including notes on crop adaptations of 18 type soils found in the area.

Washington soils, E. FULMER (*Washington Sta. Bul. 55, pp. 32*).—Chemical analyses of 25 soils from eastern Washington and 54 from western Washington, made by the same methods and with the same object in view as in previous investigations (E. S. R., 7, p. 375), are reported. The results confirm the conclusions drawn from the earlier analyses.

"The soils of the western, central, and eastern portions of the State show marked differences in their percentages of potash and lime. The potash content is generally greatest in the eastern part, and least in the western, while in the central portion the amount is intermediate. The lime content is greatest in the central part, where the minimum amount of rain falls. It is least in the western part, especially in those portions where the rainfall is 40 in. or more. An intermediate amount is found in that portion where the rainfall varies from 18 to 30 in.

"In many of the samples here reported, the amount of soda exceeds that of potash. This is unusual (except in alkali soils) and is doubtless due to the basaltic origin of the soil, and to the climatic conditions attending the soil-forming period."

The fertilizers likely to give best results on the different soils are indicated.

Ground temperature observations at Manila, 1896–1902, J. ALGUÉ (*Manila, 1902, pp. 16, pls. 3*).—A record is here given of a long series of observations on soil temperatures at depths varying from 9.84 to 59.06 in. From the data which are given in tables and diagrams the following conclusions are drawn:

In the cool season the soil temperature at a depth of half a meter is lower than the air temperature, and at 1 meter oscillates around the maximum temperature of the air. On warm days the temperature below 19.68 in. ranges higher than the air temperature, but at 1 meter also oscillates around the highest temperature at the surface. The temperature at 39.38 in. remains stationary from sunset to sunrise, and 19.68 in. from midnight to sunrise. The maximum temperature was observed at 10 a. m., both at 39.38 and at 19.68 in., from 6 a. m. at both depths. "Changes become more accentuated at 19.68 in., the rise of temperature being very remarkable after 6 a. m. This may clearly explain why at 8 a. m. underground temperature at 19.68 in. is constantly higher than the air temperature, even during the cool season. Underground temperature is lower during the warmest hours above the ground." The relation of soil temperatures to sickness and disease is discussed.

The alkalinity of soils and its effect on the growth of cereals, V. PEGLION (*Staz. Sper. Agr. Ital., 36 (1903), No. 8–9, pp. 684–694*).—The results of observations on this subject by the author and others are summarized.

Are soluble iodids absorbed by the soil? S. SUZUKI (*Bul. Col. Agr. Tokyo Imp. Univ., 5 (1903), No. 4, pp. 519–521*).—Tests are reported which show that an iodid is more quickly and completely absorbed by the soil than a chlorid.

Guide to the scientific study of soils, F. WAHNSCHAFFE (*Anleitung zur wissenschaftlichen Bodenuntersuchung. Berlin: Paul Parey, 1903, pp. 190, figs. 54*).—The second revised edition of this well-known work.

FERTILIZERS.

The fertilizer value of various nitrogenous fertilizers, with especial reference to green manure and barnyard manure, A. VON 'SIGMOND (*Landw. Vers. Stat., 59 (1903), No. 3–4, pp. 179–215*).—Three series of pot experiments carried out during 1900 and 1901 are reported. The pots used were of glazed clay 30 cm. deep and having a surface area of 410 sq. cm. The soil used was a calcareous sand poor in nitrogen. The fertilizers used were nitrate of soda, sulphate of ammonia, horn meal, dried blood, dried pig manure, fresh and well-rotted barnyard manure, and green manures of various kinds. These were applied in amounts furnishing about 135 kg. of nitrogen per hectare (120.49 lbs. per acre). The crops grown in the different experiments included barley, *Viehkraut*, white mustard, summer rape, and buckwheat. The influence of the fertilizers was studied on 2 successive crops, the fertilizers being applied only to the first.

Detailed data are given for the yields and nitrogen content of the crops, and from

these data the utilization of the nitrogen of the various fertilizers during the first and second year is calculated. The results are summarized in the following table:

Utilization of nitrogen in various fertilizers.

Kind of nitrogenous fertilizer.	In the first year.			In both years.	
	First series.	Second series.	Third series.	First series.	Second series.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Nitrate of soda	71	45.0	77	71	53
Sulphate of ammonia	62	41.0	60	67	46
Horn meal	68	38.0	61	67	46
Dried blood	56	22.0	40	59	27
Liquid manure	53	19.0	24	54	26
Dry pig manure	44	19.0	31	52	27
Green vetches turned under in the fall	44	35.0	50	50	45
Alfalfa hay turned under in the fall	39	25.0	30	41	32
Alfalfa hay turned under in the spring	....	29.0	50	....	33
Well-rotted barnyard manure applied in the fall	26	14.0	19	41	22
Fresh barnyard manure applied in the spring	31	4.5	20	35	18
Fresh barnyard manure applied in the fall	29	16.0	16	34	28
Well-rotted barnyard manure applied in the spring	16	1.0	10	30	7

The relative effectiveness of the different fertilizers as compared with nitrate of soda is shown in the following table:

Relative effectiveness of different nitrogenous fertilizers, taking nitrate of soda as 100.

Kind of nitrogenous fertilizer.	First series of experiments.	Second series of experiments.	Average.		
	Per cent.	*Per cent.*	*Per cent.*		
Sulphate of ammonia	94	87	90		
Horn meal	94	87	90

Well-rotted barnyard manure applied in the spring	42	(13)	42(27)		

The methods of exact field manurial trials (*Jour. Bd. Agr.* [*London*], *10* (*1903*), *No. 2, pp. 220–225*).—This is a summary of Wagner's views regarding the principles which should be borne in mind in conducting field experiments with fertilizers. The main factors upon which emphasis is laid are uniformity of soil; the use of numerous control plats; the employment of accurately laid out, square, fortieth-acre plats; the careful preparation, measurement, weighing, and application of fertilizers; and the weighing and sampling of the crop on the plats as soon as harvested.

The fermentation of boengkil, H. A. C. VAN DER JAGT (*Meded. Proefstat. Suikerriet West Java, 1903, No. 66, pp. 25; reprint from Arch. Java Suikerind, 1903, No. 17*).—Boengkil is a fertilizer made from peanut-oil cake. This material, when piled in large heaps, ferments and the heat has been known to cause spontaneous combustion. Since the rise in temperature may be prevented by the addition of chloroform or carbolic acid, the author concludes that it is due to micro-organisms. The addition of water to the boengkil was found to be necessary to start fermentation. It is explained that the water brings some of the material into solution and thus enables the organisms not only to multiply rapidly, but also to make use of those portions of the food material not already in solution.

It is further shown that the fermentation is due to aerobic organisms, since exclusion of air prevents a rise in temperature.

Attempts to cause spontaneous combustion failed, the author being unable to secure a temperature above 55° C. He thinks that for spontaneous combustion to occur the boengkil must be in large masses.

A study of the losses due to fermentation gave the following results for each of the principal constituents:

Losses due to fermentation of boengkil.

	Nitrogen.	Fat.	Pentosans.	Dry matter.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*
Sample 1	9.55	80.30	16.56	22.14
Sample 2	18.11	79.12	31.48	31.53

Sample 4	24.62	50.40	36.86	38.69

—H. M. PIETERS.

The management and use of barnyard manure, A. STUTZER (*Die Behandlung und Anwendung des Stalldüngers. Berlin: Paul Parey, 1903, 2. ed., enl., pp. VIII+168, figs. 19*).—This is a second enlarged edition of the author's treatise on the work of bacteria in barnyard manure, and discusses in detail the action of bacteria in manure and in soils, the production and management of barnyard manure, and the action of the manure when applied to the soil in various ways and for various crops. A list of 102 references to literature on the subject is given.

On green manuring light land, T. S. DYMOND and B. W. BULL (*Essex County Council, Education Com., Tech. Labs., 1903, Oct., pp. 28, 29*).—A brief account is given of a comparison on wheat and oats of plowing under mustard and pasturing it off by sheep. The results are slightly in favor of pasturing off the crop.

Manures in the Natal market, season 1903, A. PARDY (*Natal Dept. Agr. Bul. 4, pp. 12*).—Analyses are reported with general discussion.

The menhaden industry (*Amer. Fert., 19 (1903), No. 6, pp. 7–14*).—The nature and habits of the menhaden and the methods of catching the fish are described. The uses made of the fish and the methods of treatment for preparation of oil and fertilizer are explained. Analyses of samples of fish scrap are reported, and the fertilizing value of the material is discussed. The names of a number of firms which prepare fish fertilizers are given.

Atmospheric nitrogen for fertilizing purposes, F. H. MASON (*U. S. Consular Rpts., 74 (1904), No. 280, pp. 36, 37*).—A brief note referring to the preparation of calcium cyanamid and its value as a fertilizer (E. S. R., 15, pp. 25, 347, 423).

Fertilizers and amendments for soils deficient in lime, T. BIÉLER (*Chron. Agr. Canton Vaud, 17 (1904), No. 1, pp. 1–14*).—Simple methods of determining the lime content of soils are described, and means of supplying deficiencies of this constituent are briefly discussed.

The mineral industry: Its statistics, technology, and trade for 1902 (*New York and London: Engineer. and Min. Jour., 1903, vol. 11, pp. XXX+891, figs. 123*).—This, the eleventh annual volume of this series of reports, gives the usual summary of statistics, with special articles by different authors relating to the mineral industry in the United States and other countries, prepared under the editorship of J. Struthers. Among the subjects treated which are of special agricultural importance are ammonia and ammonium sulphate, cement, clay, gypsum, phosphate rock, potassium salts, common salt and other sodium salts, and stone.

"The production of ammonia (reported as its equivalent sulphate salt) and ammonium sulphate by by-product coke-oven plants in the United States during 1902 is estimated at 65,000 metric tons, and for 1901 at 60,000 metric tons, which

shows the active development of this industry, due chiefly to the increase in the number of by-product coke ovens now in operation." The world's production of ammonium sulphate during 1902 is stated to be 548,500 metric tons, and the imports into the United States 16,119 tons.

The production of cement in the United States during 1902 was as follows: "Portland cement, 16,535,000 bbls. (of 400 lbs.), valued at $16,637,500, as compared with 12,711,225 bbls., valued at $12,532,360, in 1901; natural hydraulic cement, 9,083,759 bbls. (of 300 lbs.), valued at $4,087,692, as compared with 7,084,823 bbls., valued at $3,056,278, in 1901, and slag cement, 547,175 bbls. (of 400 lbs.), valued at $465,099, as compared with 272,689 bbls., valued at $198,151, in 1901. . . .

' The production of clay products in the United States during 1901 increased considerably over the output of the preceding year, the aggregate value being $87,747,727, as compared with $78,704,678 in 1900. . . .

"The production of gypsum in the United States continued to increase greatly during 1902, although statistics of production during this year are not now available. The production during 1901 was 659,659 short tons, valued at $1,577,493. . . .

"The production of all varieties of phosphate rock in the United States during 1902 amounted to 1,464,668 long tons, valued at $4,636,516, as compared with 1,483,723 long tons, valued at $5,316,403, which shows a decrease of 38,955 long tons in quantity and $679,887 in value from the statistics of the earlier year."

Of the output for 1902, South Carolina supplied 313,365 tons, Florida 759,784, North Carolina 25,000, Tennessee 390,799, other States 720 tons.

"The imports of potassium salts into the United States in 1902 were as follows: Potassium chlorid, 140,980,460 lbs. ($2,141,553); crude potassium nitrate, 10,505,474 lbs. ($299,416); potassium chlorate, $1,209,148 lbs. ($60,429); all other potassium salts, 92,857,009 lbs. ($1,820,585); a total of 245,552,091 lbs., valued at $4,321,983, as compared with a total of 231,146,770 lbs., valued at $4,268,067 in 1901. The exports of domestic potash and pearl ash in 1902 were 1,408,342 lbs., valued at $66,027, as compared with 1,077,605 lbs., valued at $52,802 in 1901. The exports of foreign potassium salts in 1902, consisting of potassium chlorid, chlorate, nitrate, and other salts, aggregated 1,266,125 lbs., valued at $59,789, as compared with 633,100 lbs., valued at $43,446 in 1901."

The world's supply of potash still comes in the main from the great natural deposits of Germany, but explorations in Death Valley and elsewhere in the United States for natural deposits of potash salts are being made with some promise of success.

"The total production of salt in the United States during 1902, including that used for the manufacture of alkali and heavy chemicals, amounted to 23,849,221 bbls., valued at $5,668,636, as compared with 20,566,661 bbls., valued at $6,617,449 in 1901." The leading salt-producing States in the order of percentage of output during 1902 were as follows: Michigan 34.1 per cent, New York 35.8 per cent, Kansas 9.1 per cent, and Ohio 8.9 per cent.

"The production of soda and sodium salts [including soda ash, bicarbonate, and crystals] in the United States for the year 1902 is estimated at 562,000 metric tons, as compared with 480,000 metric tons for the year 1901."

While extensive beds of nitrate of soda are being exploited in northern San Bernardino County, Cal., most of this salt used in the United States is imported from abroad and comes from Chile. The import of nitrate into the United States in 1902 was 330,674.4 short tons, valued at $5,996,205, as compared with 233,692.5 tons, valued at $5,997,595 the previous year (see also E. S. R., 15, p. 131).

The value of the stone produced in the United States during 1901 was $55,488,137,

against $45,066,708 in 1900, not including slate and the sandstone used in the manufacture of grindstones and whetstones.

The potash deposit in the Werra district, C. BAUER (*Chem. Ztg., 27* (*1903*), *No. 88, pp. 1085, 1086*).—The deposit is briefly described and the composition of the various salts found in it is given.

The conversion of hartsalzs and mixed crude potash salts into potassium chlorid, C. BAUER (*Chem. Ztg., 27* (*1903*), *No. 104, pp. 1268–1270*).

Commercial fertilizers, E. H. JENKINS ET AL. (*Connecticut State Sta. Rpt. 1903, pt. 1, pp. 112*).—This includes a statement of the duties of manufacturers and dealers and of the experiment station in connection with the inspection under the State fertilizer law; a list of firms licensed to deal in fertilizers in the State during 1903; notes on the methods followed in sampling and collecting fertilizers; explanations regarding the analysis and valuation of fertilizer; a review of the fertilizer market for the year ended October 31, 1903; and tabulated analyses and valuations of 489 samples of fertilizing materials, including nitrate of potash, nitrate of soda, sulphate of ammonia, dried blood, cotton-seed meal, castor pomace, dissolved rock phosphate, carbonate of potash, sulphate of potash, double sulphate of potash and magnesia, muriate of potash, kainit, bone manures, slaughterhouse tankage, dry ground fish, bone and potash, nitrogenous superphosphates and guanos, tobacco stems, vegetable ashes, ashes of tobacco stalks, cotton-hull ashes, wood ashes, limekiln ashes, oyster-shell lime, sheep manure, garbage tankage, cocoanut pith, and mixed fertilizers.

Analyses of commercial fertilizers, M. A. SCOVELL and H. E. CURTIS (*Kentucky Sta. Bul. 109, pp. 117–191*).—"There were 331 different brands of commercial fertilizers registered from January 1 to August 22, 1903. Of these different brands 192 were complete fertilizers, or fertilizers containing all three of the essential ingredients, namely, phosphoric acid, nitrogen, and potash; 33 were acid phosphates, or superphosphates; 10 contained a mixture of acid phosphates and nitrogen compounds only; 44, acid phosphate and potash salts only; and 52 were classed as bones or tankage.

"Two hundred and sixty-seven samples were collected by deputy inspectors, or were sent by farmers from various parts of the State. Three hundred and thirty-one samples were those sent in by firms as official samples. Of these samples 519 were analyzed by the station.

"The results of the analyses show that of the 519 samples analyzed, 89, representing 79 brands and 29 firms, fell so far below the guaranteed analyses in phosphoric acid, nitrogen, or potash, or any two, or all three of these ingredients, that the deficiencies could not be accounted for by variations in sampling or analysis. It is probable that in most cases variations can be accounted for by hurried or careless mixing at the factories, or gross mistakes in shipping one brand for another, but in one or two instances the results show a desire on the part of the manufacturer to guarantee a higher percentage of the essential ingredients than the goods contain."

Analyses of commercial fertilizers and manurial substances, C. A. GOESSMANN (*Massachusetts Sta. Bul. 92, pp. 36*).—A report of analyses of 324 samples of fertilizing materials, including wood ashes, lime ashes, cotton waste, bone dust, wool waste, mill refuse, dried blood, peat, cotton-seed meal, manure, Peruvian guano, Belgian phosphates, soils, and mixed fertilizers. A scale of prices for 1903 is given.

Commercial fertilizers, H. J. WHEELER ET AL. (*Rhode Island Sta. Buls. 93, pp. 131–147; 97, pp. 47–60*).—These bulletins report analyses and valuations of 117 samples of fertilizing materials inspected during 1903. The fertilizers sold in the State during the year were found "to correspond more nearly with the guaranties than in any one of the past 5 years."

FIELD CROPS.

Cooperative field experiments, 1902 (*Jour. Dept. Agr. and Tech. Instr. Ireland, 3 (1903), No. 3, pp. 490–522*).—In a fertilizer test with potatoes, the best yield was obtained on a plat fertilized at the rate of 15 tons of barnyard manure, 1 cwt. of sulphate of ammonia, 4 cwt. of superphosphate, and 1 cwt. of muriate of potash per acre. The results in general indicate that the use of commercial fertilizers with a moderate application of barnyard manure is profitable. The plat receiving 20 tons of barnyard manure per acre yielded 8.9 tons, and the plat receiving only 15 tons produced 8 tons per acre. In a test of varieties Beauty of Bute, Charles Fidler, Up-to-Date, and Dr. Matthew produced the best yields. In another series of cooperative tests Black Skerries and Champion II proved much superior in yield and quality to Reliance.

The results with turnips also indicate that barnyard manure and commercial fertilizers may be profitably used in combination. Ten tons barnyard manure with 4 cwt. of superphosphate gave fully as good returns as 20 tons applied alone. Among 9 varieties of swedes Triumph, Best of All, and Magnum Bonum gave the best yields, and of 5 varieties of yellow turnips Centenary produced the heaviest yield.

In growing fodder beets it was found that an addition of 4 cwt. of superphosphate, 2 cwt. of sulphate of ammonia, and 2 cwt. of kainit to 15 tons of barnyard manure per acre, representing an outlay of 43 shillings for commercial fertilizers, resulted in a profit of 26 shillings. A substitution of 4 cwt. of salt for the kainit in this application gave somewhat contradictory results, but the average yields are in favor of the salt.

It was found that complete applications of commercial fertilizers in growing oats are more likely to give uniformly good results than incomplete applications. Kainit when used alone resulted in a loss. Sulphate of ammonia was the only fertilizer which gave a profit when applied alone. Among the varieties tested in 1900 Waverly, Goldfinder, and Canadian Banner led in productiveness. In a second series of cooperative tests Tartar King gave better satisfaction than Waverly, Goldfinder, and Pioneer. The different varieties of oats are described. A discussion on the use of fertilizers in connection with the different crops based on the results of experiments is presented.

The Essex field experiments, 1896–1903: No. 2.—On tillage crops, T. S. Dymond and B. W. Bull (*Chelmsford, Eng.: Essex Education Committee, 1903, pp. 48, fig. 1, map 1*).—This is a compilation of results of experiments carried out by 15 farmers of Essex. Tabular statements of the data obtained with the various field crops are given, together with brief discussions and summaries of the results.

Winter beans, spring beans, and clover required, in connection with 12 tons of barnyard manure per acre, an application of 3 cwt. of superphosphate. Without barnyard manure 4 cwt. of superphosphate per acre, or the same quantity of basic slag, on soil deficient in lime gave good results. These applications were also most remunerative at the commencement of rotations beginning with beans or clover. One cwt. of sulphate of ammonia in addition to the superphosphate was found advantageous only when the crops were grown for fodder. It has been found that kainit applied with barnyard manure decreases the yield. With peas on clay soil, barnyard manure and sulphate of ammonia had very little effect. Nitrogenous manures are not recommended for leguminous crops when these are to be followed by cereals in rotation. In a rotation of peas, wheat, barley, and clover, barnyard manure for peas, sulphate of ammonia or nitrate of soda for wheat, and superphosphate or basic slag for barley or clover are suggested.

Of 6 varieties of oats, Garton White Abundance led in yield of grain and straw, as well as in weight of grain per bushel. This new variety is considered as having distinct advantages over the older sorts and as being the most profitable for the

region. Nitrate of soda in ordinary seasons is regarded as being the more effective in increasing the yield of grain and straw, but as showing a lesser influence with regard to quality of grain.

On light gravelly land a complete application of commercial fertilizers for cereals was unprofitable, and pasturing a crop of green mustard proved of greater advantage than plowing it under.

Cooperative fertilizer experiments with potash in Alsace-Lorraine, A. Wolf (*Deut. Landw. Presse, 31 (1904), No. 1, pp. 3, 4, figs. 8*).—In these experiments barley, potatoes, and fodder beets were grown on light and heavy soils, and clover on heavy soils only. Each test consisted of a check plat, 1 plat receiving superphosphate or Thomas slag and nitrate of soda, and another receiving, in addition to these, either 40 per cent potash salt or kainit. The clover received no nitrogen. In all the experiments the application of potash resulted in a profit. The most profitable results in the series were obtained from fodder beets on light soil, receiving an application of 450 kg. of superphosphate, 400 kg. of nitrate of soda, and 300 kg. of 40 per cent potash salt per hectare. Potash also gave very profitable results on both kinds of soil when used as a fertilizer for potatoes in combination with nitrate of soda and superphosphate.

Cooperative experiments in top-dressing grass land, H. J. Wheeler (*Rhode Island Sta. Bul. 95, pp. 19*).—Previous work of this character has been noted (E. S. R., 15, p. 32). In 1902 cooperative experiments were conducted on 11 farms, in various sections of the State. The application used as a top-dressing during the latter part of April consisted of 350 lbs. nitrate of soda, 300 lbs. muriate of potash, and 600 lbs. acid phosphate per acre.

Results obtained at the station indicate that a reduction of 50 to 100 lbs. in the quantity of muriate of potash and of 100 lbs. in the quantity of acid phosphate applied would have been more profitable. The experiments in general showed the necessity of carefully preparing the seed bed and of seeding heavily for the purpose of obtaining a good stand of grass. The greatest loss per acre in the tests was \$11.23 and the greatest net profit \$23.59; the next greatest loss and gain were \$5.18 and \$18.64 per acre, respectively. In some of the experiments, owing to the natural fertility of the soil and the kinds of grass grown, smaller applications would have been profitable where the full application resulted in a loss. The average result of all experiments, estimating the hay at \$16 per ton, shows a net profit of \$3.60 per acre and a return of 20.9 per cent on the investment in top-dressing. In addition to the report on the experiments, directions for grass culture in Rhode Island are given.

Composition of the oils contained in the seed of Robinia pseudacacia, Caragana arborescens, Trifolium repens, and T. pratense, V. Jones (*Abs. in Chem. Ztg., 27 (1903), No. 93, Repert. 21, p. 302*).—Brief notes are given on the composition of the oils in the seeds of the different plants. The oil in the seed of red clover belongs to the series which unites the drying and nondrying oils. The solid fatty acids in the oil of this seed contain palmitic and stearic acids and the liquid fatty acids, oleic and linoleic acids, the oleic being predominant. The oil in the seed of white clover was of the same composition, with the exception that it contained a higher percentage of oleic acid.

The content of dry matter, sugar, and nitrogen compounds in fodder beets at different stages of growth, J. A. Le Clerc (*Landw. Vers. Stat., 59 (1903), No. 1–2, pp. 27–81; abs. in Chem. Centbl., 1903, II, No. 23, p. 1291*).—This article has been noted from another source (E. S. R., 15, p. 351).

Culture experiments with red clover from different countries, Gisevius (*Arb. Deut. Landw. Gesell., 1903, No. 83, pp. 182*).—Under the direction of the German Agricultural Society cooperative culture tests by 9 different experimenters were made with red-clover seed from Germany, Russia, Austria, Italy, France, Canada, and the United States. The collection of seed represented 15 different sources, and

each experimenter was furnised with 30 commercial samples, which were sown in duplicate on plats 1 are in size.

The seed was sown in 1900, and the results obtained, together with the observations made in 1901 and 1902, are reported and discussed at some length. The seed samples are described in detail and the number of weed seeds found per kilogram of seed is shown in a table, which records in this connection seeds from 174 species. The prevalence of dodder and the ability of the different kinds to withstand the winter, and the differentiating characters of the various sorts, are noted.

The conclusion is drawn that German red-clover seed, especially the kind produced in Silesia and East and West Prussia, proved superior to seed from any other source. The seed from Russia and Austria ranked next in value, the seed from France gave comparatively small returns and the seed from Italy ranked lowest. The relative values of all samples ranged from 66 to 111, and in this class seed obtained from Pennsylvania stood fourth, with a value of 103, and seed from Missouri eleventh, with a value of 99.

Indian corn in Argentina: Production and export, F. W. Bicknell (*U. S. Dept. Agr. Rpt. 75, pp. 48, pls. 7*).—This report describes quite fully the climate of Argentina in its relation to corn culture, and discusses at some length the production and exportation of the crop. Statistics on the acreage, yield, and quantities exported are presented, together with records of meteorological data. In connection with a description of the methods employed in the cultivation of the crop the varieties commonly grown are briefly noted. The results of a test made by the Argentine government of newly introduced varieties are summarized in the following table:

Results with foreign varieties of corn in Argentina.

Variety.	Time of planting.	Seed planted.	Yield.	Time of ripening.
Yellow varieties:		*Pounds.*	*Pounds.*	
Queen	November 1	4.4	418	May.
Pedrick Golden	do	4.4	330	May.
Golden	End of October	4.4	264	March.
Precious of Auxonne	December 1	4.4	176	April.
Canadian Flint	End of October	2.2	88	March.
Chester Giant	November	2.2	66	May.
Lombardy	End of October	2.2	88	March.
King Philip (brown)	do	4.4	209	May.
White varieties:				
Hickory King	November	2.2	165	May.
Horse Tooth	End of October	6.6	176	May.
Neapolitan Grand	November	4.4	110	April.
White Head	End of October	4.4	44	

Six of these varieties were obtained from North America. Pedrick Golden and Golden are recommended as the best yellow varieties.

In considering the exportation of corn the author discusses shipping facilities and proposed improvements, grading, inspection, freight rates, and prices, and quotes the opinions of experts as to the conditions necessary for successful ocean shipment.

Cowpea experiments, C. L. Newman (*Arkansas Sta. Bul. 77, pp. 32*).—In 1902 over 350 plats of cowpeas, including 54 planted with sports, selections, and crosses, were grown. The results from 1898 to 1902, inclusive, show that the largest yield of peas was obtained in the years with the least rainfall. The highest average yield of hay was also recorded for the year having the smallest precipitation. In wet weather the plants are likely to suffer from mildew, and hence rainy seasons have a tendency to decrease the yield of peas and to a lesser extent the yield of hay. Directions for the culture of cowpeas and their use as a catch crop are given.

Drilling the seed has generally given better results than broadcasting. More favorable yields were also obtained from thin than from heavy seeding. In 1900 Whippoorwill peas sown at the rate of 1 and 8 pecks per acre gave 3,314 lbs. of hay

and 31.4 bu. of peas, and 1,748 lbs. of hay and 16.4 bu. of peas per acre, respectively. In 1901 peas sown at the rate of 12.5 lbs. per acre yielded 400 lbs. of hay and 16.51 bu. of peas more per acre than peas sown at the rate of 100 lbs. per acre.

A good preparation of the soil with subsequent cultivation of the crop gave very profitable returns. The increase in the yield of hay on cultivated plats at the station was in some instances over 50 per cent and in others over 100 per cent greater than the yield on uncultivated plats.

The results of fertilizer experiments conducted in 1901 and 1902 indicate that applications of nitrogen did not benefit cowpeas on the station soil. Plats receiving phosphoric acid or potash, in combination or alone, showed a substantial increase in the yield of peas and hay. Attention is called to the fertilizing value of cowpeas by the results of growing the crop in rotation with oats or wheat. In one instance a plat sown to cowpeas in the spring produced $18 worth of hay, and afterwards a crop of oats valued at $18.50, while a plat of oats not following cowpeas gave a return of only $11.58. In another instance cowpeas produced $19.33 worth of hay and the stubble plowed under increased the following crop of wheat by 61 per cent, as compared with wheat not following cowpeas. The values of the crops in this case were $32.53 and $8.08, respectively.

A series of experiments in progress for 4 years show an average yield of wheat of 10.95 bu. per acre on plats on which no fertilizers were used and no cowpeas were grown. During the 4 years the plats upon which a whole crop of cowpeas had been plowed under before the first crop of wheat was sown yielded a total of 15.55 bu., and the plants upon which only the stubble were turned under, a total of 10.45 bu. more per acre than the plats receiving no treatment whatever. The use of cowpeas as described gave better returns than 100 or 200 lbs. nitrate of soda or 200, 400, 600, or 800 lbs. of complete fertilizers per acre applied for the first crop of wheat.

Plats of corn planted with cowpeas, either in drills or broadcasted at the last cultivation, produced an average value of total product for 2 years of $50.99, where both peas and hay were harvested, as compared with an estimate of $54.31 for the plats on which peas were gathered and the remaining portion of the crop was grazed by cattle. The average value of the total product for the 2 years on the plats without cowpeas was $23.80. Warren Extra Early, a variety suited to late planting, was used in these tests.

A series of plats which had produced a crop of wheat preceded by cowpeas sown broadcast were again planted to cowpeas in drills in June, 1901. One plat was left bare as a check. The cowpeas were harvested in the fall and a second crop of wheat sown. The average value of the wheat and the cowpeas grown as a catch crop on 7 plats in 1901 was $26.85 per acre, while the crop of wheat on the check plat was worth only $11.84. The plats planted to cowpeas in 1901 produced in 1902 an average of 2.43 bu. more wheat than the check plat, an increase of 17.8 per cent.

A test of 123 samples of cowpeas, embracing about 35 varieties under about 45 names, was made in 1902 and the results are tabulated. Calico, Coffee, Extra Early Black Eye, Iron, New Era, Red Yellow Hull, Speckled Java, Warren Extra Early, Warren New Hybrid, Watson Hybrid, Whippoorwill, and White Brown Eye produced the highest yields of shelled peas. The heaviest yield of hay, 8,700 lbs. per acre, was secured from Clay. New Era, Old Mans, Warren Extra Early, Extra Early Black Eye, and Warren New Hybrid gave a greater proportion of peas to vines than the other varieties tested and are recommended for their early maturity.

Flax experiments, 1902 (*Jour. Dept. Agr. and Tech. Instr. Ireland, 3 (1903), No. 4, pp. 663–681*).—Results for 1901 have been previously noted (E. S. R., 14, p. 348). Three plats for the purpose of testing salt, rape meal, and basic slag were added to the series in 1902, and larger quantities of kainit and muriate of potash were used.

The results of all cooperative tests showed that the flax on all plats excepting those receiving potash was slightly yellowed, that superphosphate encouraged the growth

of weeds, especially charlock and spurry; and that the muriate of potash plat presented the best appearance, being followed by the plat receiving kainit. Muriate of potash apparently increased the percentage of scutched flax to retted straw and also slightly improved the quality of the flax. The kainit plats show a greater yield of retted straw, but no increase in scutched flax as compared with the check plat. Kainit was applied at a loss, which is considered due to the unfavorable season. The use of potash gave profitable returns in some instances. The plat receiving 4 cwt. of salt per acre produced a smaller yield of retted straw and a higher percentage, but a lower total yield of scutched flax than the unmanured plat. The use of salt did not affect the quality.

A mixture of kainit and superphosphate was more effective than either of these fertilizers applied alone. The results with a mixture of kainit, superphosphate, and sulphate of ammonia were in accordance with those of the previous year. The use of 5 cwt. of rape meal per acre seemed to have increased the yield of retted straw, decreased the yield and proportion of scutched flax, and to have injured the quality. The rape meal was applied at a loss. The average returns for basic slag applied at the rate of 5 cwt. per acre indicate a reduction in the yields of retted straw and scutched flax and also in the ratio of fiber to straw. The experiments are to be continued.

Belfast Brand and Riga Child from Dutch seed and Belfast Brand and Pernau Crown from Riga seed were grown for comparison. The Riga seed gave larger yields of scutched flax than the Dutch seed, and for the varieties the results were in favor of Pernau Crown. The seed of this variety also produced a flax of superior quality to that obtained from the seed of the other varieties. As in 1901, the Russian seed gave better financial returns than the Dutch seed. Contrary, however, to the results of the previous year, the Belfast Brand of Dutch seed yielded more scutched flax and gave better financial returns than the Dutch Riga Child seed.

A comparison of the Irish and the Belgian Courtrai system of scutching gave financial results in favor of the Belgian system. The results of these scutching tests for the last 2 years are summarized as follows: "With Irish retted straw Irish mills, in the hands of Irish workers, give better pecuniary returns than does a Courtrai mill in the hands of Courtrai scutchers. With Belgian retted straw . . . the Courtrai mill gives the better returns. With straw retted in Ireland by the usual method, the Courtrai mill worked by Belgians, and fitted with modified blades, yields more profitable returns than does the Irish mill worked by Irishmen, or the unmodified Courtrai mill worked by Belgians."

An experiment to determine the influence of rippling resulted in a reduced yield of retted straw and of scutched flax. The seed obtained did not cover the expense and loss incurred. A heavy rainfall greatly influenced this trial.

Experiments with oats and barley, R. S. Seton (*Bd. Agr. and Fisheries* [*London*], *Rpt. Agr. Education and Research, 1902–3, pp. 77–86*).—The comparative weights of 2,000 grains of 14 varieties of oats, the percentage of husk, and the weight per plat of unshelled and shelled grain are tabulated. Experiments were conducted for 3 consecutive years. The grains of the new varieties obtained by selection and hybridization were the heaviest and the largest. The season influenced the weight of the grain of some varieties considerably, while upon others it had hardly any effect.

Attention is called to the difference in the number of plants of different varieties to be expected on a certain area, when the same quantity of seed by weight is sown. It is shown that the percentage of husk is influenced by the variety and the season. Goldfinder, at the head of the list in productiveness, contained 4 oz. of husk in 1 lb. of grain, and Pioneer, ranking last, contained $5\frac{1}{2}$ oz. Black Tartarian and Pioneer, both black varieties, have a high proportion of husk. In 1900 and 1901 the average weight of husk on 200 grains of all varieties was 1.82 and 1.827 gm., respectively, and

in 1902, a wet season, 1.573 gm. It is stated that a wet season generally produces larger and more uniform kernels and thus reduces the percentage of husk.

Storm King and Tartar King were the heaviest yielders in 1902, and Abundance, New Market, Goldfinder, and Waverly are considered the most generally reliable. Brief comparative and descriptive notes on the different varieties are given.

Tartar King, a large-grained variety, yielded 3 bu. of grain and 2.5 cwt. of straw more per acre when sown at the rate of 5 bu. than when sown at the rate of 4 bu. Equal weights of black and white oats were sown as a mixture for 2 years and each season the proportion of white oats in the yield was largely increased.

Among 5 varieties of barley Invincible gave the most satisfactory yield in 1902 and ranked second in point of quality. The results for 1901 and 1902 indicate that about 3 bu. of seed per acre is sufficient for barley. Treating the seed against smut gave no large increase in grain but greatly improved the quality.

The influence of lime and marl on the yield of potatoes and on their content of nitrogen and mineral matter, Ulbricht (*Landw. Vers. Stat., 59 (1903), No. 1–2, pp. 1–25; abs. in Deut. Landw. Presse, 30 (1903), No. 85, p. 734; Chem. Centbl., 1903, II, No. 23, p. 1290*).—In these experiments the plants were grown in sheet-iron cylinders, sunk into the ground, for the purpose of better controlling soil and moisture conditions and to make these uniform for the 34 different tests. A movable protection covered the entire series of cylinders.

Lime did not show a definite influence on the prevalence of potato scab, but the use of marl slightly increased the number of scab spots. In practice the author has noticed that on marled soil potatoes following rye, which had received a heavy application of kainit, were free from scab.

With one exception liming and marling increased the yield of tubers in weight, and also their content in dry matter. The lime as well as the marl appeared to increase the yield of tops more than the yield of tubers. The proportion of dry matter in the tops and tubers varied from 1:3.05 to 1:3.7, the limed and marled plats invariably showing the narrower ratios.

The plants grown in limed and marled soil contained more nitrogen in the stems and leaves and a little less in the tubers than the check plants. The nitrogen content of the leaves and stems increased with the increase of magnesium carbonate applied in the fertilizer. The smallest quantity of phosphoric acid was found in the tops of plants grown on lime-free soil. The limed and marled soil also produced plants with a higher potash content in the tops than the soil not so treated. With the exception of 4 tests both substances apparently decreased the nitrogen and potash content of the tubers. Ground limestone reduced the lime and magnesia content of the portion of the plant above ground almost in proportion to the quantity applied. When magnesium carbonate was used in connection with lime the quantity of lime in the tops was reduced and that of magnesia increased. From this result the conclusion is drawn that magnesia may, within certain limits, replace lime in the plant organism. The lime content of the tubers was only slightly increased by heavy applications of lime and marl, while the magnesia content remained practically constant.

A study of the soil after the plants had been produced showed that only a small fraction of the soil supply of lime and magnesia had been removed in the crop.

Sansevieria, O. Barrett (*Porto Rico Sta. Circ. 1, pp. 4*).—A discussion is given in Spanish on the culture and uses of several species of sansevieria, or bowstring hemp, together with brief references to the value of maguey and sisal culture for Porto Rico.

Soy bean, N. Ssemenow (*Abs. in Chem. Ztg., 27 (1903), No. 93, Repert. 21, p. 302*).—In Manchuria from $\frac{1}{8}$ to $\frac{1}{6}$ of the land under cultivation is reported as devoted to this crop. Southern Russia is considered well adapted to the cultivation of the soy bean, which prefers a light deep soil and a dry climate. The average of 16 analyses shows

the following composition: Water 9.49, proteids 34.30, fat 17.67, nitrogen-free extract 28.44, cellulose 4.79, and ash 5.31 per cent. The crop is grown for forage and the production of oil.

The influence of environment upon the composition of the sugar beet, 1902, H. W. Wiley (*U. S. Dept. Agr., Bureau of Chemistry Bul. 78, pp. 50, dgms. 5*).—This season the work was discontinued at the Iowa Station, and at the Indiana Station the crop was a complete failure. In addition to the stations reporting results in 1901 (E. S. R., 15, p. 34) data were furnished in 1902 by the Colorado and California stations. In California the work was conducted at the Pomona Substation and on alkali soil at Chino. The results obtained in the humid and the irrigated regions are discussed separately. The average data of the season are given in the following table:

Average results with Kleinwanzlebener Nachzucht sugar beets grown under different conditions of soil and climate in 1902.

Brief notes describing the soils on which the experiments are in progress are given, and the chemical and mechanical analyses of samples from these sources, made in the Bureau of Chemistry and in the Bureau of Soils of this Department, are reported. A summary of these data is shown in the table below:

Yield of sugar beets and soil data, 1902.

Fort Collins, Colo	24.0	.64	.15	.18	40.27	37.49	22.05

The geodetic data, excepting for the Colorado and California experiment fields, have been given in previous reports. At Fort Collins the average length of day from May to August, inclusive, is 14 hours 32 minutes, the latitude 40° 5′, and the altitude

4,994 ft.; and at Pomona, Cal., the average length of day is 14 hours 58 minutes, latitude 34° 3′, and the altitude 861 ft.

The results in 1902 are considered as confirming in a general way those of the 2 previous years. In their relation to the distribution of rainfall they indicate, according to the author, that the composition of the beet is largely independent of this factor, provided there is sufficient moisture to supply the growing crop.

At Madison, Wis., where the largest yield was obtained, the phosphoric acid content of the soil was higher than at any other station excepting Lexington, Ky., and Ithaca, N. Y. The quantity soluble in dilute acid, however, was largest at Madison. The potash content was higher only at Ithaca and Geneva, and the nitrogen content lower only at the Michigan Station. At Lexington, where the lowest yield was produced, the soil contained the higest percentage of phosphoric acid and nitrogen and the lowest of potash. The influence of a deficiency in 2 essential elements is shown by the results at the Michigan Station, where phosphoric acid and nitrogen were very low and the yields ranked next to the lowest. Potash and nitrogen were abundant in the soil at the Washington Station, while phosphoric acid was low, but this element was in a readily assimilable form and a yield of 26 tons per acre was obtained.

Judging the results with reference to the chemical composition of the soil, the previous conclusion that the soil is the least important factor in the environment of the sugar beet in respect to sugar content is again confirmed. It is stated that if well prepared both clay and sandy soil produce good beets, and that for this reason the beet is not well suited to determine the influence of mechanical composition of the soil on the yield. "A fundamental condition for the growth of beets is the preparation of the seed bed to a depth of at least 16 in."

The results on the alkali soil at Chino, Cal., show that beets of high quality can be produced upon soil containing at least 5,480 lbs. of alkali per acre-foot. Here as well as at Pomona the sugar content of the beets was materially reduced after October 1.

The average percentage of sugar in the beets was 2.4 per cent higher on the irrigated areas than at the other stations. Attention is called to the more equable temperature at the irrigated stations as compared with the nonirrigated areas, and this condition is considered favorable to securing a high content of sugar.

Method of harvesting sugar beets, RIEGER (*Abs. in Chem. Ztg.*, 27 (1903), *No. 93, Repert. 21, p. 302*).—The author recommends piling the beets into heaps about 3 ft. in diameter with all the leaves exposed. As the foliage withers the juices and the sugar are drawn back into the beet. This treatment practically prevents a loss in weight and gives an increase of about 1 per cent in sugar content. The beets are topped in the field and the tops and leaves are plowed under.

Seedling and other canes at Barbados in 1903, D. MORRIS (*Imp. Dept. Agr. West Indies, Pamphlet 26, 1903, pp. 69*).—A short account of the most important results of cooperative experiments with selected seedling and other canes is given. Part of the data obtained are presented in tables. The weather conditions of the season are discussed, and the rainfall of the different farms carrying on the work is recorded. It is stated that the results in general confirm those of previous years (E. S. R., 14, p. 653).

Experiments on wheat, R. H. BIFFEN (*Nature* [*London*], *69 (1903), No. 1778, pp. 92, 93*).—This article discusses the increase in the yield of wheat and the decrease in gluten content, and describes results obtained in wheat breeding which conform to Mendel's law. The effects of crossing on different botanical characters of the wheat plant as shown in certain experiments is pointed out, and examples in breeding early-maturing and rust-resistant varieties are cited.

Triticum pollonicum, ripening early in August when sown about the middle of March, crossed with Rivet wheat, ripening late in August when fall sown, resulted in hybrid grains which when sown March 15 produced plants maturing seed about the middle of September, or simultaneously with Rivet wheat sown at the same time.

Michigan Bronze and Red King, both liable to rust, were crossed with Rivet, which is practically immune. The following year the hybrids were severely attacked by rust and the grain produced was badly shriveled. From the seed of the Rivet and Red King cross 260 plants were grown, of which on June 15, 78 were free from disease, 118 slightly infected, and 64 badly attacked. June 29, when the epidemic seemed at its height, 64 plants were still uninfected and 195 were diseased.

These data lead the author to believe that the susceptibility of wheat to rust attacks is a Mendelian character.

Culture of wheat on the experimental fields of Grignon in 1902, P. P. Dehérain and C. Dupont (*Compt. Rend. Acad. Sci. Paris, 135 (1902), No. 17, pp. 654–657*).—The yields of small and large grains of a number of varieties of wheat were in all cases in favor of the large grains, but a large difference in yield was obtained only when there was a marked difference in the weight of the grains.

It was found in connection with this experiment that wheat lodged but not lying flat upon the ground ripened well and was equal in yield and quality to standing grain. A field on which fertilizers had been applied to the rows of beets was compared to a field upon which the fertilizer application had been uniformly spread. Early in the season the wheat following the beets was uneven in growth, being more luxuriant on the old beet rows, but later on this unevenness was effaced and the yield in grain and straw was slightly in favor of this field.

HORTICULTURE.

Influence of lime upon plant growth, H. J. Wheeler and G. E. Adams (*Rhode Island Sta. Bul. 96, pp. 23–44, pl. 1, fig. 1*).—A summary is given of the growth of a number of vegetables, flowers, small fruits, and trees planted on the acid soils at the station and fertilized with sulphate of ammonia or nitrate of soda, and either limed or left unlimed.

It was found that Lima beans grew well on a soil which was so acid as to entirely destroy lettuce, spinach, beets, onions, asparagus, muskmelons, and some other plants. The use of lime for these beans was found distinctly disadvantageous. Nitrate of soda and sulphate of ammonia were apparently equally effective with this crop. Pumpkins, squashes, asparagus, and rhubarb were all greatly benefited by liming, and in every case with these plants nitrate of soda proved more beneficial as a fertilizer than sulphate of ammonia. Fay and White Dutch currants were greatly helped by liming, as was also the Cuthbert raspberry. With the currants greater yields were obtained by the use of nitrate of soda than with sulphate of ammonia; but with the Cuthbert raspberry liming in connection with sulphate of ammonia gave better results on the whole than liming with nitrate of soda.

With the Ohio blackcap raspberry liming, with either nitrate of soda or sulphate of ammonia, appeared to be injurious. The results secured in liming the Snyder blackberry were conflicting; in some instances the yield was heavier on the limed soil and again upon the unlimed soil. The average results for 3 years favored the limed soil which received sulphate of ammonia. The blackberry, however, appears to thrive very well on acid soil. The yield of grapes appeared to be increased by liming on the sulphate of ammonia plat, but was not beneficial on the nitrate of soda plat. In both cases, however, liming appeared to increase the growth of the vines. The American Bell cranberry was positively injured by liming, and grew best where beets and onions failed. Acid soil seems to be best for this plant.

With flowers the poppy especially was greatly benefited by liming, as was also the pansy. In both cases, too, the best results were secured on the limed nitrate of soda plats as compared with the limed sulphate of ammonia plats. Zinnias were also benefited by liming on the nitrate of soda plat, but liming in connection with sulphate of ammonia did not prove helpful. The zinnias grew well on a soil so acid as to kill poppies.

Liming also appeared especially valuable in the case of the White Wonder Canada field pea. It was observed with this plant that nodules were abundant and quite evenly distributed upon the roots. On the unlimed plats only a very few nodules were found, and these were frequently of large size and tended to grow in clusters.

A home vegetable garden in the Palouse country, S. W. FLETCHER (*Washington Sta. Bul. 57, pp. 96, figs. 39*).—This bulletin has been written for the use especially of the inhabitants in the Palouse region of Washington. It encourages the making of gardens and gives detailed directions for the planting of all those vegetables commonly grown in kitchen gardens. It is based on the results secured at the experiment station in tests of varieties covering a number of years.

Such crops as tomatoes, melons, eggplants, squashes, pumpkins, and other tender vegetables can not be satisfactorily grown in the Palouse country without a hotbed. The necessity of thorough cultivation to preserve moisture in that region of scanty rainfall is pointed out, and the use of shallow-working tools like the spike-tooth cultivator, advocated. It has been found that Washington-grown cabbage, cauliflower, and onion seed give as good results as the best seed from other sections of the country. Puget Sound cauliflower seed has been found equal to the best Danish-grown seed. As a substitute for Lima beans, which do not mature in that region, the varieties Old Homestead and the English broad, or horse bean are suggested.

Cabbages must be started in a hotbed. The varieties Charleston, Wakefield, All Seasons, and Flat Dutch are recommended. The cultivated dandelions are recommended for greens during March and April. Endive is preferred to lettuce in midsummer. In the case of muskmelons extra-early varieties should be planted on quick soils. They should be given protection from late spring frosts and cold rains by means of hand boxes and the ends of the vines pinched. Onions grown from seed sown in the open field can not be depended upon to ripen well. By sowing in a hotbed and transplanting very early, the crop has been grown cheaper and the bulbs have regularly ripened. Australian Brown, Prizetaker, and White Pearl are recommended. For the purpose of tillage it is recommended that all peas, even the dwarf forms, be trellised. Only the early varieties of pumpkins mature. They should be started in a hotbed. Early Sugar is recommended.

Hubbard squash is not sure to mature. Better results have been secured with Boston Marrow and Marblehead. These should be started in boxes and succession sowing practiced. Nearly all varieties of summer squash do well. With tomatoes only the earliest varieties ripen. The plants when transplanted to the garden should be large and stocky and have several blossoms already formed on them. Train to a single stem. Rich soils and a northern slope are recommended for this crop. All side shoots of the vine should be kept pinched off and the vines topped to set 4 to 5 clusters of fruit. This practice hastens the ripening period. Watermelons, like muskmelons, should be started in the hotbed and hand boxes used to protect them in the field. Cole Early is considered one of the most reliable varieties.

Vegetables under cheese cloth, W. T. MACOUN (*Gardening, 12 (1904) No. 273, pp. 517, 518*).—The author reports the results of experiments in growing a number of different vegetables under cheese cloth shade at the Central Experimental Farm in Canada. Lettuce grew equally well inside and outside the enclosure, but was 2 to 4 days earlier when grown outside. The yield of beets was more than twice as heavy when grown outside the enclosure, though the tops were about equally large in both cases. Radishes were ready for use inside about 3 days before those outside. The radishes inside were perfectly free from maggots, while those outside were practically worthless from this cause. Beans also were ready for use earlier inside than outside, and were nearly as productive.

Experiments with eggplants, watermelons, and muskmelons were a failure both inside and outside, owing to the inclemency of the season. No cucumbers set inside the tent until the cloth was torn and insects admitted. Maggots, which badly affected cauliflower outside, were entirely absent on cauliflower grown inside the tent. Toma-

toes grew well inside the tent and were 6 days earlier than those grown outside, but were not so robust. Corn grew more rapidly inside than out at first, but later on was not as robust.

Some data are given showing the average temperatures during the summer months up to September 1, inside and outside the enclosure. The temperature was usually a little higher inside than out, the greater difference in any one case was 9°.

In conclusion it is stated that "cheese cloth enclosures may be of value in cities and towns where it is difficult to have a garden owing to the injury done by cats, dogs, and even young children. Vegetables will probably be tenderer, as a rule, grown inside an enclosure, though this was not the case this season owing to the wet weather. It may be useful to market gardeners for growing vegetables which are affected by root maggots."

A test by Graham Bell, at Cape Breton, Nova Scotia, is noted in which it was found that lettuce and beans were tenderer when grown under shade and that tomatoes ripened earlier, although the crop was not as large as that grown outside.

The culture of vegetable crops in the market and home gardens, W. F. Massey (*Bul. North Carolina State Bd. Agr., 24 (1903), No. 11, pp. 78*).—The author discusses this subject with especial reference to the needs of North Carolina cultivators. All the different phases of trucking and market gardening are discussed, with specific directions as to varieties and cultural methods best suited for all the more common vegetables usually grown in trucking.

The vegetable garden, J. E. Morse (*Rochester, N. Y.: Vick Pub. Co., 1903, pp. 30*).—Brief directions are given for the location and preparation of the vegetable garden and for the planting and culture of vegetables and small fruits.

Kitchen and market gardening, L. Bussard (*Culture potagère et culture maraichère. Paris: J. B. Baillière & Sons, 1904, pp. 503, figs. 172*).—This is a popular work on the culture of all of the more common market garden crops. It purports to give all of the latest information on this subject.

A Pennsylvania celery farm: Heavy fertilizing in a swamp (*Rural New Yorker, 62 (1903), Nos. 2809, p. 817; 2810, p. 834; 2811, pp. 850, 851; 2812, pp. 865, 866, figs. 3*).—An account is given of the method of celery culture observed on the farm of A. R. Niles, Tioga County, Pa. The land was originally a worthless swamp. A very successful celery farm was made out of it by thorough drainage and the use of large amounts of commercial fertilizers irrespective of any natural fertility of the land. Potash was found to be the element of most importance in the culture of celery on this land.

Generally a complete factory-mixed fertilizer is used, applications of as much as 3,000 lbs. per acre being sometimes employed. About half the fertilizer is used broadcast and half drilled 4 to 5 in. deep in the celery rows before the plants are set above it. Small dressings of lime and ashes have also proved very beneficial on this soil. The success of the industry is attributed to the fact that the soil is used mainly as a medium in which to grow the plants, and the crop fertilized as heavily as though the soil were absolutely sterile. Golden Self-Blanching is the variety principally grown.

Peas in pots and frames with varieties, G. Wythes (*Amer. Gard., 25 (1904), No. 466, p. 21, fig. 1*).—Directions are given for growing early peas in pots and frames, with notes on some of the better varieties used in England for this purpose.

The genus Phaseolus; its garden varieties, Denaiffe (*Jour. Soc. Nat. Hort. France, 4. ser., 4 (1903), Apr., pp. 222–243*).—An account is given of the botanical characteristics, the distinguishing features of the principal varieties, diseases, culture, etc., of kidney beans (*Phaseolus vulgaris*), Lima beans (*P. lunatus*), and the scarlet runner bean (*P. multiflorus*).

What the introduction of foreign varieties of fruit has done for the horticulture of the Northwest, H. C. Price (*Jour. Columbus Hort. Soc., 18 (1903), No.*

4, pp. 152–156).—The attempt to raise hardy varieties of fruit in the Upper Mississippi Valley led to very extensive importations of Russian fruits by Professor Budd, of the Iowa Agricultural College, in 1882. These fruits have been tested now in different portions of the Northwest for more than 20 years, and the author gives an estimate of their value as a factor in horticulture in the Northwest.

It is stated that in the southern part of Iowa and in the same latitude in adjoining States, the Russian fruits have not proved as satisfactory as American varieties of eastern origin; while in the northern part of Iowa and in southern Minnesota and Dakota their introduction has proved a boon, since the Russian sorts are the only varieties that will grow. One of the most important results of the introduction of Russian fruits, however, has been in the impetus it has given to plant-breeding work, in which the attempt has been made to combine the good qualities of the native American fruits with the hardiness, thrift, and productiveness of the Russian fruits.

Of the 100 or more varieties of Russian apples introduced by Professor Budd, only a few have proved really valuable. Among the more important of these are Long Field, Anisim, Antonovka, Charlamoff, Hibernal, Tetofsky, and Liveland Raspberry; and of the 50 varieties of cherries the valuable varieties are Sklanka, Duchess d'Angoulême, Brussler Braune, and Spate Amarelle.

In conclusion, it is stated that while the immediate results obtained from the introduction of the Russian fruits has been far from what had been hoped, nevertheless the experiment has paid for itself many times over, and it is believed that still greater results will yet be obtained by the crossbreeding of the Russian and American fruits.

Catalogue of fruits (*Proc. Georgia State Hort. Soc., 27 (1903), pp. I–XIX*).—This is a catalogue of all of the fruits and nuts grown in Georgia, with estimates as to their value in different localities, season of ripening, etc.

Victorian fruit in London, J. M. SINCLAIR (*Jour. Dept. Agr. Victoria, 2 (1903), No. 2, pp. 149–157*).—This is an account of shipments of apples, pears, and grapes to London in a number of different steamships, and the prices received for the fruits.

Growing fruit trees in pots, W. TURNER (*Amer. Agr., 72 (1903), No. 20, p. 403, fig. 1*).—The author has successfully grown in pots the following list of fruits: *Plums.*—Golden Esperen, Jefferson, Denniston Superb, Green Gage, Grand Duke, Mallard, The Czar, Early Transparent, and Pond Seedling. *Pears.*—Fertility, Magnate, Conference, Princess, Souvenir du Congress, Louise Bonne de Jersey, Pitmanston, Duchess, Buerre Diel. *Apples.*—Williams Favorite, Ribston Pippin, Benoni, Mother, King of the Pippins, Washington, Tompkins King, Belle de Pontoise, Bismarck, Gascoigne, Scarlet, Werner King, Peasgood Nonesuch, Lady Henniker, Bijou, Thomas Rivers, Cox Pomona, Alexander. *Figs.*—Black Marseilles, Brown Turkey, Early Violet, Negro Largo, White Marseilles.

Self-sterility in fruits (*Amer. Agr., 72 (1903), No. 26, p. 567*).—The opinions of S. D. Willard, F. A. Waugh, and J. W. Kerr are here given on the matter of self-sterility in Japan plums. Mr. Willard has found them self-fertile, with the exception of October purple. Professor Waugh states that in his experiments with Japanese plums he did not find a single variety which was reasonably self-fertile, and he looks upon the mixing of varieties for the purpose of cross pollinating the flowers as a kind of insurance rather than an absolute necessity in all cases. Mr. Kerr holds that nearly all kinds of fruits are self-sterile in some localities, and that Japanese plums are no more reliable in this respect than are apples, cherries, grapes, etc. Practically every kind of fruit, in his experience, except perhaps the Kieffer pear, has proved self-sterile when protracted rainfall prevails at blooming time.

On the relation of moisture content to hardiness in apple twigs, F. T. SHUTT (*Sep. from Proc. and Trans. Roy. Soc. Canada, 2. ser., 9 (1903–4), Sec. IV, pp. 149–153*).—Horticultural writers in recent years have urged the necessity of stopping cultivation of orchards in late summer and the planting of some cover crop for the purpose of withdrawing moisture from the soil and thus "ripening" up the wood to

prevent winter injury to the trees. It is generally believed that those varieties whose growth ripens best will prove the hardiest. It was thought, therefore, that the moisture content of the twigs of an apple tree as winter approaches would be an indication of its power to resist frost. In order to test the matter, twigs were selected from 10 varieties which contained representatives of sorts which were practically frost-proof, sorts which are killed back in severe winters, and sorts which suffer every winter to a greater or less degree.

In the first group were Duchess of Oldenburg, Yellow Transparent, and McMahon White. Varieties which were considered less hardy than these were Wealthy, Scott Winter, Scarlet Pippin, and Walworth Pippin. The varieties Hebble White, Boy Delight, and Blenheim Pippin were selected as least hardy of the 10. The twigs of these different varieties were examined every 2 weeks from January 23 to May 15. The percentage of water in the basal and terminal portions of the twigs and in the whole twig is shown in the following table:

Water in apple twigs in winter.

Variety.	Basal portion.	Terminal portion.	Whole twig.
	Per cent.	*Per cent.*	*Per cent.*
McMahon White	44.87	46.95	45.79
Yellow Transparent	45.19	46.60	45.82
Duchess	44.94	47.48	46.00
Walworth Pippin	45.36	48.18	46.58
Boy Delight	45.28	48.47	46.75
Wealthy	47.31	48.74	48.06
Scott Winter	46.95	49.44	48.21
Scarlet Pippin	47.00	49.65	48.23
Hebble White	48.58	50.31	49.74
Blenheim Pippin	49.12	51.15	50.01

After the winter was over it was found that of the trees under examination 3 only showed winterkilling, the other 7 varieties proving hardy to the tip. The tender varieties were (1) Boy Delight, with terminal buds killed and twigs in a few instances killed back 3 in.; (2) Hebble White, showing terminals of twigs in every instance killed back about 3 in.; (3) Blenheim Pippin, the tenderest of all, with terminal buds killed and wood killed back 3 to 6 in. or more. The data obtained in the investigation would therefore, in the opinion of the author, seem to show "that we have direct and definite proof that there is distinct relationship between the moisture content of the twig and its power to resist the action of frost, and that those trees whose new growth contains the largest percentage of water as winter approaches are in all probability the most tender.

"Further, it seems likely that if hardiness is dependent upon the degree of ripeness of the new growth (indicated by moisture content), then it is quite possible that it is a quality that can be materially affected by judicious cultural methods. Hardiness is evidently something more than an inherited tendency. It seems probable that it is a quality largely under the influence of the soil condition as regards moisture and temperature in the late summer and autumn months, and probably these factors rather than the severity of the succeeding winter determine the tree's immunity from frost. If in northern latitudes vegetative growth be early arrested and ripening of the new wood thus induced, either by artificial means (pruning and cover crops), or by a dry and cold autumn, varieties now considered tender might prove hardy."

The work is to be continued and the examinations of the twigs begun earlier in the season.

The composition of apple pomace from Cornouailles in 1903, J. CROCHETELLE (*Jour. Agr. Prat., n. ser., 6 (1903), No. 49, pp. 730, 731*).—The density of juice obtained from pressing cider apples is reported, as well as the amount of reducing substances and starch per liter, the composition of the juice being discussed in relation to the maturity of the apple crop.

Graft hybrid between the pear and quince, L. DANIEL (*Jardin, 17* (*1903*), *No. 404, p. 372, figs. 5*).—A number of pear trees grafted on quince stock were cut back to near the ground. As a result, several shoots sprang up near the original grafts. One of these shoots partook in a large measure of the combined outward characters of both pear and quince. This is described as a graft hybrid. Illustrations are given of the leaves of the normal pear and quince and of the graft hybrid thus obtained.

Hybrid oranges from Louisiana, J. L. NORMAND (*Amer. Gard., 24* (*1903*), *No. 461, p. 669*).—The author states that he has made crosses with *Citrus trifoliata* as follows: (1) Satsuma × *Citrus trifoliata*, (2) Mandarin × *C. trifoliata*, (3) Navel × *C. trifoliata*, (4) Boone Early × *C. trifoliata*, and (5) Ponderosa × *C. trifoliata*. These crosses have been made during the past 10 years, and a sample of each of the fruits thus far obtained from the crosses was sent to *American Gardening*, which describes them as follows:

"The hybrid Ponderosa and *C. trifoliata* (5) is a fruit $3\frac{3}{4}$ by $3\frac{1}{4}$ in., partaking more of the general appearance of the lemon than what is generally known as an orange. It has an aroma like that of the grape fruit and is about the same in color, being a pale greenish yellow and having a coarse-looking surface. The hybrid Navel and trifoliata (3) gives us a fruit 2 by $2\frac{1}{2}$ in. of a fine, deep golden yellow color, but with a pungent odor. The Mandarin and trifoliata (2) recalls the Mandarin in size and general appearance of the skin, as well as in odor. A cross of Boone Early and trifoliata (4) gives a typical richly colored sweet orange, $2\frac{3}{4}$ by $2\frac{1}{2}$ in., a very handsome fruit. The hybrid Satsuma and trifoliata (1) is like a small-sized sweet orange, 2 by $2\frac{1}{8}$ in. Compared with the Satsuma parent it is more rounded, the skin more tender, and the color rather near the golden yellow."

Mr. Normand also secured an early-fruiting variety of pecan by crossing the Louisiana thin-shell pecan and the French dwarf Preparturien walnut.

On the budding of mangoes, T. J. HARRIS (*Bul. Dept. Agr. Jamaica, 1* (*1903*), *No. 11, pp. 253–255*).—A successful method of budding mangoes is described. The essentials to be observed are as follows:

"That both the stock and the tree yielding the buds be growing rapidly. That the bud wood be a little larger in diameter than the stock to insure the area on the under side of the actual bud being brought into close contact with the wood when tied in; if the bud wood be less in diameter than the stock, a hollow space will occur between these parts that should be closely applied; acting with this against success is the thinness of the bark of the younger wood and the consequent impossibility of tying in closely. That the bud be tied in tightly, especially at the points just below and above the bud proper, but yet not tight enough to crush or bruise the bark. That the piece of bark containing the bud be removed from the wood without bruising, bearing in mind that the bending will bruise or crush the cells of a plant. That the moisture be retained in the bud during the time required to join up by using tying material that will prevent evaporation, i. e., waxed tape. This is made by dipping three-eighths in. tape into a melted mixture of 1 lb. beeswax, a piece of resin the size of a hen's egg, and half a wineglass of raw linseed oil; scraping off the superfluous wax with a dull knife after cooling. The bud wood should be near the stock to insure no time being lost between the taking off of the bud and its insertion in the stock."

The bud wood used should be 4 to 6 seasons old and 1 to $1\frac{1}{2}$ in. in diameter, and in any case larger than the stock on which it is to be grafted. The piece of bark containing the bud in the center is made about 3 in. long and three-fourths in. wide. Large seedling trees may be cut off and the sprouts arising from the stump budded. Not more than 3 sprouts should be allowed to grow to each stump. In placing the bud on the stock care should be taken to make a space large enough so that the bud patch can be moved slightly from side to side and up and down. Union takes place

under the bud and not at the sides. If the bud is still green 2 weeks after budding the whole of the stock above the bud may be cut off.

The Georgia fig; its possibilities and promise, H. N. STARNES (*Proc. Georgia State Hort. Soc., 27 (1903), pp. 46–58*).—This is a popular account of the possibilities of the fig industry in the South, with a discussion of the different classes of figs, method of propagation, pruning and training, winter protection, diseases, varieties, etc.

Irrigation in small fruit growing, C. DECKNER (*Proc. Georgia State Hort. Soc., 27 (1903), pp. 34–38*).—The method followed by the author in irrigating 20 acres of orchard and gardens in Georgia is described. On light, loose, sandy soil the application of the water by sprinkling is advocated, but where the soil is heavy and inclined to bake it is held that the water should be applied in narrow furrows between the rows of the crop.

In the plant described the water is delivered to the field direct from the pump in a 2-in. iron pipe. In the case of strawberries, holes are made in the pipe at proper intervals so that 10 or 12 rows can be irrigated at one time. The water is kept running slowly until the ground is thoroughly saturated.

Growing fancy strawberries, F. E. BEATTY (*West. Fruit Grower, 13 (1903), No. 3, pp. 1, 2, fig. 1*).—The 5 principal varieties grown by the author are Warfield for the early sort, fertilized by Michel Early and Lovett Early—1 row on each side with 3 rows of Warfield between—followed by Clyde and in turn by Gandy. The 3 varieties—Warfield, Michel Early, and Lovett Early—are grown preferably on rich, sandy loam with a southern exposure. All these varieties are inclined to run to vine, and to prevent this as much as possible plants are selected that show a tendency of strong fruiting-bud power. The largest crowned plants which stool low to the ground are selected. The fertilizers used for these sorts are much richer in phosphoric acid and potash than in nitrogen.

In the case of Clyde, which has a fault of producing more fruit than foliage, plants are selected which show a disposition to run to plant and runners, rather than those showing a tall upright position. In setting out plants of this variety the soil is first heavily fertilized with composted manure, which is then plowed under and a crop of cowpeas grown. The peas are turned under in the fall and the ground dressed with about 50 bu. of wood ashes per acre. The plants are kept thoroughly cultivated throughout the summer, and the following spring are fertilized with about 75 lbs. of nitrate of soda per acre when the straw is taken off them. With the Gandy variety, low heavy-crowned plants are used and a much more sparing application of nitrogenous fertilizers made. Instead, larger quantities of bone meal and muriate of potash are used.

In picking for market the berries are graded in the field. The picker is furnished with a stand with 4 boxes, 3 of which receive the first-grade fruit as picked, and the other the second-grade fruit.

Ringing the currant vine, T. HARDY (*Jour. Dept. Agr. Victoria, 2 (1903), No. 2, pp. 147, 148*).—The author states that in South Australia it has been definitely proved that not only larger crops but also larger-sized berries are obtained as a result of ringing the currant grape. In some instances the crop has been increased one-half by ringing. On the other hand, the ripening of the fruit has been retarded from 10 days to 2 weeks, and the grapes from ringed vines are distinctly less sweet and lighter in color. The weakening effect of ringing on the life of the vine is discussed.

Definite experiments on this phase of the problem appear to be wanting. The author has found, however, that a simple incision without removing any of the bark has proved as effective in increasing the yield as when a ring of bark was removed, and caused considerably less injury to the vines. In whatever manner the ringing is done it is held that it should be made when the vine is in bloom, as

it seems that the check then given causes the setting to be more satisfactory. Weakly vines should not be ringed in any case. This process should be reserved for only the more vigorous vines.

Specific variations of grapes, A. JURIE (*Rev. Vit., 20 (1903), No. 520, pp. 647–652, figs. 9*).—An account is given of a number of specific variations in the normal product obtained by grafting grapes. Illustrations are given of several of the more striking results obtained, showing reciprocal action between stock and scion. The author states as a result of his investigations that the graft is a more certain and more powerful means of hybridization than sexual hybridization, and that, as with herbaceous plants, it may be carried out with a perfectly definite end in view.

On the variations in grafted vines, L. RAVAZ (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 51, pp. 743–750, figs. 8*).—A controversial article in which variations in vines alleged to be due to grafting are considered by the author to be due to ordinary causes of variation.

Morphological variations in the leaves of grapes as a result of grafting, A. JURIE (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 52, pp. 764–767, figs. 3*).—An illustrated account is given of observations along this line.

Direct producers and fruitfulness, J. M. GUILLON (*Rev. Vit., 20 (1903), No. 521, pp. 671–675*).—This is an account of the yields of a number of varieties of direct producers on different soils. In some cases analyses of the product as regards alcohol and acid contents are given. Very unsatisfactory results have been reported with direct producers on chalky soils; in one locality on such soils they were gradually destroyed by phylloxera. In another instance on deep clay soils they gave very poor results.

In a third case on the low, rich plains in the neighborhood of Cognac, where the vineyards are submerged during a portion of the winter, thus protecting them in part from the attacks of the phylloxera, better results were obtained. In this case the soil contained about 25 per cent of lime with considerable clay. The test was made in a very exposed situation with pure vinifera sorts in comparison with direct producers. Late frost killed the growing shoots of the vinifera vines so that not a single berry was produced. The direct producers, however, made a fairly good crop from which an excellent grade of wine was made. One of the noticeable features of the direct producers under observation was their tendency to produce fruit from the base of the vine to the extremities. Analyses are given of several samples of the grapes from direct producers, with reference to alcohol, acidity, must, skin, seeds, etc.

Improvements in methods of bench grafting, E. H. TWIGHT (*Pacific Fruit World, 17 (1904), No. 15, p. 11*).—Good results in the bench grafting of resistant varieties of grapes seem to be difficult to obtain owing to the care which must be taken in performing the numerous details involved. In this article the author describes quite completely the method, previously noted (E. S. R., 14, p. 1071), of packing the grafts in a mixture of moss and charcoal and forcing them into growth by the aid of artificial heat before transplanting them to the nursery.

It is believed by the writer that by this method from 50 to 75 per cent of the grafts made will be successful. Not only can this comparatively high percentage be obtained, but the necessity of wrapping the graft when made is done away with and a much better callus secured. It is proposed to undertake experiments at the California Experiment Station on a commercial scale along this line.

Influence of the soil on the composition of the tea leaf and the quality of the tea, I, A. W. NANNINGA (*Meded. 's Lands Plantentuin, 1903, No. [illegible], pp. [illegible]*).—The author refers to previous work on this subject, especially to that of Bamber and Mann. The former stated that the presence of iron compounds in the soil was favorable to a higher quality in the tea, while no relation could be found between the presence of phosphoric acid, potash, and lime in the soil and the quality of the tea.

The author took samples of tea leaves from several plantations having similar cli-

mate and altitude conditions but different soils. The leaves were gathered and at once dried in the sun. They were then sent to the laboratory, ground, and subjected to analysis for iron, nitrogen, phosphoric acid, silicic acid, caffein, and ash. The various soils from each plantation were also analyzed—the surface soil to 20 cm. deep, and the subsoil 20 to 50 cm. deep. Preliminary analysis of leaves of different ages, but all of proper age for gathering, showed that great care is necessary to have all the leaves of the same age, since some of the substances varied greatly with the age of the leaves.

Some of the conclusions of the author are as follows: (1) The chemical composition of the soil, especially the quantities of those substances taken up by the plant, has an influence clearly demonstrable by chemical analysis on the composition of tea leaves produced on such soil. (2) This influence is most clearly marked in the case of manganese, but also for phosphoric acid, lime, and magnesia. (3) In general, a soil poor in one of these plant foods produces leaves that contain less than an average amount of this substance, while soils that are rich in these plant foods produce leaves containing larger amounts of these substances, up to a certain maximum.—H. M. PIETERS.

Plants cultivated for the preparation of aromatic drinks. Tea, F. A. VON STÜRLER (*Cultura, 15 (1903), No. 177, pp. 174–188, pls. 2, figs. 4*).—This is a full discussion of tea culture, including botanical descriptions, soil and climatic requirements, propagation, insects and diseases, harvesting, pruning, drying, fermenting, and other matters connected with the preparation of tea; as well as with its testing, mixing, and packing.—H. M. PIETERS.

Coffee (*Der Kaffee. Berlin: Julius Springer, 1903, pp. VI+174, figs. 7, map 1*).—This book, which is issued by the Imperial Health Office, contains information on the botany and chemistry of coffee, methods of harvesting and preparing coffee for the market, the adulteration of coffee, physiological effects of coffee and coffee substitutes, and German laws relative to coffee and coffee adulteration. In addition, certain statistics are given on the production of coffee in different countries and on the consumption of coffee.

Cacao: Its culture and preparation, with special reference to Samoa, C. ETTLING (*Der Kakao. Berlin: Dietrich Reimer (Ernst Vohsen), 1903, pp. V+39, pls. 3*).—An account of methods of cacao culture in Samoa, from the planting of the seed to the fermentation and drying of the cacao beans.

Cocoa in Trinidad and Grenada, P. PREUSS (*Bul. Dept. Agr. Jamaica, 1 (1903), No. 4, pp. 73–76*).—This is a note taken from the recent report of Dr. P. Preuss (E. S. R., 14, p. 662) on the use of shade in the culture of cacao trees in these localities and on the methods of cultivation and pruning observed.

The culture of cacao and its enemies, L. KINDT (*Die Kultur des Kakaobaumes und seine Schädlinge. Hamburg: C. Boysen, 1904, pp. 157, figs. 38*).—This book is intended for the use of practical planters in the growing of cacao. It contains complete cultural directions, including the use of intercultural and leguminous crops and shade trees, and descriptions of the more injurious insects and fungus diseases affecting cacao, with recommendations as to methods for their control.

India rubber and gutta-percha, H. FALCONNET, T. SEELIGMANN, and G. L. TORRILHON (*London: Scott, Greenwood & Co., 1903, pp. 402, figs. 86*).—About two-thirds of this book is devoted to India rubber and one-third to gutta-percha. Both of these subjects are considered with reference to their historical, botanical, arboricultural, mechanical, chemical, and electrical aspects. Special emphasis has been laid on the chemistry and commercial uses of these materials. A bibliography of 404 sources of information on these subjects is appended. This is the English edition of the work, which has been translated from the French by J. G. McIntosh.

Rubber planting on the Isthmus of Tehuantepec, H. C. PEARSON (*New York: The India Rubber Pub. Co., 1903, pp. 27, figs. 45, map 1*).—This is a record of a journey

on the Isthmus of Tehuantepec in which a number of typical rubber plantations were visited and the methods followed in Castilloa rubber production observed. Considerable other information on the nature of the country, labor problems, etc., is included.

Para rubber seed (*Agr. News [Barbados], 2 (1903), No. 43, p. 392*).—A letter by F. J. Holloway is reprinted from the Agricultural Bulletin of the Straits and Federated Malay States, in which it is stated that an investigation was made as to whether the tapping of a Para rubber tree caused the seed to be of less value for planting than the seed obtained from trees which had not been tapped. After testing the matter with seeds from both tapped and untapped trees, his experience leads him to conclude that there is not the slightest difference in the resulting trees grown side by side for the past 4 years.

Para rubber extraction (*Jour. Jamaica Agr. Soc., 7 (1903), No. 10, pp. 401–404*).—Experiments by A. D. Machado are reported, in which it was found possible to tap Para rubber trees every second day for 6 months in every year without in the least hurting or impairing the growth of the tree and at the same time secure the greatest possible amount of latex.

Instead of the "herring-bone" gash, which is commonly used in tapping these trees, Mr. Machado found that the best results were obtained from a series of incisions not more than 1½ in. long and ⅛ in. wide. The flow of the latex has been found more copious on the morning of a day following a heavy shower of rain than on a dry day. In fact, in very dry weather it may be advisable to cease tapping altogether. Tapping is usually begun at 6 o'clock and continues for a half hour. At 7 o'clock the cups are gathered in and the latex passed through a sieve to insure cleanliness, after which a small amount of acetic acid is added to hasten coagulation and the latex then poured into enamel soup plates. Coagulation is usually complete within a half hour.

The English walnut in southern California, Elizabeth A. Ward (*Amer. Mo. Rev. of Reviews, 29 (1904), No. 168, pp. 64–67, figs. 4*).—This is a popular account of methods of growing English walnuts in southern California, and of harvesting, bleaching, and marketing the crop. It is stated that 1,500 lbs. of nuts per acre, or about 75 lbs. per tree, is a good average yield.

Walnut culture and walnut blight (*Pacific Fruit World, 17 (1904), No. 14, p. 12*).—The writer has found the greatest profit in walnut growing when the trees were set 40 ft. apart each way. The cost of producing nuts with trees this distance apart was at the rate of \$2.77 per cwt., with trees 44 ft. apart \$3, and with trees 50 ft. apart \$3.58 per cwt. An instance is cited in which the addition of lime at the rate of 20 tons of air-slaked lime from a sugar-beet factory greatly increased the yield of nuts.

In 1902 two sprayings with Bordeaux mixture, once just before the leaves came out and once after the nuts were well set, resulted in 50 per cent less of infected nuts than where trees were left unsprayed. In 1903 the same orchard sprayed but once, just before the trees leaved out, produced 34 per cent less of infected nuts than unsprayed trees. The cost of spraying a 12-year-old walnut orchard was 21 cts. per tree for the first spraying and 39 cts. per tree for the second. The cost of applying the spray, using a power sprayer, 6 men and 4 horses, was about ¼ ct. per gal. for material and labor.

Walnut and filbert growing, J. B. Pilkington (*Northwest Hort., 17 (1904), No. 1, p. 9*).—This is a paper read by the author before the Northwest Fruit Growers' Association, in which the growing of walnuts and filberts in Oregon is discussed. The author states that the culture of walnuts has spread from northern California into southern Oregon, and that this northward extension of walnut growing is based upon the use of the best French varieties, since these varieties are hardier in resistance to frost and to leaf burn from summer heat.

The varieties Praeparturiens, Franquette, Mayette, Chaberte, and Parisienne have all been successfully grown in Oregon. These varieties are all late bloomers and often bear full crops when the tender soft-shell varieties are destroyed by frost. The nuts are of good size and flavor, and while not as large as the paper and soft shell varieties, they are considered equally good. The trees are reported free from the bacteriosis which seriously affects soft-shell nuts in California. Trees come into bearing 6 to 8 years after planting.

Relative to filbert culture the author mentions 1 plantation in Oregon, planted with the Barcelona variety, in which the yield was upward of 15 lbs. of nuts per tree. At this rate filbert culture is believed to be more profitable than prune culture. Other good varieties of filberts are the red and white Avelene and the Du Chilly. They are described as good and prolific bearers, thin shelled, hardy, early, and free from pests.

Grafting chestnuts (*Amer. Agr.*, *72* (*1903*), *No. 24*, *p. 503*).—A writer states that in grafting chestnuts on sprouts in cut-over land he has secured a growth of 85 to 97 per cent of the scions set. The scions for grafting are cut late in winter and kept in moist sawdust in a cool place. Grafting takes place after freezing weather is over and the buds are just beginning to expand. Whip or tongue grafting is preferred. The graft should be well covered with grafting wax.

Relations of climate to horticulture, J. W. Smith (*Jour. Columbus Hort. Soc.*, *18* (*1903*), *No. 4*, *pp. 143–151*).—A number of tables are given. One table shows the monthly and annual mean temperatures at Wauseon, Ohio, for the years 1870 to 1902, inclusive; another shows the total monthly and annual precipitation from March 1871 to 1902, inclusive; and a third shows the dates of blossoming of apples, peaches, pears, plums, and cherries at that place for the years 1877 to 1903.

Report of the first meeting of the Society for Horticultural Science (*Amer. Gard.*, *25* (*1904*), *No. 466*, *pp. 25, 26*).—This is a report with abstracts of the papers and discussions presented at the recent meeting of the Society for Horticultural Science, held at St. Louis, December 28 and 29, an account of which is noted elsewhere (E. S. R., 15, p. 538).

On the use of ether and chloroform for the forcing of shrubs and of lilacs in particular, E. Lemoine (*Jour. Roy. Hort. Soc.* [*London*], *28* (*1903*), *No. 1–2*, *pp. 45–51*).—This is a review of European experimental literature on the forcing of plants by the use of ether and chloroform.

Tried to force by ether and failed, J. Hutchinson (*Amer. Gard.*, *24* (*1903*), *No. 463*, *p. 702*).—An account is given of an attempt made to force Lily of the Valley pips after subjecting them to etherization as a substitute for freezing. Well-matured pips were lifted before frost and the plumpest selected and treated to ether for 72 hours, after which they were put in a dark place and kept at a temperature of 80° with strong bottom heat. The results were not satisfactory, as the pips did not respond to the heat and moisture as they would have done had they been well frozen.

SEEDS—WEEDS.

The Georgia seed-growing industry, N. L. Willett (*Proc. Georgia State Hort. Soc.*, *27* (*1903*), *pp. 15–28*).—This is a popular account of the seed industry in Georgia. The cultural methods observed in growing crops for seed are given for the following plants: Collards, turnips, mustard, okra, pearl millet, cotton, oats, burr clover, chufas, asparagus, melons, second-crop Irish potatoes, beardless barley, rye, multiplying onions and shallots, Mexican June corn, Spanish peanuts, upland rice, Johnson grass, vetches, sorghum, cowpeas, Lima beans, peaches, etc.

The author holds that second-crop Irish potatoes which are obtained from plantings made in July or August are much better for seed in the Southern States than the best Maine-grown sorts.

Sainfoin, D. FINLAYSON (*Aynsome Agr. Sta., Grange-over-Sands, Cent. Seed-Testing Lab. Farmers' Bul. 4, pp. 7, figs. 8*).—A description is given of a sainfoin (*Onobrychis sativa*) and its variety, the giant sainfoin. Descriptive notes are given of the seed of sainfoin and the more common adulterants are briefly described. The seed of sainfoin should have a purity of at least 98 per cent and a germination of 88 to 90 per cent.

Report of the Seed Control Station at Lund, Sweden, for 1902, B. JÖNSSON (*Kvartalsskr. Malmöhus Läns K. Hushåll. Sälsk., 1903, No. 1, pp. 132–143*).

Report of the Wermland County Seed Control Station, Chemical Laboratory, and Milk Control Station at Molkom for 1902, J. A. ANDERSSON (*Red. Verm. Frökontrollanst. och Kem. Lab. Molkom, 1903, pp. 30*).

The weed problem: Some observations and experiments, E. KORSMO (*Tidsskr. Norske Landbr., 10 (1903), Nos. 6, pp. 247–280; 7, pp. 295–330*).—The material of this report is arranged in 2 parts, the first describing the author's observations in different Scandinavian countries, the second giving the results of his investigations in Norway.

Among the investigations the author reports on the influence of weeds on the yield and money value of different crops. These observations include 3 crops, grass, barley, and potatoes, grown on different plats, each comprising areas of the same size and same crop, one of which served as an example of clean land and the other of weed-infested land. The harvested product was carefully weighed and calculated to the yield per hectare, and the following results were obtained:

Effect of weeds on yield and money value of crops.

Crop.	Yield per hectare.		Percentage lost in money value.
	Clean.	Weedy.	
	Kg.	*Kg.*	*Per cent.*
Hay	6,180	[a]1,740 + 2,890	47
Barley:			
Grain	2,286	833	46
Straw	3,795	[a]1,735 + 2,407	
Potatoes	22,101	11,330	49

[a] Weight of weeds included with hay and straw.

Investigations were carried on to determine the number of viable weed seeds in a square meter of a fallow field to the depth of 25 cm. As determined by 3 different weedings, the viable weed seeds in the field investigated were 10,332 per square meter. In the field intended for spring grain, the same crop having been sown for 4 successive years, 33,574 viable seeds were found per square meter. In a third field, which was fallowed, the viable weed seeds found were 1,755.

Some experiments are reported on the effect of grinding screenings for the destruction of the weed seed. Two lots of mill screenings, which contained from 25 to 47 per cent weed seed, were ground and the samples examined for weed seeds. In 100 gm. of screenings thus ground only 1 weed seed was found capable of germination. A report is given on the number of seeds produced by different species of weeds and the effect of the use of unclean seed or grain on the distribution of weeds. The viability of different varieties of weed seeds is commented upon, and notes are given on the chemical composition of 18 weeds which were subjected to analysis.

Experiments were conducted on the use of barnyard manure as a source of weed distribution, and it was found that a considerable number of weed seeds go over in the solid feces in a viable condition.

A discussion is given on different methods of combating weeds, and in the opinion of the author no single treatment will suffice to destroy weeds completely, but the work must be continued from year to year with the means at hand.—F. W. WOLL.

An injurious weed, C. FRENCH (*Jour. Dept. Agr. Victoria, 2 (1903), No. 1, pp. 65–67*).—A description is given of St. John's Wort (*Hypericum perforatum*), which has become a serious pest in parts of Australia. Various suggestions are given for its eradication and estimates of the probable cost.

Some introduced species of dodder in Germany, W. KINZEL (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), No. 5. pp. 177–180*).—Notes are given on a number of species of Cuscuta which have been recently introduced into Germany in clover and other seeds. Among those mentioned are *C. planiflora*, *C. racemosa*, *C. lupuliformis*, *C. gronovii*, etc.

Concerning the germination of dodder seed, W. KINZEL (*Naturw. Ztschr. Land- u. Forstw., 1 (1903), No. 3, pp. 104–110*).—The results of the study of the germination of a number of species of Cuscuta are given.

DISEASES OF PLANTS.

The Granville tobacco wilt, F. L. STEVENS and W. G. SACKETT (*North Carolina Sta. Bul. 188, pp. 79–96, figs. 15*).—A preliminary account is given of a very destructive disease of tobacco which has made its appearance in Granville County, N. C. Inasmuch as there may be other wilt diseases found to affect tobacco plants, the authors purpose distinguishing this particular form under the name of the Granville wilt, and have stated that a preliminary description of the disease was given in a press bulletin issued by the station August 22.

The first indication of the disease is seen in the drooping of the leaves, which become soft and flabby as though suffering from want of water. The wilted leaves soon die and finally the whole stalk is destroyed. At the early stages of the disease a cross section of the stem shows a yellowish discoloration of the woody portion. In more advanced stages the wood is found to be filled with black streaks, and these become so abundant in the later stages that the woody tissue is almost entirely discolored.

The root seems to be the seat of the original infection, and any plant sufficiently advanced with the disease to show symptoms in its foliage will have its roots in an advanced stage of decay. The disease is most conspicuous in the largest roots, but the smallest fibers on close examination are similarly affected. When all the roots of the plant are diseased the death of the plant naturally follows very quickly, and in such cases the progress of the disease in the stem is cut off by the death of the plant. If only one root be affected, the disease in the stem will be on the side nearest the affected root. The spread of the disease is much more rapid in a longitudinal than in a transverse direction.

There are said to be a number of diseases of tobacco which are recognized by tobacco growers, but the Granville wilt may be readily distinguished by the diseased roots and the black streaks in the wood. Corroborative evidence is at hand which seems to show that the disease increases in severity year by year after the first infection in a field. It is further noticed that soil once seriously affected may recover to some extent if tobacco should not be raised on the ground for a number of years. The disease may be carried from an affected field to one lying below it by the flood water which has been contaminated on the upper field. In the region covered by this report tobacco is the chief money crop, and as some fields are almost entirely destroyed, the loss is very great.

The history of the observation of the disease and its distribution are briefly outlined, and a number of factors are suggested as to its probable cause. As a result of a careful examination, the authors have found the blackened portions of the root, stem, and leaves to be filled with bacteria. They are never present in healthy parts of the plant, but being so abundant in the diseased portions it is strongly believed that these germs cause the Granville wilt. This hypothesis can not be definitely

established, however, until the disease has been artificially produced by the inoculation of healthy plants. Various methods of carrying on investigations are suggested, and notes given as to the length of time which the organisms are able to survive in the soil.

As means of preventing loss, the authors suggest the destruction of the diseased plants, great care in preventing infection through soil carried on implements or the feet of animals from infected to other fields, crop rotation, and the planting of resistant varieties of tobacco.

The wilt disease of tobacco and its control, R. E. B. McKenney (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 51, pt. 1, pp. 6, fig. 1*).—A description is given of the wilt disease of tobacco, which has been under observation for some time in North Carolina. The disease makes its appearance when the tobacco plants have attained about one-third of their growth, and the first evidence of the disease is the sudden wilting or drooping of one or more of the leaves. This is followed by the wilting of other leaves, and later the stem blackens and rots, the plant being destroyed.

The cause of this disease is said to be similar to that which causes the wilt of cotton, watermelon, and cowpea and, as shown by comparison with these diseases, the Fusarium to which the disease is attributed, gains entrance to the plant through the fine roots. It is a soil fungus, and for its eradication all diseased plants should be collected and burned. Tobacco and other susceptible crops should be cultivated in long periods of rotation, and as an additional means of getting rid of the fungus in the soil the author recommends autumn plowing and burning of the stubble. Breeding resistant varieties is thought to possibly be of value and experiments along this line are under way. As an additional precaution it is recommended that no fertilizers containing kainit or muriate of potash be used. Observations and experiments on this disease are being continued, and it is hoped that some definite method of control may be discovered in the near future.

The mosaic disease of Sumatra tobacco. I, Report of experiments conducted at Deli during 1901–2 on the mosaic disease, F. W. T. Hunger (*Meded. 'S Lands Plantentuin, 1903, No. 63, pt. 1, pp. 103*).—The report is given in 3 chapters, covering the field work, the laboratory work, and the discussion of remedies and preventives, respectively.

The field experiments were designed to show whether various methods of treating the seedlings and mature plants did or did not influence the occurrence of the disease. A number of seedlings were transplanted 1, 2, or 3 times before being finally planted in the field, but it was found that this had no effect upon the occurrence of the disease. Seedlings that were pulled while the soil was dry and transplanted were afterwards more seriously affected than seedlings that were pulled out of wet soil.

At different ages plants were topped to determine the effect of this operation upon young and older plants. It was shown that of plants topped at 3 weeks of age the percentage of diseased plants was less than when the plants were topped at 6 weeks of age. But it also developed that out of 1,200 plants on new ground not one developed the disease, though they were topped at ages varying from 2 to 6 weeks.

Cuttings from healthy and from diseased plants were rooted. Those from the diseased plants did not flourish and all developed the disease, but while those from the healthy plants grew well every plant subsequently became diseased. When scions from diseased plants were grafted upon healthy stems the old leaves on the healthy stems did not become diseased, but all the new growth on the old stems was diseased. Scions from healthy plants grafted upon diseased stems developed the disease immediately after the union was formed.

Tests were made to determine the effect of fertilizers, potassium nitrate and ammonium sulphate being tried. These were applied at the time of seeding and also at the time of transplanting, but no marked effect could be noticed. Observations made to

determine whether diseased plants became centers for the further spread of the disease showed that they did not.

An effort was made to determine whether weather conditions were influential in connection with the occurrence of the disease. The results were not conclusive, but it is pointed out that more diseased plants were found after a heavy rainfall and a day of high temperature than at other times.

While the author recognizes the fact that the disease can be caused by the injection of sap from diseased plants into healthy ones, he denies that the disease can be communicated by the external application of the diseased sap, provided care is taken that the diseased sap does not run down the stem and get into the soil among the roots.

To determine whether the seed used influenced the presence of the disease, seeds were selected from healthy and from diseased plants, but no marked difference was observed in the results. In a test with small, large, and medium-sized seeds it was found that the medium-sized seeds produced the smallest percentages of diseased plants, while the number of diseased plants from the large and small seeds was about equal.

In regard to the cause of this disease the author, while admitting that it is physiological, contends that it is not due to the retarding effect of oxydase and peroxydase on diastatic ferments. He has previously maintained that the apparent excess of oxidizing enzyms in the diseased leaf was really due to the smaller amount of sugar, tannin, and organic acids contained in these leaves, as compared with that contained in healthy leaves, and in the present paper he states that these enzyms do not retard the conversion of starch into sugar. Ten cc. of a solution giving a strong reaction with guaiac were added to 25 cc. of potato starch in 1 per cent solution, and 20 mg. pure diastase and an equal amount of the same oxydase solution, after being heated at 110° for half an hour, was added to a like amount of starch and diastase. The heated solution gave no reaction with guaiac. The conversion of the starch into sugar proceeded with the same rapidity in both cases, the active oxydase in the one solution having no retarding effect.

Believing that the retarding effect observed by some authors was due to the presence of tannic acid, the author prepared a solution of this acid from the alcoholic extract of tobacco leaves and added this to the oxydase solution. In one case this was heated so as to precipitate the tannic acid and thus render it inactive. The results showed that in the solution containing the unheated tannic acid the conversion of the starch proceeded much more slowly than in the other solution, thus confirming his opinion. He also maintains that oxidizing enzyms will not diffuse and hence can not be taken up by the roots of plants.

The author is unable to throw light on the nature of the disease. In general he attributes it to the inability of the thin-leaved Deli tobacco to withstand unfavorable external influences, or, in other words, to the constitutional weakness of a close-bred strain, by reason of which the physiological processes are disturbed by unfavorable surroundings. He admits, however, that he is unable to explain the phenomenon of infection, and that his explanation of the disease is incomplete. The remedy suggested is to breed resistant plants.—H. M. PIETERS.

Fungus diseases of cotton, L. LEWTON-BRAIN (*West Indian Bul., 4 (1903), No. 3, pp. 255–267, figs. 3*).—Descriptions are given of a number of fungus diseases of cotton, the information being largely drawn from publications of this Department, the Alabama Station, etc.

A fruiting stage of Rhizoctonia solani, F. M. ROLFS (*Science, n. ser., 18 (1903), No. 466, p. 729*).—While studying the Rhizoctonia of the potato, the author became convinced that the fungus is not a sterile one, as has been frequently claimed, and much time has been given to a study of the fruiting stage.

Observations show that potato plants developed from tubers which are more or less covered with sclerotia of this fungus usually have their subterranean parts covered with a dark-brown cobweb-like mycelium. This covering frequently extends up the green stems 1 to 3 in., or more, above the ground, forming a thin layer of a greenish-white color. This layer does not adhere firmly to the stem and cracks easily when it becomes dry; consequently it disappears soon after the death of the plant. The tip of the outermost branches of this layer produced spores. Thus far pure cultures of the fungus have not been directly obtained from the spores, but cultures made from the hymenial layer invariably produce a luxuriant growth of Rhizoctonia.

The character of the fungus agrees on the one hand with *Corticium vagum*, and on the other hand with *Hypnochus solani*, and it is thought that probably these 2 species may eventually prove to be the same.

The formalin treatment for wheat and oat smut, R. K. BEATTIE (*Washington Sta. Bul. 54, pp. 8*).—The author estimates the losses in 1902 to the oat and wheat harvest, in Washington, due to smut, at $2,500,000. Notes are given on various individual losses, followed by a brief popular description of the smuts attacking the cereals.

Soaking the seed grain for a few minutes in copper-sulphate solutions is quite extensively followed, but the investigations of the author show that the treatment is not sufficiently prolonged. Instead of dipping the grain and allowing it to remain in the solution from 5 to 20 minutes, as is the common practice, the author suggests that the soaking should be for at least 12 hours. A better treatment, however, is recommended in the substitution of formalin solution for the copper-sulphate solution. The method of treatment is described in detail.

"Takeall" and "whiteheads" in wheat crops, W. L. SUMMERS (*Jour. Agr. and Ind. South Australia, 7 (1903), No. 5, pp. 297–299*).—Notes are given on the disease of wheat which has been determined to be caused by the fungus *Ophiobolus graminis*. This fungus has been the cause of considerable loss in various parts of the country, and while in Europe it is said that the use of phosphates has been beneficial in reducing the amount of disease, their use in Australia has not been followed with a reduction of loss. The greatest benefit has been found by burning over the stubble fields prior to plowing.

Uredinous infection experiments in 1903, W. A. KELLERMAN (*Jour. Mycol., 9 (1903), No. 68, pp. 225–238*).—In continuation of experiments reported for 1902 (E. S. R., 14, p. 530), the author has carried on experiments with various species of rusts during 1903, 22 species being used and 9 successful inoculations secured. As in the former investigations, very early inoculations have proved advantageous in this kind of investigation.

The occurrence of Puccinia phragmitis in Nebraska, J. M. BATES (*Jour. Mycol., 9 (1903), No. 68, pp. 219, 220*).—The author reports having found æcidia, which proved to be *Puccinia phragmitis* on rhubarb in Nebraska, which appears to be a new host for this country. By subsequent investigations a number of species of Rumex were found affected in a similar way.

Letters on the diseases of plants, N. A. COBB (*Agr. Gaz. New South Wales, 14 (1903), No. 10, pp. 955–986, figs. 31*).—The author discusses apple canker, peach curl, various diseases of citrus fruits, diseases of passion vines and walnuts, leaf curl of the potato, and various root rots and timber rots. So far as known remedies are given for these different pests.

A method for rendering cucumber and tomato plants immune against fungus parasites, G. MASSEE (*Jour. Roy. Hort. Soc. [London], 28 (1903), No. 1-2, pp. 142–145*).—Cucumbers and tomatoes grown under glass are highly susceptible to disease, the principal reasons for which are the soft foliage and the presence of fungi

and nematodes in the soil. The author briefly describes a number of the more common diseases to which these plants are subject, and gives an account of experiments conducted with the object of ascertaining whether substances taken up by the roots of the plants would not render them immune to the attacks of fungus parasites. Among the various substances tested copper sulphate alone proved adapted to the conditions of the experiment.

Cucumber and tomato seed were sown, and the plants grown in the house having a mean temperature of 75° F. Three hundred seedlings of each kind were subjected to the experiment, 50 of each being used as check plants. When the seedlings were about 2 weeks old the cucumbers were grouped around a number of large cucumber plants badly attacked with disease, and tomato seedlings in a similar way about diseased tomato plants. At this period the treatment consisted of watering the plants every third day with a solution containing 1 part of copper sulphate in 7,000 parts of water. The check plants, which were not watered with the copper solution, were indiscriminately mixed with the treated plants.

After a month's treatment all the tomato plants were perfectly free from disease, while one or both cotyledons of 34 of the cucumber plants showed symptoms of disease. At the same time a considerable number of the untreated plants of both kinds were affected. At this stage both treated and check plants were sprayed with water containing spores, causing their respective diseases and under this treatment all the check plants became badly diseased within 2 weeks. After 6 weeks' treatment with solution of copper sulphate of the strength above indicated the solution was increased to 1 part of copper sulphate and 6,000 parts of water and the soil about the plants soaked every fourth day until the end of the experiment, which lasted for 11 weeks. At this time both cucumber and tomato plants were bearing good crops of well-matured fruit. Not a single tomato plant treated with copper-sulphate solution showed a trace of disease and in the case of the cucumber plants the disease never progressed beyond the cotyledons, as noted above. An examination was made of the fruits of both tomato and cucumber and only slight traces of copper sulphate were present.

The author calls particular attention to the fact that so far as his experiments have been conducted the above method of treatment secures immunity against fungus parasites when applied to cucumbers and tomatoes only. Upon other plants markedly different effects were observed. *Luffa ægyptiaca*, a plant closely allied to the cucumber, was killed by 2 waterings of a solution of 1 part copper sulphate and 6,000 parts of water. On the other hand, barley remained perfectly healthy when treated with a solution of 1 part in 500, and in addition became badly affected by the grass mildew, *Erysiphe graminis*. As a proof that the solution of copper sulphate is absorbed by the plants, the author quotes experiments with garden nasturtium, where the effect of too strong a solution was shown by the bleaching of the tissues surrounding the water stomata. Grasses similarly treated showed a like bleaching of the tips of the leaves.

Danger arising from the presence of fungi or nematodes in the soil may be guarded against by sterilizing the soil with gas lime.

Tomato leaf spot, D. McAlpine (*Jour. Dept. Agr. Victoria, 2 (1903), No. 1, pp. 70, 71, pl. 1*).—A description is given of the tomato leaf spot due to attacks of *Septoria lycopersici*. This disease has become quite prevalent in parts of Australia, occasioning considerable loss. Its effect as produced upon the host plant is described, and based on suggestions given in Alabama Bulletin No. 108 (E. S. R., 12, p. 569), spraying with Bordeaux mixture is recommended for its prevention.

An apricot blight, W. Paddock (*Colorado Sta. Bul. 84, pp. 14, pls. 2, figs. 2*).—The author's attention was called to a disease of apricots in the fall of 1902, the injury greatly resembling that caused by the common pear blight. A careful examination of the diseased tissues and inoculation experiments showed that the apricot blight

is of bacterial origin and due to the same organism as that causing the fire blight of pears. The detailed results of his experiments are given. As preventive treatment the author suggests the pruning of the diseased portions of the trees and attention given to prevent infection being carried from one tree to another.

Collar rot of citrus trees (*Jour. Jamaica Agr. Soc., 7 (1903), No. 11, pp. 435–438*).—A description is given of a disease of citrus trees attributed to *Fusisporium limoni*. This disease may be recognized by an exudation of gum at the collar of the plant, the decay of the bark in patches, and the subsequent disagreeable odor, as well as by the unhealthy appearance of the foliage and the death of the small shoots. The effect of imperfect drainage, close planting, improper propagation, etc., as contributing to this disease are described, and various methods of prevention are given. Based upon experiments which have been conducted in Florida, the author recommends washing the trees with solutions of sulphurous acid, carbolic acid, or a sulphur wash, a formula for which is given.

Canker in cacao (*Jour. Jamaica Agr. Soc., 7 (1903), No. 11, pp. 450, 451*).—Based upon successful practice in Ceylon, rules are given for the prevention of canker in cacao, which include the thinning of shade so that sun and air can reach all parts of the trees, the destruction of all diseased parts, and careful attention to the subsequent development of the trees.

Pests of orchard and fruit garden, M. C. COOKE (*Jour. Roy. Hort. Soc. [London], 28 (1903), No. 1–2, pp. 1–44, pls. 3, figs. 10*).—Descriptive notes are given of a large number of diseases of orchard and garden fruits and, so far as known, methods of treatment are suggested.

Root diseases of fruit and other trees caused by toadstools, C. V. PIPER and S. W. FLETCHER (*Washington Sta. Bul. 59, pp. 14, figs. 5*).—According to the authors, the prune growers of Washington have suffered severe loss by the death of their trees, and an examination showed that the injury was quite similar to that observed in young orchards after a hard winter. The trees bore the appearance of having been frozen, the inner bark being killed at the collar of the plant. An examination of specimens showed, however, that the trees were infested with rhizomorphic strands of a fungus, which was later determined to be *Armillaria mellea*. The effect of this fungus on the tree as shown by the appearance of the leaves, roots, and trunks is described. A careful examination of the diseased trees shows the presence of the black strands just beneath the ground, and later the fruiting stage or the mushrooms appear.

The extent of injury due to this fungus is indicated in statements made regarding the losses in a number of orchards, nearly one-half the trees in one orchard having died within the last few years. A brief description is given of the fungus and its distribution. With a single exception, it has only been observed to attack prune trees. As the disease has not a wide distribution, the authors suggest the pruning of all diseased trees and care in subsequent planting. The trees should be kept in a healthy, vigorous growth by good culture, and under no circumstances should the mushroom form be allowed to be produced on the trees, as it is through these that the wide distribution of the disease takes place.

A second form of root disease is described, which is attributed to another form of *Armillaria mellea* which attacks wild cherry, crab apple, maple, and fir trees. This fungus differs from the previous one in the bulbous enlargement of the base of the fruiting form. The injury caused by this rot is not as severe as that previously described, and at present no serious loss is anticipated from this source. A technical description of the fungus is given.

A leaf-curl disease of oaks, E. M. WILCOX (*Alabama College Sta. Bul. 126, pp. 171–187, pl. 1, figs. 3*).—This bulletin is designed to call attention to one of the fungus diseases of oak trees that threatens to destroy many of these trees, particularly in cities and towns. The disease makes its appearance early in the spring before the

new leaves are mature. At this time gray or bluish spots appear on the leaf, and by the rapid growth of the leaf at these points the surface becomes convex on one side and concave on the other. In some of the narrow-leaved species of oaks the spots become confluent over a large portion of the leaf, so that it is as badly curled as in the case of the peach-leaf curl, which is due to a closely related parasite. By the rapid spread of the disease from leaf to leaf partial or complete defoliation of the tree may occur early in summer. This defoliation has a weakening effect upon the tree and a cumulative effect may result in the final destruction of the tree.

The fungus causing the disease has been determined as *Taphria cærulescens*, a description of which is given. The fungus is not perennial within the tissues of the host plant, and experiments with Bordeaux mixture have shown that it can be successfully combated by 3 or 4 sprayings of that fungicide. The applications should be begun early in the season and continued until the leaves have attained their mature size. A list is given of 10 species of oaks which are known to have been infected by this fungus, and the distribution of the parasite throughout the State of Alabama and the United States is indicated. A bibliography of the more important articles relating to the disease concludes the bulletin.

Dead horse-chestnut trees, M. C. Cooke (*Jour. Roy. Hort. Soc.* [*London*], *2*[illegible] (*1903*), *No. 1–2, p. XXII*).—A brief report is given of the destruction of horse-chestnut trees, which is believed to be due to *Stereum purpureum*, although it does not appear that this species has been hitherto recognized as causing the destruction of forest trees. A related species, *S. hirsutum*, which is common as a saprophyte, is also known to become parasitic and it is thought probable that the species in question has the same faculty.

ENTOMOLOGY.

The enemies of agriculture, A. L. Herrera (*Las plagas de la agricultura. Mexico: Ministerio de Fomento, 1903, pp. 435–626, pls. 9, figs. 18*).—This is a continuation of the author's general work on the subject of insect pests and fungus diseases (E. S. R., 14, p. 467). Notes are presented on the insect pests of beans, peas, and other legumes, and on insects injurious to corn, apples, citrus fruits, olives, pear, pine, and other forest trees, and cultivated plants. A discussion is also presented on mosquitoes, grasshoppers, the use of parasitic fungi in the destruction of insects, and San José scale.

Entomology and agricultural parasitology, G. Guénaux (*Entomologie et parasitologie agricoles. Paris: J. B. Baillière & Sons, 1904, pp. XII+588, figs. 390*).—This volume constitutes one of a general series entitled Agricultural Encyclopedia, and edited by G. Wery. The subject-matter includes a description of the various forms of lower animals which are injurious to crops and domesticated animals. The pests discussed in the volume include protozoa, worms, mollusks, myriapods, arachnids, and insects. The injurious insects are classified according to their systematic position and also according to the crops, animals, or products which they attack. Chapters are also presented on beneficial insects and on remedies for controlling injurious species.

Report of the chief inspector of nurseries and orchards, A. F. Burgess (*Columbus: Ohio State Bd. Agr., 1902, pp. 34, figs. 8*).—Brief notes on the inspection work of the Ohio State Board of Agriculture during the year 1902, with statistical data concerning the number of trees and amount of nursery stock inspected and the remedies recommended. Brief notes are also given on peach yellows, black knot, cankerworm, gypsy moth, and San José scale. A copy is given of the nursery and orchard inspection law of Ohio, together with a list of nurserymen of the State, and an appendix in which remedies for various fungus and insect pests are described.

Insects injurious and beneficial, E. P. Venables (*Rpt. Supt. Farmers' Insts. British Columbia, 4* (*1902*), *pp. 45–48*).—During the season of 1902 plant lice, espe-

cially the apple plant louse, were unusually abundant, but they were somewhat reduced during the latter part of the season by the presence of parasites. Plant lice also occurred in large numbers on hops and other cultivated plants. Notes are presented on San José scale, cutworms, grasshoppers, wireworms, etc.

Report of the entomologist, W. W. Froggatt (*Agr. Gaz. New South Wales, 14 (1903), No. 9, pp. 797–803, pl. 1*).—A short account of the operations of the entomologist during the past year. Brief mention is made of the Hessian fly, codling moth, woolly aphis, fowl tick, botfly, various scale insects, locusts, bumble bees, and other species.

Insectarium notes and insects found about the Hawkesbury College, W. W. Froggatt (*Agr. Gaz. New South Wales, 14 (1903), No. 10, pp. 1019–1027, pls. 2, fig. 1*).—Economic and biological notes are presented on *Protoparce convolvuli, Earias fabia, Teia anartoides, Ocinara lewinæ, Gelechia simplicella* on soy beans, *Pentadon australis, Aleurodes vaporariorum, Heliothrips hæmorrhoidalis,* etc.

Report of the inspectors under Vegetation Diseases Act, J. Martin, Jr., et al. (*Agr. Gaz. New South Wales, 14 (1903), No. 9, pp. 870–875*).—Statistics are presented on the quantities of fruit, nursery stock, etc., reported at various points and inspected by various officials. The greater part of this material was fumigated with hydrocyanic-acid gas, and in this connection notes are presented on the extent of infestation of fruits and trees with San José scale.

Fruit and plant inspection, G. Quinn (*Rpt. Min. Agr. South Australia, 1903, pp. 23–26*).—A report is presented on the progress of orchard and garden inspection in various parts of South Australia and on the inspection of imported fruit and nursery stock. Particular attention is devoted to a discussion of the codling moth and *Aspidiotus coccineus.*

Report of the entomologist and vegetable pathologist, H. Tryon (*Queensland Agr. Jour., 13 (1903), No. 5, pp. 460–466*).—Brief notes are given on a large number of injurious insects and fungus diseases which prevailed during the year. The author also calls attention to the collections and educational work of his department.

Injurious insects and other animals observed in Ireland during the year 1902, G. H. Carpenter (*Econ. Proc. Roy. Dublin Soc., 1 (1903), IV, No. 9, pp. 195–218, pls. 2, figs. 7*).—*Hepialus humuli* is reported as injurious to oats and potatoes. The use of gas lime and deep plowing are recommended in the control of this insect. Notes are also given on crane flies, wheat-bulb fly, carrot fly, *Pegomyia betæ, Enchytræus parvulus,* rose sawfly, wood lice, *Syagrius intrudens* on ferns, *Cryptococcus fagi* on beets, Mediterranean flour moth, *Anobium paniceum, A. domesticum,* and *Tyroglyphus longior.*

Insects injurious to fruits and garden vegetables, J. Wortmann (*Ber. K. Lehranst. Wein, Obst- u. Gartenbau, Geisenheim, 1902, pp. 203–215, figs. 6*).—Economic and biological notes on *Ramphus flavicornis* and nematode worms in fig leaves. Brief notes are also given on beneficial insects and on a method of controlling *Tortrix ambiguella.* Since the pupæ of this insect pass the winter in various sheltered locations it was found necessary to destroy them on the stakes used in vineyards. For this purpose the stakes were temporarily removed, tied in bundles, and dipped in boiling water for a period of 3 to 5 minutes. Good results were obtained by this treatment.

British Tyroglyphidæ, A. D. Michael (*London: Ray Society, 1903, vol. 2, pp. VII + 183, pls. 20*).—This volume completes the author's monograph on this family of mites. A detailed index is presented covering the matter in both volumes, together with a bibliography of literature relating to the subject and a list of foreign species of Tyroglyphidæ. Descriptions are given of species belonging to various genera, including Chortoglyphus, Fusacarus, Trichotarsus, Hericia, Tyroglyphus, etc.

A monograph of the Cynipidæ of Europe and Algeria, J. J. Kieffer (*Monographie des Cynipides d'Europe et d'Algérie. Paris: A. Hermann, 1903, vol. 2, No. 1,*

pp. 288, pls. 9). In this part of the author's monograph of the Cynipidæ the following subfamilies are discussed: Allotriinæ, Eucoelinæ, and Figitinæ.

The larvæ of Trichoptera, R. STRUCK (*Mitt. Geogr. Gesell. Naturhist. Mus. Lübeck, 2. ser., 1903, No. 17, pp. 43–124, pls. 7*).—A detailed description of the more important anatomical features, habits, and life history of various species of this group.

Observations on wasps, C. JANET (*Observations sur les guêpes. Paris: C. Naud, 1903, pp. 85, figs. 30*).—A discussion is presented on the anatomical details, feeding habits, life history, parasites, and construction of the nests of *Vespa crabro*, *V. media*, *V. silvestris*, *V. saxonica*, *V. rufa*, and other species of this genus and also of Polistes.

Biology of the genus Chermes with special reference to C. piceæ, O. NÜSSLIN (*Verhandl. Naturw. Ver. Karlsruhe, 16 (1902–3), pp. 3–20*).—As a result of the study of *Chermes piceæ* and other species of this genus the author comes to the conclusion that *C. piceæ* is reproduced parthenogenically and that the disadvantages of this form of reproduction are partly overcome by the existence of a long-lived larval form.

How to combat the Mexican cotton-boll weevil in summer and fall, E. D. SANDERSON (*Texas Sta. Circ. 4, pp. 4*).—The remedies for this insect, as mentioned by the author, consist in growing an early maturing cotton, and in destroying the beetles by grazing the cotton with cattle and pulling and burning stalks which are unused. It is also recommended that the land be plowed deeply in late fall or early winter.

Insects attacking cotton in the West Indies, H. A. BALLOU (*West Indian Bul., 4 (1903), No. 3, pp. 268–286, figs. 4*).—Economic and biological notes are presented on cotton worm, bollworm, Mexican cotton-boll weevil, cotton-plant louse, scale insects, cutworms, grasshoppers, *Dysdercus andreæ*, *D. annulliger*, species of Phytoptus, etc.

Some insects attacking the stems of growing wheat, rye, barley, and oats, with methods of prevention and suppression, F. M. WEBSTER (*U. S. Dept. Agr., Division of Entomology Bul. 42, pp. 62, figs. 15*).—The chief purpose of this bulletin is to present descriptions and notes on the habits and life history of a number of small insects of cereal crops. The injury due to these insects has frequently been mistaken for the attacks of the Hessian fly. The species specially considered in the bulletin are *Isosoma grande*, *I. tritici*, *I. hordei*, *I. captivum*, *I. websteri*, *I. hirtifrons*, *I. secale*, *I. fitchii*, *Meromyza americana*, *Oscinis carbonaria*, and *O. soror*.

In connection with a discussion of each one of these species various suggestions are made regarding cultural methods which will materially assist in controlling the pests. According to the author's observations it may be stated as a general rule that the same remedies which tend to hold the Hessian fly in check are effective against other small cereal insects. The cultural remedies most confidently recommended include the destruction of grass and other plants on which these pests may live in the neighborhood of grain fields, rotation of crops, burning of stubble, and late seeding.

A brief account of the principal insect enemies of the sugar beet, F. H. CHITTENDEN (*U. S. Dept. Agr., Division of Entomology Bul. 43, pp. 71, figs. 65*).—This material has already been abstracted from another source (E. S. R., 15, p. 379).

Catalogue of the Museum of the Experiment Station for Sugar Cane in West Java, W. VAN DEVENTER (*Proefstat. Suikerriet West Java, Bul. 6, 1903, pp. 46, pl. 1*).—A list is presented of the varieties of sugar cane in the museum and of the species of insects and other injurious animals and fungus diseases which occur on sugar cane. The different species of insects and fungus pests are briefly described and recommendations are given regarding the best methods for combating them.

The sugar-cane borer (Chilo simplex), E. P. STEBBING (*Indian Mus. Circ. Agr. Econ. Ent., No. 3, pp. 6, figs. 2*).—This insect may be controlled by cutting out and destroying infested canes and burning or burying all discarded tops and refuse after the crop has been cut over.

The Bengal rice hispa (Hispa ænescens), E. P. Stebbing (*Indian Mus. Circ. Agr. Econ. Ent., No. 2, pp. 4, fig. 1*).—This insect may be controlled in the rice nursery by spraying the young seedlings with Paris green or some other arsenical.

The rice sapper (Leptocorisa acuta), E. P. Stebbing (*Indian Mus. Circ. Agr. Econ. Ent., No. 1, pp. 4, figs. 2*).—Notes are given on the distribution, food plants, and injury caused by this insect. It is preyed upon to some extent by tiger beetles. The remedy recommended by the author consists in the use of a winnowing apparatus smeared with any sticky substance. This apparatus can be brushed over the heads of the rice and will thus remove a large proportion of the insects.

The cutworm (Agrotis ypsilon), E. P. Stebbing (*Indian Mus. Circ. Agr. Econ. Ent., No. 6, pp. 5, fig. 1*).—According to the author's experience this insect may be controlled by the use of poison baits and by direct application of London purple or some other arsenical in a dry form, mixed with lime and ashes.

Observations on the sunflower—its attraction for the fiddler beetle, J. Neish (*Jour. Jamaica Agr. Soc., 7 (1903), No. 8, pp. 321, 322*).—According to the author's observations the fiddler beetle may be readily attracted to sunflowers and may be destroyed on this plant. By sowing sunflower seed around groves of citrus fruits the damage to these fruits may be somewhat checked.

A new jointworm parasite from Russia, W. H. Ashmead (*Canad. Ent., 35 (1903), No. 12, pp. 332, 333*).—*Homoporus vassiliefi* is described as a new species parasitic upon *Isosoma eremitum*.

Seventeen-year locusts in Kentucky, H. Garman (*Kentucky Sta. Bul. 107, pp. 81–100, pls. 4, figs. 3*).—The distribution of the periodical cicada in Kentucky is indicated by counties in connection with a map showing the relative prevalence of this insect. The cicada was found to be especially fond of the black locust for the deposition of its eggs. Notes are given on the injury done by the cicadas and on the time of their appearance and disappearance. The species recognized by the author as occurring in Kentucky are *Cicada pruinosa*, *C. septendecim*, *C. cassinii*, and *C. tibicen*. All these species are described. Notes are given on the life history of the periodical cicada and on the broods which are known to occur in Kentucky. The most important natural enemy of the cicada in Kentucky is *Massospora cicadina*.

The migratory locust (Acridium peregrinum), E. P. Stebbing (*Indian Mus. Circ. Agr. Econ. Ent., No. 5, pp. 9, figs. 5*).—The habits and life history of this species are briefly described. In controlling the insect the author recommends plowing the soil so as to bury the eggs, crushing and burning the young grasshoppers, and the use of extensive smudges.

How to destroy locusts (*Transvaal Agr. Jour., 1 (1903), No. 2, pp. 44–46*).—The methods recommended for the destruction of locusts include the use of screens and pits, locust fungus, and arsenical poisons. The screen and pit system consists of stretching screens made of cheap cloth for any desired distance in a straight line and digging pits at intervals of about 10 yards along the length of the screens. The locusts fall into the pits in searching for a way around the screens, and are prevented from crawling out by zinc bands placed around the opening of the pits. This method is applicable only to the earlier stages before the locusts are able to fly. Locust fungus is said to be effective only when the air is damp. Good results have been obtained in spraying with a mixture of arsenic, soda, and sugar.

Platyparea pœciloptera and its injuries to asparagus, A. Giard (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 24, pp. 907–910*).—The larvæ of this fly mine into the stems of asparagus in longitudinal channels and cause serious damage. The injury produced by this insect has perhaps been in many cases attributed to the attacks of asparagus beetles. The only natural enemy of the insect as observed by the author is a species of myriapod.

Spraying for the San José scale with modifications of the sulphur-salt-lime wash, and chemical notes on this wash, C. V. Piper and R. W. Thatcher

(*Washington Sta. Bul. 56, pp. 31*).—Extensive experiments were made with various modifications of the California and Oregon washes on orchards, including peach, pear, prune, plum, apple, cherry, and apricot trees. During these experiments nearly 20 formulas for these washes were employed, varying in composition from 1 to 1½ lbs. of lime and 2 to 8 gals. of water for each pound of sulphur.

In conversation with orchardists it was found that a great many modifications of the published formulas have been used on a large scale, the purpose of the modifications being to secure more effective formulas. Nearly all formulas, except the most dilute, were quite effective. It was found that after the application of the lime-sulphur wash many of the female insects came out from under the scale, but all of these insects were found to die without reproducing. The criteria relied upon in determining the death of the scale were a change of color from a pale yellow to a dull orange and a shrivelling of the body. A series of laboratory experiments with various insecticides was carried out by R. E. Snodgrass. As a result of all these experiments it is recommended that the formula of the wash be 1 lb. sulphur, 1 lb. lime, and 4 gals. water, and that the salt be omitted.

Potash lye alone was found to be ineffective and injurious to peach trees. The lime-sulphur wash is just as effective when applied cold as hot. Kerosene or crude California distillate petroleum was effective as a summer spray when used in strengths of 10 and 12 per cent. Pear and peach trees were injured by the lime-sulphur wash when this remedy was applied to young leaves. A chemical study of the lime-sulphur wash showed that, after the union of the sulphur and lime products is complete, the excess of lime remains in the form of milk of lime or whitewash.

A monograph of the Coccidæ of the British Isles, R. Newstead (*London: Ray Society, 1903, vol. 2, pp. VIII+270, pls. 42, figs. 7*).—This volume completes the author's monograph on this subject. The first volume has already been noted (E. S. R., 13, p. 968). The number of species of Coccidæ found in the British Isles is 88, together with 4 varieties, and of this number 51 species and 2 varieties have apparently been introduced from foreign countries. The genera treated in this volume include Lecanium, Pulvinaria, Kermes, Dactylopius, Ripersia, Orthezia, etc.

The date-palm beetle (Oryctes rhinoceros), E. P. Stebbing (*Indian Mus. Circ. Agr. Econ. Ent., No. 4, pp. 5, fig. 1*).—This insect appears to have no important natural enemies. The destruction of dead and decaying trees, removal and destruction of rubbish, and the destruction of grubs of beetles which may be found about the roots of trees are recommended for controlling this pest.

The orange weevil, E. S. Panton (*Bul. Dept. Agr. Jamaica, 1 (1903), No. 11, pp. 249–253, figs. 2*).—*Præpodes vittatus* is described in its different stages and notes are given on its habits and life history. This insect does the most of its injury in the larval form. The pest may be controlled by hand picking the beetles, thorough cultivation, and application of lime or sulphate of potash as a dressing around affected trees. Mention is made of *Elis atrata* as a natural enemy of this pest.

Report on the distribution of Phylloxera vastatrix in Austria in 1901, F. Kurmann et al. (*Bericht über die Verbreitung der Reblaus in Österreich im Jahre 1901. Vienna: Dept. Agr., 1902, pp. 356, pl. 1*).—A detailed account is presented by the inspectors in various parts of Austria regarding the prevalence and distribution of Phylloxera, with special reference to the methods which have been employed in controlling the spread of this insect. Copies are given of the laws and regulations of Austria regarding this matter.

Grapevine root worm, E. P. Felt (*New York State Mus. Bul. 72, pp. 55, figs. [illegible]*).—In the present bulletin the author presents the results of observations and experiments made in 1902 and 1903, chiefly in the Chautauqua grape belt. The subjects discussed in the bulletin include an account of the area of infestation, signs of the presence of the insect, injuries due to this insect in Ohio, its early history in this country, a description of the species in its native stages, notes on its life history, an

account of the oviposition of the insect, with notes on the number of eggs laid by different females, habits of the larvæ and pupæ, and experimental work in controlling the pest.

The remedies tested by the author included the destruction of the eggs, pulverizing the soil and mounding, spraying with arsenical poisons, collecting the beetles, destroying the pupæ, spraying with kerosene emulsion or crude petroleum, and applying carbon bisulphid and calcium carbid to larvæ in the soil. As a result of the author's experiments and observations it is concluded that no one method can be depended upon in controlling the pest.

It is recommended that cultural operations be so planned that the earth may be removed from about the base of the vines, or otherwise cultivated at the time when the majority of the insects are in the pupal condition. These cultural operations in conjunction with the collection of the beetles, especially by elaborate beetle-catchers described by the author, and by thorough spraying with some arsenical poison, preferably arsenate of lead, afford a practical solution of the difficulty.

Flea-beetles, R. MARÈS (*Bul. Agr. Algérie et Tunisie, 9* (*1903*), *No. 20, pp. 429, 430*).—Brief notes on the habits and means of combating the common flea-beetles, especially that of the grape.

Notes on Staphylinus olens and Eriocampa adumbrata, H. FAES (*Chron. Agr. Canton Vaud, 16* (*1903*), *No. 21, pp. 599–604, figs. 3*).—*Staphylinus olens* is said to feed to a large extent upon the insect pests of grapevines. Notes are also given on the life history and habits of *Eriocampa adumbrata.* This insect is injurious to various kinds of fruit trees, including the apple, pear, peach, cherry, and plum trees. The larvæ of the insect can be destroyed by applications of lime, tobacco, sulphur, pyrethrum, or soap suds.

Insects affecting forest trees, E. P. FELT (*New York State Forest, Fish and Game Com. Rpt. 1901, pp. 479–534, pls. 16, figs. 26*).—The author discusses the habits, life history, and means of combating a number of forest insects, including *Dendroctonus terebrans, Tomicus calligraphus, T. cacographus, T. pini, T. cælatus,* pine sawyer, ambrosia beetles, white pine weevil, pine-bark chermes, pine-leaf miner, *Polygraphus rufipennis,* etc.

The vertical distribution of forest insects in Switzerland, C. KELLER (*Mitt. Schweiz. Centralanst. Forst. Versuchsw., 8* (*1903*), *No. 1, pp. 3–80, pls. 10*).—The author discusses in detail the gall formations on deciduous and coniferous trees of various species, and presents an account of injury to other parts of these trees by noxious insects and vertebrates. Especial attention is given to the vertical distribution of the species discussed.

The protection of wood and bark against the attack of insects by causing the absorption of their reserve starch, E. MER (*Mém. Soc. Nat. Agr. France, 140* (*1903*), *pp. 233–247*).—In the author's experience not very satisfactory results have been obtained in protecting wood against insects by means of artificial insecticide treatment. Since insects which attack wood and bark feed largely upon the reserve food material in these products, an attempt was made to cause the resorption of the starch by means of special treatment.

It was found that the process of ringing trees at the upper part of the trunk caused the gradual disappearance of the starch at all points below the ring. The starch was transformed into other substances or was used up in the growth of the cambium layer. Wood thus deprived of its reserve starch was found to be well protected against the attacks of species of Anobium and Lyctus. The disappearance of the starch in the trunks of trees may also be brought about by cutting off the branches, or by allowing the whole tree to remain upon the ground several months after felling. According to the author's experience a period of 5 or 6 months is sufficient to bring about the almost total disappearance of the starch.

Spraying with distillates, W. H. VOLCK (*California Sta. Bul. 153, pp. 31,*

figs. 5).—Distillates include all oils derived from crude oil by distillation. They vary considerably in their specific gravity and their physical properties. Emulsions made from California oils have as a rule been less satisfactory than those made from eastern kerosene, and mechanical mixtures are considered much superior to emulsions.

The distillates are considered from the standpoint of their insecticide value and also with regard to the injury caused by them to leaves and fruits. The vegetable tissues are injured by the penetration of oil into the interior of the plant substance, and this penetration varies in extent and rapidity according to the number of stomata and other anatomical structures of the leaves. The chief toxic effects of the oils in the plants are due to diffusion. A drop of oil upon an orange leaf spreads more rapidly and also evaporates more readily than upon an apricot leaf; it therefore causes less injury upon the former than upon the latter. The heavier oils cause more injury than lighter oils, on account of their slow evaporation. Older leaves, on account of their roughness, prevent the drops of oil from spreading and thus become injured to a great extent. Very young leaves may become entirely covered with the film or oil, and thus be killed. The injury from distillates is in the author's opinion not due to any impurities in the oils, but to the oils themselves.

Notes are given on the effects of mixed oils, general and local injury of these oils, methods of application, and the influences of weather conditions, temperature, etc. The more force used in the application of the oils the greater the amount of penetration. A pronounced humidity of the atmosphere has the effect of opening the stomata in the leaves and thus allowing greater penetration of the oil. The injury to plants from oils is due to the prevention of transpiration, exclusion of the air, and to chemical toxic effects. The latter effects are manifested within 60 hours in an atmosphere containing gasoline, by a general bleaching process.

The practical bearing of these investigations is discussed by the author. It appears that many species of insects and mites escape the most careful spraying with distillates; in fact black scale and other insects survive the severest treatment which trees will stand, in sufficient numbers to reinfest the plant within a short time. An extensive reappearance of young scales was noted within from 2 to 3 weeks after spraying. According to the author no applications of distillates can be made without more or less injury to trees and fruit. Both leaves and fruit become spotted and drop. Two applications are all that can be economically applied in 1 year, since experience has shown that if 3 or 4 applications are required, spraying will not be less expensive than fumigation.

Sulphur sprays for red spiders, W. H. VOLCK (*California Sta. Bul. 154, pp. 11, figs. 4*).—This bulletin is occupied with an account of experiments in the destruction of a species of Bryobia on almond and other deciduous trees, and a species of Tetranychus on orange. Mites were inclosed in small cells and subjected to the action of sublimed sulphur. All mites thus treated died within a short time, or if they laid eggs the eggs did not hatch. Mite-infested branches were dusted with sublimed sulphur and inclosed in paper bags without being removed from the tree. The mites were nearly all destroyed within a period of a month.

During these experiments it was found that the use of ground or sublimed sulphur was effective in destroying mites. The trees may be dusted when wet with dew, but results from the use of the dry method are not always satisfactory. Spraying with a finely divided sulphur mixed with water is recommended. In order to cause the sulphur to adhere for as long a period as possible on the leaves experiments were made in mixing flour paste, lime, and other adhesive materials with the spray. The best results were obtained from the admixture of flour paste. Good results were also obtained when adding sulphate of potash to the sulphur spray. During the winter of 1902 about 100 orange trees were sprayed with sulphur and the results were quite satisfactory. The trees and fruit were not injured. Almost equally good results were obtained with sublimed and ground sulphur, but it is recommended that the sulphur should be in a finely divided condition.

The red spider of the almond proved to be much more resistant to insecticides than that of the orange, and sulphid of potash was therefore mixed with the sulphur spray. The majority of the mites were killed by this treatment and the author believes that the foliage can be saved, even in very advanced cases of injury from mites. Contact insecticides proved to be less effective than sulphur. Of the contact sprays, the distillates were most effective. Formulas are given for the preparation of sulphur sprays, with or without sulphid of potash.

Directions for treatment of insect pests and plant diseases, E. D. SANDERSON and E. C. GREEN (*Texas Sta. Circ. 3, folio, figs. 4*).—Brief notes on the important insect and fungus diseases of various cultivated plants.

Insect enemies of books, C. HOULBERT (*Les insectes ennemis des livres. Paris: Alfonse Picard & Sons, 1903, pp. XXXVIII + 269, pls. 3, figs. 59*).—This volume contains a general account of the various insects which injure books and the means for combating them. A summary of the proceedings of a congress for the study of the insect enemies of books held in Paris in August, 1900, is presented by H. Martin. A bibliography of 94 titles relating to this subject is also given.

The insects injurious to books are classified according to their systematic position, and details are presented on the habits and life history of the various species. The orders of insects concerned are Coleoptera, Orthoptera, Thysanura, Pseudoneuroptera, Hymenoptera, and Lepidoptera. Certain species of mites are also regarded as injurious to books. The remedies which have been applied in controlling these insects are classified as mechanical, chemical, physical, and biological. The mechanical remedies include the use of mechanical shock in destroying the insects, and also direct search for insect pests in books, shelves, and cases in libraries; in this group of remedies the author also includes various species of traps, and the use of wood and other materials especially liked by different species of insects and which may be readily removed and destroyed after becoming infested.

The chemical remedies include the use of odorous material, such as camphor, naphthaline, benzine, essence of turpentine, tobacco, and aromatic plants, as well as asphyxiating substances, such as sulphur dioxid, bisulphid of carbon, etc., and toxic substances, such as alum, borax, pyrethrum, quassia, arsenic, and corrosive sublimate. Directions are given for applying these various chemical insecticides. The physical remedies include the use of heat and cold. Cold may be used effectively in getting rid of cockroaches, while many species of insects may be destroyed by subjection to a high temperature, which is harmless for books. Brief notes are also given on the use of fungus and bacterial diseases and animal parasites in the destruction of insect enemies of books.

Attention is called to special methods of construction and management of libraries for the purpose of preventing infestation by insects. In some cases it is recommended that the thread used in sewing books be treated with quassia or tobacco decoction to prevent its being destroyed by insects. *Anobium paniceum* is considered as the most injurious and most widely distributed insect pest of books.

Concerning mosquito migrations, J. B. SMITH (*Science, n. ser., 18 (1903), No. 467, pp. 761–764*).—Several observations are recorded showing that *Culex sollicitans* is a migratory species and wanders long distances from the marshes where the larvæ have lived. This fact, in the author's opinion, must be taken into consideration in adopting measures for the extermination of mosquitoes.

Observations on the characters and habits of Anopheles mosquitoes and their larvæ, S. P. JAMES (*Sci. Mem. Med. and Sanit. Depts. India, n. ser., 1902, No. 2, pp. 27–58, figs. 21*).—Descriptive notes are given on the anatomy and habits of various species of Anopheles for the purpose of assisting in the differentiation of these species. Special attention is given to the structures which are recognized as possessing value in specific determination. The species of Anopheles found in India are classified and an analytical table is presented to assist in their determination.

Notes are given on the favorite breeding places of the larvæ and on fish and other

animals which assist in the destruction of the larvæ. According to the author' observations the greatest distance to which adult Anopheles fly in India is about three-fourths of a mile.

Variations induced in larval, pupal, and imaginal stages of Bombyx mori by controlled varying food supply, V. L. KELLOGG and R. G. BELL (*Science, n. ser., 18 (1903), No. 467, pp. 741–748*).—The experiments reported in this paper were undertaken for the purpose of determining the relation between the quantity and quality of food and the development and variations in silkworms. The changes in the quality of food were brought about by feeding lettuce in the place of mulberry leaves, while in another series of experiments the quantity of the mulberry leaves fed was made to vary according to desired changes.

These experiments were carried on for a period of 3 years. The characters studied in the silkworms for the purpose of judging of the effect of these varied conditions were the size and weight of the larvæ, the promptness of molting and spinning, fertility and mortality. Silkworms fed on lettuce leaves appeared to adapt themselves quite readily to this diet; the larval skin, however, was thinner usually, and the time consumed in metamorphosis was twice as long as that of larvæ fed on mulberry leaves. In the silkworms fed on mulberry leaves a definite and constant relation was observed between the amount of feed and the size. With regard to the fertility of the eggs it was found that the better nourished the insects the more fertile the eggs.

Experiments in sericulture in Tunis, F. VERRY (*Bul. Dir. Agr. et Com. [Tunis], 8 (1903), No. 29, pp. 501–509*).—The eggs of a number of varieties of silkworms, including the Bagdad and the Yellow Chinese races, were obtained for the purpose of testing their adaptability to the conditions in Tunis. Good results were obtained in the quantity and quality of silk produced.

FOODS—NUTRITION.

Experiments on the metabolism of matter and energy in the human body, W. O. ATWATER and F. G. BENEDICT (*U. S. Dept. Agr., Office of Experiment Stations Bul. 136, pp. 357, pl. 1, figs. 14*).—Continuing previous work (E. S. R., 13, p. 972), the details are reported of 21 experiments, made with the respiration calorimeter, upon the metabolism of matter and energy in the human body. In some of the experiments reported carbohydrates predominated in the diet, and in others fat, while in a smaller number of cases the subjects fasted. In a number of tests the subjects rested, and in others work was performed.

Modifications in the apparatus and experimental methods adopted since the previous report are described, and the results of the present experiments and those previously reported are discussed at length, the subjects including among others the demand of the body for nourishment, the elimination of carbon dioxid, water, and heat; body temperature; heat production *v.* heat elimination; respiratory and carbon dioxid thermal quotients; amounts of energy derived from different nutrients; fats *v.* carbohydrates as protectors of body material and as sources of energy for muscular work; carbohydrates and fats *v.* protein as sources of energy for muscular work; and the efficiency of the body as a machine. The conservation of energy in the body is also spoken of and the experiments with the respiration calorimeter are regarded as a demonstration of the application of this law to the living organism.

The accuracy of the apparatus is shown by the fact that in the check experiments in 1902, when alcohol was burned in the respiration chamber for a period aggregating 380 hours and 44 minutes, the total estimated heat was 34,230 calories and the amount found 34,288 calories, or 100.2 per cent of the theoretical value. The theoretical amount of carbon dioxid produced was 10,984 gm. and the total amount measured was 10,982.3 gm., or 100 per cent. The theoretical amount of water due to combustion of alcohol was 7,974.8 gm., and the amount measured 8,225.9 gm., or

slightly more than the theoretical quantity. These results are in harmony with those obtained in earlier experiments.

In the experiments reported the amount of oxygen consumed was calculated, and the values obtained are used in a discussion of the respiratory quotient. The authors believe that the carbon dioxid thermal quotient also serves as an index of changes taking place in the body. Concerning this quotient they state that, "in comparing the results of these experiments, it was found that the amounts of carbon dioxid and heat produced varied so uniformly that it was believed the ratio of one to the other would afford means of judging of changes which occur in the body. This ratio, which we have called a carbon dioxid thermal quotient, is nearly uniform in experiments with the same conditions of food and work, but changes notably with changes in diet, which accords with the fact that, in the oxidation of the various nutrients of food and the corresponding compounds in the body, the ratio of carbon dioxid to heat is nearly uniform for different compounds of the same class and that the values are sufficiently distinctive to characterize the class.

"From the composition and heats of combustion of the different classes of nutrients the ratios of carbon dioxid to heat produced by oxidation are easily computed. Provided the amount of oxygen were measured, similar ratios could be computed for carbon and heat and oxygen and heat, and would doubtless give useful data. Such ratios might be designated carbon thermal quotient and oxygen thermal quotient."

Concerning the relative merits of fats and carbohydrates as sources of energy for muscular work, the general conclusion drawn from the experiments reported is that "the fats were slightly inferior to isodynamic amounts of carbohydrates as parts of a ration for muscular work. But while the natural inference is that calorie for calorie the carbohydrates were slightly superior to the fats as sources of muscular energy, the difference observed was very small and may have been due to some individual peculiarity of the subject with whom the more directly comparable experiments were made rather than to any inherent difference in the capacity of the materials to yield energy for external muscular work."

The experiments reported also furnish information regarding the different nutrients as sources of energy for muscular work. The conclusions drawn are that a considerable amount of the energy of external muscular work in these experiments must have come from material other than protein, and that "it is in the highest degree probable that the larger part of the material which was broken down and oxidized to supply the energy of external muscular work consisted of carbohydrates and fats.

"These conclusions agree fully with the general belief of physiologists, that all of the nutrients of food, proteids, fats, and carbohydrates may supply energy for muscular work, but that the chief source is in the carbohydrates and fats. They leave no basis whatever for the theory that the proteids are the sole source of muscular energy."

As regards the efficiency of the body as a machine, the results obtained with the different subjects varied somewhat under different experimental conditions. Considering the results of the different experiments the efficiency ranged from 13.3 to 20.2 per cent, and in the latest experiments the average was over 19 per cent in all cases. It appeared that whatever the amount of work which the subject of the experiments did with the muscles used in turning the wheel of the bicycle ergometer, he transformed about 5 calories of energy in his body for every one which was utilized in the performance of mechanical work.

"In all these cases the subjects were fairly efficient machines, as will be seen when it is remembered that the ordinary steam engine transforms only about 15 per cent of the energy of the fuel into work. It is quite possible that something more satisfactory than the ergometer may be devised for utilizing the external muscular work performed by the subject."

Experiments on the digestibility of vegetables, A. P. BRYANT and R. D. MILNER (*Amer. Jour. Physiol., 10 (1903), No. 11, pp. 81–99*).—The digestibility of cabbage, potatoes, beets, green corn, and apple sauce was studied in experiments carried on with healthy young men, each of the articles enumerated being added to a simple basal ration and the digestibility of the foods under consideration calculated from the digestibility of the ration as a whole. The average results which were obtained follow:

Coefficients of digestibility of vegetables.

Kind of vegetable.	Protein.	Fat.	Nitrogen-free extract.	Crude fiber.	Ash.	Energy.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Cabbage, average of 3 tests	[a]47.4	[a]40.2	81.6	77.3	55.1	59.5
Potatoes, average of 3 tests	73.1	[b]15.8	99.0	74.3	76.6	93.6
Beets, average of 3 tests	72.4	[b]100.0	96.7	84.4	75.3	89.7
Apple sauce, average of 2 tests	19.1	97.9	99.4	95.2	90.0	98.8
Green corn, 1 test	83.9	41.2	96.6	59.3		86.2

[a] Average of 2 tests only. [b] One test only.

The authors' conclusions follow: "So far as sources of protein or fat are concerned, the vegetables included in these studies may be considered as of little value. They do, however, contain carbohydrates, which the results of these and other experiments indicate to be quite well digested and absorbed; and they may, therefore, be considered as of value as sources of energy, a large proportion of which appears to be available to the body. The chief value of many vegetables, however, is perhaps aside from the nutrients or energy they furnish; they add a pleasing variety and palatability to the diet, supply organic acids and mineral salts, and give the food a bulkiness that seems to be of importance in its mechanical action in maintaining a healthy activity of the alimentary tract. Possibly the result of these conditions is a favorable influence upon the digestion of other food eaten with the vegetable; at least such an effect was suggested by the results of some of these experiments."

In connection with the above experiments the balance of the income and outgo of nitrogen was also determined.

The relative digestibility of some edible fats and oils, J. F. MOORE (*Arkansas Sta. Bul. 78, pp. 33–41*).—The relative digestibility of cotton-seed and other vegetable oils and common culinary fats of animal origin was studied with mice and guinea pigs. In the experiments with mice the fats were mixed with flour and water to a stiff dough which was baked. The guinea pigs were fed wheat bran on which the fat or oil was blown in a fine spray. The following table summarizes the results obtained, the values for mice being the average results of 2 tests and those for guinea pigs the results of 1 test:

Average digestibility of fats and oils. Experiments with mice and guinea pigs.

Kind of oil.	Cooked fat. Experiments with mice.	Raw fat. Experiments with guinea pigs.
	Per cent.	*Per cent.*
Home-rendered lard	96.81	
Home-rendered lard, soft, melting point 27.0° C		88.78
Home-rendered lard, hard, melting point 36.9° C		73.88
Beef suet, melting point 44.9° C		73.66
Refined cotton-seed oil, light	96.19	93.37
Refined cotton-seed oil, heavy		90.47
Olive oil	97.70	88.81
Peanut oil		85.77
Corn oil		86.47
Crude cotton-seed oil	96.97	89.93

"The more fluid oils and soft fats were more completely digested than the heavier oils or the hard fats.

"The effect of an increase in the melting point of a fat on the percentage of digestibility becomes less as the melting point approaches or goes above the temperature of the body. . . .

"It is apparently true, in the cases before us at least, that cooked fats and oils are considerably more digestible than those eaten raw. In cooking a fat there is probably more or less dissociation into glycerine and fatty acids, which, if the theory is correct that the presence of fatty acids is conducive to a more perfect digestion of the fat, will help to explain the higher percentages of digestion in the experiment with the mice. In that work the oils were cooked in the preparation of the food, while in the work with the guinea pigs the oils were fed raw.

"Nothing developed in these experiments to indicate that the vegetable oils used are in any manner inferior to the animal fats as articles of food. In heat producing power the 2 classes are equal, while the vegetable fats appear to have been more completely digested. . . .

"It must be left very largely to the fancy of the individual consumer to decide which class of fats is to be preferred."

Poultry as food, Helen W. Atwater (*U. S. Dept. Agr. Farmers' Bul. 182, pp. 40*).—In this bulletin data regarding the composition and food value of poultry are summarized and discussed. The topics treated of include among others varieties of poultry, fattening poultry and its effect on food value, dressing and marketing, marks of good poultry, cooking, nutritive value of poultry and its cost, and the place of poultry in the diet. The term "poultry," as used, covers chickens, turkeys, guinea fowls, ducks, geese, pigeons, swans, peafowls, pheasants, and quail.

As regards composition the author states that "poultry does not differ as much as is commonly supposed from meat of other domestic animals used for food. Individual kinds and specimens, of course, vary in the relative amounts of protein and fat contained, and there are certain flavors present in poultry which differ from those in other meats. But these differences are so small that they are practically negligible in ordinary diet. Nor is there as much difference in digestibility as is often stated. On the average, poultry is somewhat more easily digested than beef and mutton, but only very slightly. The difference in digestibility between the various kinds of poultry probably depends on the amount of fat contained, the fatter sorts being least easily digested.

"Tenderness of fiber may have something to do with both ease and thoroughness of digestion, and, if so, young birds are more easily digested than old, and the less-used muscles of the chicken, such as the breast, more so than the much-used muscular tissues of the legs. Similarly, white-fleshed birds may be more easily digested than dark-fleshed, because the fibers of their flesh are less closely set; but this is not fully proved. Indeed, very little is positively known on this subject, and that little seems to indicate that the differences in thoroughness of digestion are very slight, and that cooking has much more to do with the digestibility of the birds than these slight differences in composition and texture."

Poultry as food, R. D. Milner (*Connecticut Storrs Sta. Bul. 27, pp. 20, fig. 1*).—On the basis of a large number of analyses of poultry and poultry products which have been made by the station, the food value of poultry is discussed. Statistics are quoted regarding the extent of poultry raising in the United States, and especially in Connecticut; and the importance of this industry to Connecticut and the desirability of increasing it are pointed out.

Alcohol as a food, R. Rosemann (*Arch. Physiol.* [*Pflüger*], *100* (*1903*), *No. 7–8, pp. 348–366*).—The author discusses the nutritive value of alcohol and calls attention to the use of alcohol as a condiment, and related topics.

Standards of purity for food products (*U. S. Dept. Agr., Office of the Secretary, Circ. 10, pp. 13*).—The food definitions and official standards of purity for food products for the United States are given, which were prepared by a committee representing the Association of Official Agricultural Chemists, commissioned by the Secretary of Agriculture in accordance with an act of Congress of March 3, 1903. The committee consisted of W. Frear, E. H. Jenkins, M. A. Scovell, H. A. Weber, and H. W. Wiley. The foods include meat and the principal meat products, milk and its products, sugars and related substances, and condiments.

The standards, the committee state, are based "upon data representing materials produced under American conditions and manufactured by American processes or representing such varieties of foreign articles as are chiefly imported for American use.

"The standards fixed are such that a departure of the articles to which they apply, above the maximum or below the minimum limit prescribed, is evidence that such articles are of inferior or abnormal quality.

"The limits fixed as standard are not necessarily the extremes authentically recorded for the article in question, because such extremes are commonly due to abnormal conditions of production and are usually accompanied by marks of inferiority or abnormality readily perceived by the producer or manufacturer."

The standards adopted for lard and dairy products follow:

"Standard lard and standard leaf lard are lard and leaf lard, respectively, free from rancidity, containing not more than 1 per cent of substances, other than fatty acids not fat, necessarily incorporated therewith in the process of rendering, and standard leaf lard has an iodin number not greater than 60. . . .

"Standard milk is milk containing not less than 12 per cent of total solids and not less than 8.5 per cent of solids-not-fat, nor less than 3.25 per cent of milk fat. . . .

"Buttermilk is the product that remains when butter is removed from milk or cream in the process of churning.

"Pasteurized milk is standard milk that has been heated below boiling, but sufficiently to kill most of the active organisms present and immediately cooled to 50° F. or lower to retard the development of their spores.

"Sterilized milk is standard milk that has been heated at the temperature of boiling water or higher for a length of time sufficient to kill all organisms present.

"Condensed milk is milk from which a considerable portion of water has been evaporated.

"Sweetened condensed milk is milk from which a considerable portion of water has been evaporated and to which sugar (sucrose) has been added."

According to the standards, skim milk shall contain not less than 9.25 per cent of milk solids. Condensed milk and standard sweetened condensed milk are standard sweetened and unsweetened milks condensed until they contain, respectively, not less than 28 per cent milk solids, of which not less than one-fourth shall be milk fat. The standard condensed skim milk is skim milk from which a considerable portion of water has been evaporated.

"Standard milk fat or butter fat has a Reichert-Meissl number not less than 24 and a specific gravity not less than 0.905 (40° C. /40° C.)."

Standard cream is required to contain not less than 18 per cent of milk fat. Evaporated cream is defined as cream from which a considerable portion of water has been evaporated. Standard butter is required to contain not less than 82.5 per cent butter fat. Standard renovated or process butter must contain not less than 16 per cent water and at least 82.5 per cent butter fat. Whole milk or full cream cheese containing in the water-free substance not less than 50 per cent butter fat is designated as the standard.

A standard winter-wheat flour, G. L. TELLER (*Chicago: The Operative Miller Press* [*1903*], *pp. 4*).—Fifteen patent flours from Illinois, Missouri, Indiana, Michigan, and Tennessee were analyzed. They were believed to "represent fairly well the patent flours manufactured from the soft winter wheat in this section of country." A blend of this flour, which is regarded as a standard, and 5 less representative samples, were also analyzed. The values reported are discussed with special reference to the outlining of a scale of comparison.

Preparation of modified milk by precipitating casein with carbon dioxid, S. SZÉKELY (*Arch. Kinderheilk., 36* (*1903*), *No. 1–2, pp. 79–85*).—A method of preparing modified milk approximating mother's milk in composition is described, the principal feature of which consists in precipitating casein with compressed carbon dioxid. According to the author, this precipitation is accomplished without changing the chemical composition of the casein. The precipitate carries with it the calcium united to the casein, and also the tricalcium phosphate suspended in the milk. By the addition of the proper amount of cream and milk sugar a modified milk is obtained which, it is stated, has practically the same composition as mother's milk. When the process of manufacture is completed no carbon dioxid remains in the milk. The gas, as employed, possesses strong germicidal properties, and the resulting product is practically sterile.

Report of the Government Hospital for the Insane (*Washington: Department of the Interior, 1903, pp. 72, pl. 1*).—This report, in addition to statistical and other data, contains an account of a number of dietary studies made during the year 1902-3 by the hospital cooperating with the Department of Agriculture. Of the 27 studies, each of one week's duration, 23 were made with male patients (approximately 1,600 individuals) and 4 with employees (approximately 125 individuals).

"It appeared that on an average the patients consumed food furnishing 93 gm. of protein, 103 gm. of fat, and 361 gm. of carbohydrates per man per day, the fuel value of the diet being 2,705 calories. The food eaten by the employees furnished 125 gm. of protein, 165 gm. of fat, and 466 gm. of carbohydrates, the fuel value being 3,800 calories. . . . It was noted in connection with these investigations that the food purchased was of good quality; that it was stored, handled, and cooked in a cleanly way, and that the service was as good as could be expected under existing conditions."

It was found that the waste, as is perhaps usual at such institutions, was quite high. Suggestions which proved of immediate benefit were made for checking this and for improving the dietary in other ways.

Cookery for the sick and convalescent, C. H. SENN (*London: The Food and Cookery Pub. Agency* [*1903*], *pp. VIII, 38*).—The desirability of preparing foods with great care for the sick and convalescent is briefly discussed and a number of recipes are given.

Diet without salt and its effect upon the body, especially upon the assimilation of food and the metabolism of nitrogen in man, C. M. BELLI (*Ztschr. Biol., 45* (*1903*), *No. 2, pp. 182–222*).—According to the author, in his experiments the consumption of an insufficient amount of sodium chlorid did not modify the digestive functions nor the assimilation of nutrients. The nitrogen metabolism was somewhat affected, being hastened a little when the foods eaten contained no added sodium chlorid. It returned to the normal as soon as the cooked foods contained their usual quantity of added salt. The report includes a bibliography.

Proteid synthesis in the animal body, Y. HENDERSON and A. L. DEAN (*Amer. Jour. Physiol., 9* (*1903*), *No. 6, pp. 386–390*).—In addition to arrowroot and lard, a dog was fed proteid-cleavage products obtained by treating lean beef with concentrated sulphuric acid under the influence of heat, the nitrogenous substances being separated and purified until a biuret reaction was no longer noticeable. The compo-

sition and energy value of the food and the income and outgo of nitrogen were determined.

The authors believe the experiment shows "that the nitrogenous substances in the diet were not immediately and wholly converted into urea and excreted; that they were, on the contrary, to a considerable extent retained; and that portion which was expended (appearing in the urine) exerted a marked proteid-sparing action. These reactions seem to us, however, to afford a sufficient explanation of the facts without invoking the more radical hypothesis of proteid synthesis. The diminution in the nitrogen excretion from 1.9 gm. in the fore period to 0.8 gm. in the after period of fasting suggests that the protoplasmic waste had not been made good, and that the retention of nitrogen is not in itself a proof of proteid synthesis."

New experiments on the physiological action of the proteoses, F. P. UNDERHILL (*Amer. Jour. Physiol., 9 (1903), No. 6, pp. 345–373, pl. 1*).—Experiments with dogs were made to determine the effects of intravenous injections of typical native proteids, proteoses prepared by the digestion of animal proteids with vegetable enzyms, proteoses prepared from proteids and enzyms both of vegetable origin, and proteoses prepared from vegetable proteids by hydrolysis with acids or superheated water. Some tests were also made as to the causes of the toxic effects which have been attributed by other investigators to the injection of proteids. Some of the author's principal conclusions follow:

"There is at present no occasion for attributing the physiological effects following the injection of proteoses into the circulation to the presence of contaminating substances derived from animal tissue or elsewhere. Typical purified vegetable proteids which, when injected are themselves inert in this regard, yield on hydrolysis with acids, or even water alone, proteoses which provoke the characteristic reactions. The proteoses which are formed by the action of proteolytic enzyms of vegetable origin (bromelin, papaïn) on purified proteids, likewise alter *in vivo* the coagulability of the blood and call forth the other well-known symptoms of proteose injections.

"The proteoses occurring in nature in the vegetable kingdom are similarly active, as was to be expected if the toxic properties are a function of these products *per se*. No method of 'purification' has been found which will deprive proteoses of this characteristic physiological behavior in the circulation: when the chemical make-up of the proteoses is profoundly altered and they lose their chemical identity, the typical physiological action may also be lost. . . . Recent studies on immunity have shown equally striking natural differences among animals, and have again emphasized the influence which the mode of introduction of toxins may exert."

Concerning the tryptic digestion of gelatin, T. R. KRÜGER (*Ztschr. Physiol. Chem., 38 (1903), No. 3–4, pp. 320–322*).—A chemical study of the peptone produced by the action of tryptic ferment on gelatin is briefly reported.

On the formation of glycogen from glycoproteids and other proteids, L. B. STOOKEY (*Amer. Jour. Physiol., 9 (1903), No. 3, pp. 138–146*).—The possibility of the formation of glycogen from proteids was studied with hens, the proteids selected being ovomucoid, pancreas nucleoproteid, chondrin, syntonin, casein, sodium casein (alone and with saccharose), and leucin. Some of the author's conclusions follow:

"The outcome of the feeding experiments with those substances which yield carbohydrate cleavage products—ovomucoid, pancreas nucleoproteid, chondrin—scarcely permits any positive conclusion to be drawn. In some of the more satisfactory trials, where the period of feeding was more prolonged and the utilization of the food was apparently better, appreciable quantities of glycogen were found. These do not, however, exceed in amount the maximum glycogen content (0.97 per cent) which has been . . . [previously noted in the liver of the fasting hen]; although, like the writer, most other investigators have noted very small quantities only. . . .

"The feeding of simple proteids—syntonin, casein, and its sodium salts—failed to yield an increase of glycogen in the liver when a single dose was given. But after trials lasting several days, during which considerable quantities of casein were ingested, an accumulation of glycogen too large to be attributed to any residual store in the liver was repeatedly found. . . . It has already been pointed out that negative results in experiments like the present ones do not necessarily indicate the incapacity of the substances fed to promote glycogen formation."

The author discusses the possibilty of leucins being the important intermediate bodies in the formation of sugar and glycogen in the body from carbohydrate-free proteids, and notes that the 2 experiments, which he reports, "do not, at least, speak against the possibility under discussion; nor do they justify any far-reaching statements. The physiologist must look forward to a more profound acquaintance with the chemistry of the proteid molecule before the final word can be spoken."

On the formation of dextrose in metabolism from the end products of a pancreatic digest of meat, P. G. Stiles and G. Lusk (*Amer. Jour. Physiol.*, *9* (*1903*), *No. 6, pp. 380–385*).—Tests are reported in which dogs were given the product obtained by the pancreatic digestion of washed meat. The digestion was continued for 14 months with proper precautions against putrefaction, and the result was described as a dark sirupy fluid, with but little sediment or suspended matter, containing 1.33 per cent nitrogen and giving only a doubtful biuret reaction. "The taste and odor were pronounced but not foul." It was found that 5 gm. of nitrogen fed in the form of these pancreas digestion products, according to the authors, may give rise to the formation of about 12 gm. of dextrose.

"The same amount of nitrogen fed as native proteid would be expected to produce 18 to 19 gm. of sugar. No light is thrown upon the question whether the sugar in our experiments was formed after a proteid synthesis had occurred or more directly from the amido-bodies. Neither have we any evidence as to the relative importance of the several digestive products which were fed. . . . The experiment shows that it is impossible for a large sugar radical to exist in the proteid molecule. The amido nitrogen fed was quantitatively eliminated, and did not protect the body's proteid as do meat and gelatin under similar circumstances."

Salivary digestion in the stomach, W. B. Cannon and H. F. Day (*Amer. Jour. Physiol.*, *9* (*1903*), *No. 6, pp. 396–416*).—Experiments reported on salivary digestion in the stomach were carried on with cats, the authors' earlier investigations having shown that, like the stomach of the dog, rat, rabbit, guinea pig, and man, the stomach of the cat is separated into 2 parts—the quiet cardiac end and the active pyloric end. The animals were fed powdered crackers mixed with a uniform amount of filtered human saliva, and after the expiration of from one-half to 2 hours were etherized, killed, and the stomach contents examined, care being taken to keep the material in the cardiac and pyloric portions separate.

From the results of their experiments the authors believe that the commonly accepted idea that the action of ptyalin is inhibited soon after the ingestion of food is not conclusively proved, and that there is little or no warrant for the commonly accepted accounts of mixing currents in the stomach. Observations show that in many animals, including man, gastric peristalsis occurs only in the pyloric end of the stomach; the cardiac end remains undisturbed by the waves. Food in the pyloric end is soon mixed with the gastric secretions, but food in the cardiac end of the stomach is not mixed with the acid gastric juices for 2 hours or more, and in this region, therefore, during that time salivary digestion may go on undisturbed.

In experiments with cats it appeared "that the percentage of sugar present is about the same in the 2 portions at the end of a half hour, and at the end of an hour the cardiac portion contains about 80 per cent more sugar in unit volumes than the pyloric portion. The actual amount of sugar present in the fundus is relatively

much greater than this ratio would indicate, for the fundus contains after an ordinary meal about five times as much food as the pyloric portion. After an hour the ratio of the sugar percentages in the 2 parts of the stomach begins to approximate unity again. This change is probably due largely to diffusion of sugar from the fundus into the pyloric end, and to some extent to absorption. The diffusion of the sugar does not to a marked degree remove the ptyalin from the food. . . .

"When liquid food is given, when small amounts of food are given, and when the stomach is massaged, sugar percentages in the 2 parts of the stomach are nearly the same.

"Mixing proteid with carbohydrate food protects the ptyalin from the action of free hydrochloric acid in the relatively small pyloric part of the stomach and on the surface of the cardiac contents. The greater mass of the food, lying in the fundus, undergoes uninterrupted amylolysis, not because the proteid protects the ptyalin, but because the food in this region is not mixed with the gastric juice.

"Much of the starch not changed to sugar is changed to dextrin, and thus, since dextrin is not readily fermented, the food is saved to the organism. The especial value of this process lies in the fact that it occurs to the greatest degree in the fundus, in which region the hydrochloric acid, inhibiting the action of many of the organized ferments, does not for some time make its appearance.

"In the early stages of gastric digestion, if food has been properly masticated, the fundus serves chiefly for the action of the ptyalin; the pyloric portion, after a brief stage of salivary digestion, is thereafter the seat of strictly peptic changes. Later, after 2 hours or more, as the contents of the fundus become acid, the food in the stomach as a whole is subjected to the action of proteolytic fermentation."

Oxidations in the animal organism, E. Enriquez and J. A. Sicard (*Les oxydations de l'organisme. Paris: J. B. Baillière & Sons, 1902, pp. 87*).—The nature and function of oxidizing ferments, particularly those found in the animal body are discussed and the author's experiments and those of other investigators are summarized. A bibliography of the subject is appended.

The sugar-forming ferment of the liver, L. Borchardt (*Arch. Physiol. [Pflüger], 100 (1903), No. 5–6, pp. 259–297*).—Experiments, which are reported in detail, led to the conclusion that as regards kind of action and the products formed there is no appreciable difference between the ferment in the blood, which cleaves glycogen, starch, and maltose, and that in the liver. The effects of both alcohol and heat on the 2 ferments are also very similar. The ferment found in the liver is much more active than that found in the blood.

The effect of lecithin on the growth of the white rat, S. Hatai (*Amer. Jour. Physiol., 10 (1903), No. 1, pp. 57–66, fig. 1*).—The effects of lecithin on the amount and character of body growth were studied in experiments with white rats. Those which received the lecithin either by injection or by feeding, according to the author, gained on an average 60 per cent more than those receiving none, the gain being accomplished more rapidly. The central nervous system and the peripheral nerves of the rats fed lecithin were found to be normal. The rats which had been fed lecithin, in the author's opinion, showed the greater power of resistance to unfavorable changes in their surroundings and his experiments are thought by him to confirm those of earlier investigators who claim "the physiological effect of the lecithin to be that of a stimulating agent for normal growth."

ANIMAL PRODUCTION.

Commercial feeding stuffs, H. J. Wheeler, A. W. Bosworth, and J. W. Kellogg (*Rhode Island Sta. Bul. 94, pp. 151–171, figs. 6*).—In compliance with the State feeding-stuff law, 153 samples were collected and examined, including cotton-seed meal; linseed or flax meal; gluten meal and feed; distillers' grains; brewers' grains; wheat bran middlings and mixed feed; corn meal; peanut meal; rice meal; hominy

or chop feeds; proprietary feeds; provenders; beef scraps and bone meal, and condimental feeds. The results obtained are discussed and a number of the feeding stuffs are described.

Condimental feeds, the authors state, "are for the most part made up of ordinary feeding stuffs, and contain drugs in very small quantities. The cost of these feeds ranges from 5 to 50 cts. per pound, and when one considers the fact that the most expensive of any of the drugs usually contained in them can be purchased for less than 10 cts. per pound, it must be obvious that it would be cheaper for the user to purchase the drugs as desired or necessary, and mix them with the ordinary feeding stuffs."

According to the authors, the inspection of feeding stuffs during the past winter has brought to notice "a number of common adulterations. A few of these can be readily detected by the purchaser if he will make a careful examination of the material.

"The usual adulterant of cotton-seed meal is the hull of the seed. This adulterant was formerly easily distinguished by the black appearance, but now the hulls are so finely ground together with waste cotton that they can be recognized only with great difficulty.

"Gluten feed has been sometimes sold as gluten meal. . . .

"Gluten meal is a homogeneous, yellow, granular substance, and its general appearance is quite different from that of the feed.

"In one case dried distillers' grains were being sold as gluten meal. . . .

"Distillers' grains are much darker than gluten feed, and for the reason that gluten feed is made entirely of corn refuse, and the distillers' grains of a mixture of cereals, the two can be distinguished by the barley hulls which are found in the distillers' grains but not in the feed.

"Some of the 'mixed feeds' [which in Rhode Island should consist solely of pure wheat bran and middlings] found upon the market have been found to be grossly adulterated.

"If coarsely ground, the hulls, corncob, etc., used in adulterating 'mixed feed' may usually be detected by taking a small handful of the feed and spreading it in a thin layer upon the palm of the hand. If finely ground, however, the corncob is difficult to distinguish. If hulls are present, they will appear as small, shiny particles, much lighter in color than the brown particles of the bran. In this case care must be taken not to confuse the germ of the wheat with the hull, for the germ is one of the valuable parts of the feed. Its color is nearly like that of the hulls, its high content of fat giving it a glossy appearance. The hulls, however, are hard and not easily broken, but the germs are soft and can be split readily.

"The other feeds which have been adulterated are by-products from starch and hominy manufacture. These are sold under several names, such as chops, hominy, chop feed, hominy feed, and hominy chops.

"These feeds are adulterated with corncob and corn meal. The pure feed has a smooth, slightly oily feeling when rubbed between the fingers, and if adulterated it will feel more granular. Yellow corn meal can be detected by the yellow particles of the kernel, which are not found in the pure feed. Corncob can not be so easily detected."

Analyses of commercial feeding stuffs sold in Maryland, H. B. McDonnell (*Maryland Agr. Col. Quart., 1903, No. 22, pp. 2–10*).—In accordance with the State feeding-stuff law, which is quoted, the protein and other extract were determined in a number of samples of cotton-seed meal, linseed meal and flax meal, gluten meal and feed, hominy feed, corn oil-cake meal, mixed, commercial and proprietary feeds, poultry feed, animal bone, meat meal, and similar products. A list of licensed feeding stuffs is given.

Beet diffusion residue and molasses, M. Schmoeger (*Landw. Vers. Stat., 59 (1903), No. 1–2, pp. 83–155, figs. 10*).—The anatomical structure of beet tissue, the

composition and feeding value of beet sugar by-products, and related topics are discussed, the article being a critical summary of investigations which have been reported on these topics. The references to the publications cited are given in every case and constitute an extended bibliography of the subject.

Groundnuts in the West Indies (*Imp. Dept. Agr. West Indies, Pamphlet 25, 1903, pp. 26*).—A summary of information regarding the cultivation of peanuts, the composition and feeding value of peanut cake and meal, the possible uses of peanuts as food, etc.

Some results in steer feeding, D. W. May (*Kentucky Sta. Bul. 108, pp. 101–116, pls. 7*).—After a short preliminary period, a test was begun November 25 with 8 lots of 4 steers each to learn the relative value of a number of concentrated feeds largely used by Kentucky feeders. Part of the steers were grade Shorthorns and the others grade Angus. All were allowed the run of a closely cropped blue-grass pasture and at all times had free access to good clover hay. Lot 1 was fed ear corn, lots 2 and 8 corn-and-cob meal, lot 3 corn-and-cob meal and cotton-seed meal 3:1, lot 4 corn-and-cob meal, cotton-seed meal and bran 2:1:1, lot 5 corn-and-cob meal and gluten meal 3:1, and lots 6 and 7 corn-and-cob meal and dried distillers' grains in the proportion of 2:1 with the former lot and 1:1 with the latter.

At the beginning of the trial 16 to 18 lbs. of grain were fed per head per day, but as the test progressed the amount was increased and the proportion of ingredients in the grain mixtures was changed somewhat. The gains ranged from 1.66 lbs. per head per day in the case of lot 1 (ear corn) and lot 8 (corn-and-cob meal) to 2.23 lbs. with lot 7 (corn-and-cob meal and distillers' grains). With this latter lot less grain was required per pound of gain, and the gains were most economically made, the values being 8.82 lbs. and 8.9 cts., respectively. The largest amount of grain, 12.96 lbs., was required per pound of gain with lot 8 (corn-and-cob meal), and in this case also the gain was most expensive, costing 13.3 cts. per pound.

The steers were sold and slaughtered, the dressed weight being in every case not far from 61 per cent of the live weight. According to the author's calculations, ranking ear corn and corn-and-cob meal at the same price, the additional gains made on the ground grain were not profitable.

"With clover hay fed with corn there is less need for a nitrogenous grain feed than when corn stover, straw or other roughage richer in carbohydrates is fed. In this experiment, while less grain was required per pound of gain where nitrogenous by-products were fed, yet in some instances owing to the high cost of the by-products the gains cost more."

Dried distillers' grains with corn the author considers to be, under the experimental conditions, the most economical of the grain rations tested. "It proved not only the cheapest feed, but it took less grain per pound of gain when it entered largely into the ration. It seems probable that this by-product could be made much more profitable by drying and feeding as in this experiment, rather than by feeding directly from the still as slop."

As regards the effect of breed on gains made, the author states that, disregarding the 4 poorest animals, the Shorthorn grades required 10.88 lbs. of grain per pound of gain, and the Angus grades 11.85 lbs. "Experiments will not determine the superiority of one breed over another. They may indicate the differences between certain bunches of cattle, but the value of a breed of beef cattle will be established by the wisdom and the care of the improvers of that breed. . . .

"Whether type influences the rate of gain in beef cattle is a doubtful point that will take much experimenting to determine. . . . It seems probable that inheritance plays a more important part in the ability of an animal to lay on fat, as is often observed with mankind, and this factor of inheritance is one of the points considered in building up our beef breeds. As long as the butcher will pay more for the better type of cattle it will continue to be more profitable, laying aside other considerations, to grow that kind."

During the test 35 pigs, averaging 87 lbs. each in weight, followed the steers. Beside the undigested feed which they gathered they consumed 4,560 lbs. of refuse grain from the feeding troughs and gained 3,882 lbs. in weight.

Steer feeding, F. B. LINFIELD (*Montana Sta. Bul. 48, pp. 153–165, figs. 4*).—The comparative merits of different grain rations supplementing clover hay ad libitum were tested with 4 lots of 6 steers each, 3 lbs. of chopped grain being fed per head daily at first, the amount being later increased to a full feed of 5 lbs. In the 111 days of the test, which began December 1, 1902, the lot fed wheat made an average daily gain of 2.10 lbs.; the lot fed oats, 1.69 lbs.; the lot fed barley, 2.34 lbs., and the lot fed a mixture of equal parts of wheat, oats, and barley, 2.53 lbs., the average for all the rations being 2.15 lbs. per steer. The cost of a pound of gain ranged from 4.2 cts. on a mixed grain ration to 6.1 cts. on oats, averaging 5.2 cts. for all the rations. Considering the test as a whole, 12.8 lbs. of clover hay and 1.9 lbs. of grain were required per pound of gain.

Though the fact is recognized that definite conclusions can not be drawn, yet the author believes that the test indicates that a mixed grain ration is superior to a single variety of grain, the rations tested ranking as follows: Mixed grain 100, wheat 99.5, barley 84.5, and oats 84. It was noticed that the cattle tired of the wheat after about 2 months and a change was necessary to induce them to continue eating it. This, the author states, was likewise true of all the grains fed, but not to the same extent as with the wheat.

"After a gradual change of the rations to mixed grain with bran the cattle ate the mixture with relish and made the most rapid gains of the winter.

"The experiments made at the station for the past 3 years seem to show that on the average the profit to be made in fattening 2 to 3 year old steers, with Montana prices for feeding stuffs, must come from an increase in the value of the purchased weight of the steer.

"This fact, however, does not make less important the study of the relative values of feeding rations. In this test the difference in returns between the best and the poorest ration was $3.52 per steer, by no means an unimportant item."

Experiments in fattening lambs, F. B. LINFIELD (*Utah Sta. Bul. No. 78, pp. 55, figs. 2*).—Continuing work previously reported (E. S. R., 13, p. 174) on the value of local-grown feeding stuffs for sheep, a test beginning December 31, 1900, and covering 3 periods of 4 weeks was made with 4 lots, each containing at the start 25 lambs, weighing about 38 lbs. All were fed alfalfa hay. In addition lot 1 was fed wheat screenings, lot 2 chopped wheat, and lot 3 wheat screenings and bran. Lot 4 was fed straw in addition to alfalfa hay with bran also in the second period and bran and wheat screenings in the third period.

During the test the average daily gain on wheat screenings (lot 1) was 0.115 lb., on chopped wheat (lot 2) 0.110 lb., on wheat screenings and bran (lot 3) 0.118 lb., and on straw and grain (lot 4) 0.103 lb. per lamb. The grain eaten per pound of gain ranged from 2.82 lbs. with lot 4 (straw and grain) to 5.9 lbs. with lot 1 (wheat screenings). The former lot ate the largest amount of coarse fodder (13.43 lbs. of alfalfa and 0.81 lb. of straw) per pound of gain. The smallest amount (8.47 lbs. of alfalfa) was eaten by lot 3 on wheat screenings and bran. The cost of a pound of gain ranged from 4.67 cts. with lot 4 (straw and grain) to 6.28 cts. with lot 2 (wheat).

On January 16, 1902, a test similar to the above, except that molasses and sugar-beet pulp were also fed, was begun with 6 lots of lambs averaging 56 lbs. in weight, lots 1 and 2 each containing 16 lambs, and lots 3 to 6 each 17 lambs. As before, alfalfa hay was fed to all the lots, with grain or other feed in addition. On wheat screenings the lambs in lot 1 during the 78 days of the test made an average daily gain of 0.217 lb.; lot 2, on bran and molasses, 0.2 lb.; lot 3, on beet pulp ad libitum, 0.207 lb.; lot 4, on a limited amount of beet pulp (8 to 50 lbs. per lot daily), 0.133 lb.; lot 5, on beet pulp ad libitum, supplemented by equal parts of wheat screenings and bran,

0.330 lb.; and lot 6, on a limited amount of beet pulp (8 to 50 lbs. per lot daily) and the same grain mixture as the preceding lot, 0.214 lb. The cost of a pound of gain ranged from 2.94 cts. with lot 5 (pulp ad libitum and grain) to 4.22 cts. with lot 6 (a limited amount of pulp and grain), being on an average for all the lots 3.56 cts.

Discussing this and the earlier tests the author points out that with not far from 6 lbs. of alfalfa hay, 3.87 lbs. of wheat screenings were required per pound of gain. With the other grains tested the amounts were a little higher. Under similar conditions 17.86 lbs. of beet pulp were required per pound of gain in addition to 7.97 lbs. of alfalfa hay. Feeding bran and screenings diminished the amount of both alfalfa hay and pulp required per pound of gain. When beet-sugar molasses formed a part of the ration 1.42 lbs. of this material and 1.5 lbs. of bran, together with 8.1 lbs. of alfalfa hay, were required per pound of gain.

"The cheapest gains were made on the rations in which an excess of pulp was fed, and there is but slight difference in the cost of one pound of gain whether grain was fed or not with the pulp. In either case it was below 3 cts. The ration that came next in cheapness of gain was that in which molasses was fed. . . .

"In considering the profits to be obtained from any ration, yet another point must be kept in mind; that is, the value of the finished product. Our experience last winter showed that a full grain ration fattened the lambs more rapidly, and in a given time gave a finished animal that was worth more per pound. We thus obtained more for the original weight of the lambs as well as for the gains made. We received one-fourth cent per pound more for the grain-fed lambs. This would mean 14 cts. on the original weight of 56 lbs. per lamb, or $14 on a hundred lambs, an important consideration.

"Viewed in this light, the ration of lucern and mixed grain, or screenings, with or without beet pulp, proved the most profitable ration in fattening lambs."

Analyses are reported of the feeding stuffs used.

Sheep feeding, F. B. LINFIELD (*Montana Sta. Bul. 47, pp. 32, pl. 1*).—The comparative value of different grain rations (wheat screenings, wheat, oats, barley, and a mixture of equal parts of wheat, oats, and barley) supplementing clover hay in finishing sheep for market was studied with 5 lots of lambs and 5 lots of wethers. Two of the lots of wethers contained 23 animals and all the other lots 22 animals each at the beginning of the trial. The test covered 95 days in the winter of 1902-3.

The comparison was so arranged that each ration was tested with both lambs and wethers, the maximum amount of grain fed being 1 lb. per head daily. In the case of the lambs the gains ranged from 0.22 lb. per head per day on oats to 0.287 lb. on wheat screenings. With the wethers the gains ranged from 0.19 lb. on mixed grain to 0.287 lb. on barley. Considering the test as a whole the lambs made an average daily gain of 0.263 lb. at a cost of 4.49 cts. per pound and required 8.03 lbs. clover and 3.11 lbs. grain per pound of gain. In the case of the wethers the average daily gain was 0.238 lb. per head, the cost of a pound of gain 6.3 cts., and the feed required per pound of gain 13.49 lbs. clover and 3.38 lbs. grain.

The lots were marketed in Chicago, the dressed weight of the lambs and wethers being respectively 54.8 and 51.1 per cent of the live weight. When kept for 12 hours without food or water the lambs shrank 2 per cent in weight and the wethers 3 per cent. The author states that considering this test and other results obtained in the last 2 or 3 years, the shrinkage in shipping lambs has been 8.3 per cent and in the case of wethers 7.8 per cent, while on an average it has cost 78.66 cts. per head to ship and sell lambs and $1.165 to ship and sell wethers. Making allowance for the labor involved in feeding there was a profit in the test reported of $2.09 per lamb and $2.55 per wether.

Sheep-feeding experiment, O. C. HIGBEE (*Nebraska Farmer, 35 ([illegible]), No. 47, p. 1136*). On the basis of a test with 2,600 old sheep, the details of which are briefly reported, the feeding of cooked corn is recommended. The author believes that

"sheep will eat a greater quantity of corn per day cooked than dry, . . . will fatten enough faster to pay for the extra corn eaten . . . [and] can be fattened in a much shorter time."

The college lambs, J. D. Towar (*Jour. Agr. and Ind. South Australia, 7 (1903), No. 3, pp. 142, 143*).—For several years raising lambs for early market has been studied, Dorset Horn and Shropshire sires being bred originally with high-grade merinos and later with first-cross Dorset ewes and Dorset-merinos.

"The Dorsets have each year come two or three weeks earlier, and with that advantage have each time excelled the Shropshires in the early market. Yet it has been commonly observed that the Shropshires made the faster growth, nearly overtaking the Dorsets by the time the latter were 4 months old. The young Dorsets . . . invariably commanded the higher price in the sale yard."

Experiments in feeding swine, E. E. Elliott (*Washington Sta. Bul. 58, pp. 24*).—The relative merits of full rations of different grains and grain mixtures were tested with 4 lots of 3 pigs each, most of them averaging a little over 100 lbs. in weight. In 8 weeks the lot fed rolled wheat made an average daily gain of 1.13 lbs. per pig at a cost of 3.07 cts. per pound, and the lot fed a mixture of rolled wheat and barley with ground peas 3:3:2 made an average daily gain of 1.14 lbs. per head at a cost of 3.64 cts. In the case of the lot fed rolled barley the average daily gain was 0.72 lb. per pig and the cost of a pound of gain 5.52 cts., and with the lot fed rolled wheat and barley 1:1 these values were, respectively, 0.71 lb. and 5.23 cts. Similar differences were observed in the feed required per pound of gain, the values being 4.73 and 4.07 lbs. for the lots fed rolled wheat, and peas and grain, and 7.35 and 7.47 lbs., respectively, for the lots fed rolled barley and a mixture of wheat and barley.

In a second test made under much the same conditions with 3 lots of 3 pigs each, the average daily gain per pig in 14 weeks was 0.59 lb. on a mixture of barley, wheat, oats, and peas 4:4:3:1, the cost of a pound of gain being 5.07 cts. and the feed required per pound of gain 6.37 lbs. The lot fed chopped barley made an average daily gain of 0.62 lb. per pig at a cost of 5.17 cts., requiring 6.53 lbs. of feed per pound of gain. The most satisfactory results were obtained with the lot fed chopped wheat, the average daily gain being 0.72 lb., the cost of a pound of gain 3.78 cts., and the feed required per pound of gain 5.25 lbs.

The principal conclusions drawn were in effect that wheat appears to be the feed best adapted for long-continued feeding. In each case the pigs receiving this grain made steadier advancement than any of the other lots.

The addition of peas or oats to a mixed ration did not show any practical advantage over wheat alone. "This should not be taken, however, as conclusive evidence against the feeding of these grains in combination." The greater cost of peas stands in the way of their profitable use as a grain feed when combined with the grains studied.

The results secured from barley were in both tests disappointing. Whether fed in combination or alone, it stood at the foot of the list.

The general results as regards the amount of food eaten are, it is believed, somewhat above the averages reported elsewhere. The same holds true of the gain per day.

With fat hogs bringing 5.5 to 6 cts. per pound, there is a large profit to be made in feeding wheat. This can not be said of barley.

In all the work done the fact stands out prominently that wheat alone when fed in a proper manner, and under conditions calculated to secure good results, will give greater profits than any of the other grains tested. "To expect to reap returns by throwing it on the ground in the mud, or without crushing or soaking it, or in some other way making it more palatable and digestible, is sure to result in failure."

To feed the animal below rather than up to the limit of its capacity is regarded as probably the wiser plan. During the feeding period the pigs must have sufficient exercise to enable them to maintain their appetite. No extra amount of care will replace this requirement.

The second of the reported experiments indicates that feeding hogs for a long period without change of rations or feeding grounds may prove decidedly unprofitable.

Clovers: Indispensable in a poultry dietary, H. E. Moss (*Reliable Poultry Jour., 10 (1903), No. 11, pp. 1038, 1039*).—The importance of fresh and cured red clover and alfalfa as part of a poultry ration is discussed. On the basis of experience the author believes that about one-third of the mash fed poultry should be made up of red clover or alfalfa. In addition to the nutrients which it supplies, clover is believed to heighten the color of the egg yolk.

DAIRY FARMING—DAIRYING.

Methods of milking, H. H. Wing and J. A. Foord (*New York Cornell Sta. Bul. 213, pp. 51–66, figs. 6*).—Tests of the Hegelund method of milking were made with the university herd and with 2 private herds.

Twelve cows of the university herd were divided into 3 groups of 4 cows each. Group A was milked in the regular manner for 5 weeks, with the exception, however, that the residual milk obtained by the Hegelund method was determined during the second and fourth weeks of the period. The conditions were the same for group B, except that the residual milk was determined during the second and third weeks. Group C was milked for 4 weeks, the residual milk being determined during the second week by stripping, and during the third week by the Hegelund method. The experiments began May 13 and closed June 17, a change from stable to pasture being made at the end of the second week. The average data are presented in the following table:

Yields per cow per week by regular and Hegelund methods of milking.

	Number of period.	Regular milking.		Residual milking.	
		Yield of milk.	Yield of fat.	Yield of milk.	Yield of fat.
		Pounds.	*Pounds.*	*Pounds.*	*Pounds.*
Group A (4 cows)	1	189.9	7.435		
	2	189.0	7.204	7.28	0.605
	3	216.3	8.837		
	4	220.8	8.574	6.38	.528
	5	220.2	8.737		
Group B (4 cows)	1	174.7	6.338		
	2	169.0	6.073	9.43	.597
	3	189.5	7.135	8.73	.611
	4	198.9	7.040		
	5	195.1	7.316		
Group C (4 cows)	2	159.9	5.773		
	3	162.8	5.904	[a]10.36	.694
	4	163.2	5.721	10.30	.712
	5	167.2	5.951		
Average		186.9	7.003	8.75	.625

[a] Secured by stripping.

"Considering Group A, the figures seem to justify the conclusion that the residual milk procured by the Hegelund method in the second and fourth weeks was not detrimental to the production at the regular milkings: in other words, it would appear that the milk secured by after-milking was all gain.

"If the total weekly production from the regular milkings of Group B is studied carefully, and in connection with Group A, a similar conclusion may be made, although it is perhaps not so evident at the first glance."

The residual milk obtained either by after-milking or stripping varied from 3.75 to 13.60 lbs. per cow per week, and the fat from 0.401 to 1.011 lbs., the averages

being, respectively, 8.75 and 0.625. The residual milk secured by stripping was practically the same as that secured by the Hegelund method.

In a private herd of 9 cows the residual milk secured per cow per week averaged 4.91 lbs., containing 0.556 lb. of fat. In this experiment, which lasted only 2 weeks, it was quite apparent, however, that the regular milking was done more thoroughly than usual.

In another test of 1 day's duration the residual milk obtained from 9 cows by the Hegelund method averaged 1.94 lbs. per cow.

Results obtained at the Wisconsin Station are cited, and a description of the Hegelund method is quoted from Bulletin 96 of that station (E. S. R., 14, p. 694). "After reviewing all the work at both the Cornell and Wisconsin Stations, it seems safe to say that the advantage of the Hegelund method over stripping, under our conditions, still remains to be proved.

"It is the opinion of the writers that the stripping as well as the milking, except in unusual cases, should be done with the whole hand and not with the thumb and forefinger alone. In milking, the thumb should be turned out and never enclosed within the palm, as is often done. The hand should be opened wide enough to allow the teat to fill to its full capacity, aided by a slight upward pressure upon the udder; the thumb and forefinger should then be closed, followed by the second, third, and fourth fingers in the order named."

Clean milking is advised, and manipulations of the udder and stripping should be resorted to if necessary to accomplish this purpose.

Milk; its production and uses, E. F. WILLOUGHBY (*London: Charles Griffin & Co., Ltd., 1903, pp. 259, figs. 55*).—The author attempts to give "within a small compass and in a convenient form information on every question that might arise in connection with the economic, medical, or chemical aspects of the industry."

The book is written by a medical man, and is largely devoted to the sanitary aspects of milk production. Its value to the practical dairyman is very questionable, although considerable space is devoted to breeds of cows, stabling, feeding, diseases, and general equipment and management of the dairy. Indeed, some of the statements are so unwarranted as to cause surprise at their being incorporated in a book which otherwise has merit. For instance, in discussing the feeding of cows, the unqualified statement is made that "brewery grains, distillery wash, and silage must be condemned *in toto*," and the subject is dismissed with the further comment that they are injurious to the health of cows and render their milk easily prone to spoil and wholly unfit for infant feeding. In the chapter on the diseases of cows, the existence of contagious abortion is declared to be impossible, and supposed cases of this disease are explained by the cows "having partaken alike of the same poisonous plants."

Abstracts are given of sanitary regulations, and the Bang method of controlling tuberculosis is outlined. The composition of milk is discussed, and its value as a food and as a therapeutic agent is considered at some length. Cheese making is not treated, but a chapter is devoted mainly to butter making. The chapter on milk analysis is stated to be drawn mostly from Richmond's Dairy Chemistry. A concluding chapter is devoted to the bacteriological examination of milk.

The composition of milk in the north of England, II, S. H. COLLINS (*Jour. Soc. Chem. Ind., 23 (1904), No. 1, pp. 3–6, dgms. 3*).—Tests were made of 2 dairy herds in the north of England. One was represented by 12 cows, the milking being done at 5 a. m., 1 p. m., and 6 p. m. The tests were made during January, February, and March. The second herd was represented by 22 cows, the milking being done at 5.30 a. m. and 4.30 p. m.

The results for the first herd showed that the percentage of fat was below the legal standard of 3 per cent for 15 out of 72 tests of the morning milk, and 5 out of 72

of the evening milk. On only one occasion were the solids-not-fat below the legal standard of 8.5 per cent. The results for the second herd showed less than 3 per cent of fat on 5 out of 124 occasions in the morning and 11 out of 123 in the evening; and solids-not-fat less than 8.5 on 16 out of 122 occasions in the morning and 21 out of 124 in the evening.

Summarizing the results of the present study with those reported in a previous paper (E. S. R., 14, p. 695), it was found that 96 tests out of 984, or about 10 per cent, were below the standard. "These figures suggest that there is some truth in the opinion that milk in the north of England is not as rich as that in the south, and can not be judged by the same standard." On the basis of the tests of individual cows the author discusses the probability of the mixed milk being below the standard.

Aerated preserved milk (*British Med. Jour., 1904, No. 2245, pp. 84-86*).—This is an editorial account of the preservation of milk by aeration and pasteurization as carried out by a dairy company in England, the process consisting in (1) heating the milk to 150° F. and passing it through a machine in which the fat globules are broken up into small particles; (2) cooling to 40°, and aerating with a mixture of oxygen and carbon dioxid (3:1) under pressure of 50 lbs.; and (3) bottling in sterilized bottles and corking tightly, heating to 150° for 30 minutes, cooling, and again heating as before.

Milk bottled November 2, 1903, was sweet when tested December 8; an exception being made of 2 half-pint bottles which kept only until November 24. After opening the bottles the milk remained sweet at laboratory temperatures for from 4 to 8 days, which is considered the most remarkable fact in connection with the milk. The milk tasted perfectly sweet, although not absolutely the same as fresh milk. There was, however, no taste of boiled milk. The cream showed no tendency to rise, and could not be separated by centrifugal force. The main physical difference between this milk and fresh milk was in the extremely fine subdivision of the fat globules in the former case. No differences were observed as regards the quantity or quality of the different constituents. Artificial digestion experiments showed no difference in the digestibility of the treated milk and fresh milk. All 3 processes—the disintegration of the fat globules, aeration, and heating to 150°—were found essential to the success of the method.

The process of aeration and subsequent heating, as shown by bacteriological investigations, did not completely destroy all spore-bearing bacteria. Diphtheria bacilli added to the milk were not destroyed by aeration alone, but were apparently by aeration and subsequent heating. Caseous material from a tuberculous guinea pig was added to milk, one bottle being kept as a control and one subjected to aeration and heating. A guinea pig inoculated with the sediment from the control bottle developed typical tuberculosis in 18 days, while 2 guinea pigs inoculated with the treated sample showed no signs of the disease upon autopsy at the end of 28 days.

Homogenized milk, P. BUTTENBERG (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 20, pp. 964-968*).—Attention is called to the effect of heat and mechanical action in delaying the spontaneous separation of cream, and a description is given of the method of Gaulin for rendering milk homogeneous in which these 2 factors, as well as that of pressure, are utilized. In this method milk heated to 85° C. is forced under pressure of 250 atmospheres through tubes of 1 mm. diameter and then between closely applied plates of agate and metal, by which process the fat globules are very finely divided.

While the fat globules in ordinary milk may vary in size from 0.0016 to 0.0100 mm., those in milk treated by this method measure usually about 0.0008, and seldom exceed 0.0028 mm. No separation of the fat was observed in a sample of this milk 6 months old, although it had been kept at 37° for 1 week. The apparatus in most common use requires 7 horsepower and permits the treatment of about 1,000 liters of

milk per hour. It is noted that factories are established in Germany, France, Belgium, Holland, England and Norway; and that milk so treated has been on the market for about 1 year.

In determining the fat in homogenized milk the Adams method gave much lower results than the Gottlieb method.

Report upon the results with different kinds of pure and impure milk in infant feeding in tenement houses and institutions of New York City: A clinical and bacteriological study, W. H. PARK and L. E. HOLT (*Sanitarian, 52 (1904), No. 410, pp. 13–41*).—It was the purpose of this investigation to compare the results of infant feeding in tenement houses in winter and summer and to determine how far such results were due to the character of the milk used, and also to what extent the results were modified by the care the infants received and the surroundings in which they lived.

The observations were made by a number of physicians during the summers of 1901 and 1902 and the intervening winter. In each case the period of observation was about 10 weeks and the conditions were, as far as possible, the same as before this period. Nearly all the infants were observed in their homes twice a week.

A bacteriological study was made of the milk used. In all 239 varieties of bacteria were isolated. Of this number 139 were grown in pure cultures and fed to kittens without injurious effects except in one instance. The results, as a whole, show no relation between special varieties of bacteria in milk and the health of infants. Several forms of milk were used, the poorest being that purchased from small stores. The bacteriological content of this milk ranged in the summer of 1901 from 4,000,000 to 200,000,000, and averaged about 20,000,000 per cubic centimeter. In the summer of 1902 it averaged about 3,000,000. During the winter the number of bacteria in the store milk ranged from 100,000 to 5,000,000, and averaged 400,000 per cubic centimeter. The form of heating milk generally employed was found to kill from 95 to 99 per cent of the bacteria.

Of the 211 cases under observation in the winter, 156 did well, 41 did fairly well, 8 did badly, and 6 died. Of the 421 cases under observation in the summer, 184 did well, 108 did fairly well, 88 did badly, and 41 died. The great difference in the results between winter and summer conditions is ascribed primarily to heat, bacteria and their products in the milk being considered a secondary factor except where contamination was extreme or pathogenic organisms were present.

"During cool weather neither the mortality nor the health of the infants observed in the investigation was appreciably affected by the kind of milk or by the number of bacteria which it contained. . . . During hot weather, when the resistance of the children was lowered, the kind of milk taken influenced both the amount of illness and the mortality; those who took condensed milk and cheap store milk did the worst, and those who received breast milk, pure bottled milk, and modified milk did the best. The effect of bacterial contamination was very marked when the milk was taken without previous heating; but, unless the contamination was very excessive, only slight when heating was employed shortly before feeding. . . . When milk of average quality was fed sterilized and raw, those infants who received milk previously heated did, on the average, much better in warm weather than those who received it raw. The difference was so quickly manifest and so marked that there could be no mistaking the meaning of the results." Children over 3 years of age were not ordinarily affected at any season of the year by the bacteria in the milk unless the contamination was excessive.

Pasteurization of milk: Conditions and processes necessary for the destruction of pathogenic bacteria without injuring the quality of the products, M. HENSEVAL and G. MULLIE (*Rev. Gén. Lait, 3 (1903), Nos. 4, pp. 73–80; 5, pp. 97–103; 6, pp. 121–126*).—This is essentially a review of recent investigations

on the sources of bacteria in milk; hygienic precautions to be observed in the production and handling of milk; changes in milk produced by heating, including the precipitation of albumin, the formation of a surface membrane, the lessening of the tendency of the cream to rise, the decomposition of the albuminoids and the destruction of ferments; the effect of pasteurization upon the digestibility of milk and upon its suitability for infant feeding, and more particularly the different methods of pasteurization.

The authors conclude that milk of unknown origin should be pasteurized, and that this process when properly done destroys the pathogenic bacteria without injuring sensibly the value of the milk as a food.

Influence of the "scalded layer" on the efficiency of pasteurization of milk, H. L. RUSSELL and E. G. HASTINGS (*Rev. Gén. Lait, 3 (1903), Nos. 2, pp. 34–39; 3, pp. 49–56*).—This article, which was read before the recent International Congress of Hygiene and Demography, is in part a summary of experiments previously noted (E. S. R., 13, p. 986). The resistance to heat of the tubercle bacillus, a micrococcus, and *Bacillus prodigiosus*, was greatly increased when the method of pasteurization used permitted the formation of a surface membrane. When heated in a closed vessel and subjected to constant agitation, thus preventing the formation of a surface membrane, a temperature of 60° C. maintained for 15 minutes destroyed all tubercle bacilli.

It is believed that when properly done pasteurization at 60° for 15 minutes is sufficient to destroy all nonspore-bearing pathogenic bacteria without materially altering the flavor or appearance of the milk or cream.

Destruction of tubercle bacilli in heated milk, W. RULLMANN (*Rev. Gén. Lait, 3 (1903), No 1, pp. 15, 16*).—Tubercle bacilli introduced into milk were not destroyed by heating at 65° C. for a half hour, the milk meanwhile being subjected to constant agitation.

Process butter, R. W. CLARK and J. A. CROCKETT (*Utah Sta. Bul. 79, pp. 56–61*).—This bulletin is issued as a warning against the promoters of a churning process claimed by them to increase the yield of butter by incorporating abnormally large quantities of water and casein. A sample of butter made by this process scored 44 points out of 100 and showed the following composition: Water 26.05, fat 67.35, casein 4.16, and salt 2.44 per cent. In several churning experiments at the station butter was made which showed a water content ranging from 22.86 to 36.37 per cent. The State law establishing a standard for butter of not less than 83 per cent of butter fat is quoted.

Influence of feeding cotton-seed meal and sesame cake on the properties of butter fat, A. J. SWAVING (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 3, pp. 97–115; abs. in Centbl. Agr. Chem., 32 (1903), No. 11, pp. 759–761*).—In 3 series of controlled experiments butter made from cows fed cotton-seed meal responded invariably to the Halphen reaction. This influence of cotton-seed meal was manifested within 24 hours from the beginning of the feeding period, and lasted several days after its close. The reaction varied to a certain extent with the amount of meal fed. In certain cases it was equivalent to that shown by an artificial mixture of 5 per cent of cotton-seed oil and 95 per cent of butter fat.

The cotton-seed meal exerted no appreciable influence on the yield of butter nor the refractometer and Reichert-Meissl numbers. Butter made from cows fed sesame cake, on the contrary, showed no transmission of the active principle of this material as determined by the Badouin and Soltsien tests.

The composition of the butter fat of individual cows in Holland, J. KLEIN and A. KIRSTEN (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 4, pp. [illegible]*).—The Köttstorfer, Hehner, Reichert-Meissl, and refractometer numbers were determined on 42 samples of butter fat obtained from 5 cows at different times during one

year. The cows varied in age from 4 to 13 years, and were in different stages of lactation when the samples were secured. The feeding also varied from time to time.

The glycerin varied in amount from 11.99 to 13.07, averaging 12.46 per cent; the total fatty acids from 94.18 to 94.63, averaging 94.48 per cent; the insoluble nonvolatile fatty acids from 84.23 to 90.46, averaging 87.86 per cent; oleic acid from 32.31 to 50.68, averaging 39.71 per cent; and the soluble volatile fatty acids from 4.07 to 9.95, averaging 6.47 per cent. The refractometer number varied from 41.7 to 45.9, and the Reichert-Meissl number from 19.1 to 43.5. Feeding and the stage of lactation are believed to be the most important factors affecting the composition of the butter fat.

Variations in the composition of butter, A. BONN (*Rev. Internat. Falsif., 16 (1903), pp. 129-132; abs. in Chem. Centbl., 1903, II, No. 26, p. 1461*).—The author reviews considerable analytical data concerning variations in the composition of butter, and draws the conclusion that some definite standard should be adopted. He suggests a saponification number of 218, a Hehner number of 88, and a content of volatile fatty acids as butyric acid of 5.5 per cent.

Making butter with ferments containing starch, J. VANDERPLANCKEN and A. J. J. VANDEVELDE (*Sep. from Rpt. 6, Flemish Cong. Nat. Sci. and Med., 1902, pp. 4*).—The Belgian law requires the addition of starch and sesame oil to oleomargarine in order to make it more easily detected. The authors observed that certain ferments used in butter making are mixed with starch, and their investigations showed that this starch appears in the finished butter, making it, therefore, impossible to determine with certainty the addition of oleomargarine by this method.—H. M. PIETERS.

A comparison of the bacterial content of cheese cured at different temperatures, F. C. HARRISON and W. T. CONNELL (*Rev. Gén. Lait, 3 (1903), Nos. 4, pp. 80-85; 5, pp. 103-111; 6, pp. 126-137; 7, pp. 150-155; 8, pp. 173-180*).—The bacterial flora of Canadian Cheddar cheese and the relation of the bacteria to the changes occurring during the process of ripening, were investigated at the Ontario Agricultural College at Guelph and the Eastern Dairy School at Kingston, Canada. The cheeses subjected to bacteriological examinations were cured (1) in an insulated curing room having a temperature varying usually between 60 and 65°, and averaging 62.2° F.; (2) in an ordinary curing room in which no attempt was made to control the temperature; (3) in cold storage at about 40° F.; and (4) in an ordinary curing room for 1, 2, or 3 weeks and then in cold storage.

The bacteria found were divided into 4 classes: (1) Lactic-acid bacteria, including several varieties, of which the commonest was *Bacillus acidi lactici;* (2) gas-forming bacteria, mainly varieties of *B. coli communis* and *B. lactis ærogenes*, but including occasionally a species resembling *Proteus vulgaris;* (3) digesting bacteria, consisting of *Micrococcus aureus lactis, M. varians lactis, B. fulvus,* and *B. halofaciens;* and (4) indifferent bacteria, including various forms of sarcina, yeast, and torula, *B. subtilis*, and occasionally one or two other species in small numbers. The lactic-acid bacteria were the only forms constantly present in very large numbers. The scorings and the bacteriological data are presented in detail in tabular form.

The bacterial content was usually highest at the time of taking from the press, although occasionally the maximum was not reached until 2 to 5 days later. The total number of bacteria in cheese under 4 days old varied from 110,750,000 to 635,000,000 per gram. After the first few days there was a gradual and continuous decline in the number of bacteria. The bacterial content remained high for a longer period, and the decline was more gradual in the case of cheese kept in cold storage than in cheese cured in an ordinary curing room. The cold-storage cheese showed invariably the highest bacterial content, and with this was associated better body and flavor in the cheese. It is therefore inferred that the higher bacterial content is the chief factor in determining the flavor of cheese properly made from normal

milk. The lactic-acid bacteria were practically the only species present, and these decreased, not only in number, but in acid-producing power, with the lapse of time. Undesirable species of bacteria were found in nearly all of the cheeses examined, but these were always in insignificant numbers and soon died out. They seemed unable to grow at a temperature of 40°.

In the Guelph experiments the cheese placed immediately in cold storage ranked first in quality, that placed in cold storage after 1, 2, and 3 weeks ranking next, in the order mentioned. In the Kingston experiments the cheese ripened in the regulated room was superior to that ripened in the ordinary curing room. According to the authors, the most noticeable fact concerning the best cheese was the high content of lactic-acid bacteria and the length of time that these organisms remained alive. The bacterial flora of the cheese made in the 2 localities was very similar.

Notes on Cheddar cheese making, R. T. ARCHER (*Jour. Dept. Agr. Victoria, 2 (1903), No. 2, pp. 137–140*).—Notes are given on the treatment of overripe milk and on the prevention of gassy curd.

Improved cream separator (*Sci. Amer., 89 (1903), No. 26, p. 482, fig. 1*).—A description of a new separator of the centrifugal type, recently patented.

Thirty-First Annual Report of the Wisconsin Dairymen's Association (*Madison, Wis.: Democrat Printing Co., 1903, pp. 192*).—Among the papers presented at the annual meeting held in February, 1903, mention may be made of the following: A Fond du Lac County Census and its Lessons, by C. P. Goodrich, in which data are given on the cost of food and the quantity and value of the product of different herds; Needs of the Wisconsin Cheese Industry, by U. S. Baer; Dairy Possibilities in Northern Wisconsin, by F. Reitbrock; The Wisconsin Feeding Stuffs Law and its Importance to the Farmer, by W. A. Henry, covering essentially the substance of Bulletin 97 of the Wisconsin Station (E. S. R., 14, p. 790); and reports of cheese and creamery instructors.

Missouri Dairy Association (*Mo. Bul. Missouri State Bd. Agr., 3 (1903), No. 9, pp. 50, figs. 3*).—Abstracts of the addresses delivered before the annual meeting held in December, 1903.

VETERINARY SCIENCE AND PRACTICE.

The care of animals, N. S. MAYO (*New York: The Macmillan Co., 1903, pp. XVI+459, figs. 59*).—In this volume the author seeks to give an account of the proper care of animals, with special reference to their physical needs and comfort in health and disease. Attention is called to the great importance of proper sanitation in preventing the development of animal diseases. The subjects discussed in the volume include feeding, watering, and exercise of animals; care of animals in stables and yards; care of pets; judging and handling horses; lameness and shoeing of horses; symptoms of diseases; treatment for diseases; surgical cases; breeding; veterinary obstetrics, and discussion of various animal diseases classified according to the part or organ affected. A chapter is also presented on the common prescriptions and doses of veterinary medicines.

Animal diseases, J. M. CHRISTY (*Transvaal Agr. Jour., 2 (1903), No. 5, pp. 14–[illegible]*).—Notes are given on sarcoptic, psoroptic, and symbiotic scabies of horses and mules, foot-and-mouth disease in cattle, scab in sheep, glanders, contagious pleuro-pneumonia, and rinderpest.

The diseases of stock and how to treat them, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 23 (1903), No. 5, pp. 577–584*).—Brief popular notes on gall sickness, colic in horses, and respiratory diseases.

Veterinary studies for agricultural students, M. H. REYNOLDS (*St. Paul: Author, 1903, pp. XXIII+246, figs. 86*).—The purpose of this volume, as announced by the author, is to furnish material for class work in instruction of students in vet-

erinary science in agricultural colleges. The author found in his experience that students in such institutions were quite unequally prepared for veterinary instruction, and the various matters which are considered necessary for such instruction are included in this volume. The subjects discussed by the author include anatomy, physiology, pathology, cause and prevention of disease, a description of the common diseases of domesticated animals, obstetrics, and the administration of medicines.

Surgical and obstetrical operations for veterinary students and practitioners, W. L. WILLIAMS (*Ithaca, N. Y.: Author, 1903, pp. IX+210, figs. 48*).—This volume is based to a considerable extent upon Operationskursus, by W. Pfeiffer, with numerous additions by the author. The subjects discussed include operations on the head, neck, trunk, genital organs, extremities, and embryotomy.

Annual report on progress in the field of pathogenic micro-organisms, P. VON BAUMGARTEN and T. TANGL (*Jahresber. Fortschr. Lehre Path. Micro-organ., 17 (1901), 2. Abt., pp. XII+1114*).—This report contains extended bibliographies relating to pathogenic bacteria, fungi, and protozoa, together with brief abstracts of the more important articles. The material is classified according to subject-matter, and the abstracts and related bibliographical lists are brought together. Extended author and subject indexes are added to the report.

The most important Italian literature on general pathology and pathological anatomy published in 1902, O. BARBACCI (*Centbl. Allg. Path. u. Path. Anat., 14 (1903), No. 16–17, pp. 673–709*).—A classified list is presented of Italian literature published in 1902 relating to technique, methods of investigation, tumors, cell structure, immunity, intoxications, infectious diseases, organic diseases, etc. A brief abstract is given of the more important works.

Immunity and narcosis, J. J. SNEL (*Berlin. Klin. Wchnschr., 40 (1903), No. 10, pp. 212–214*).—The experiments recorded in this paper were undertaken for the purpose of determining the influence of narcosis upon the persistence of immunity. Guinea pigs were used for the experiment and were inoculated with anthrax. The narcotic substances used in these experiments included ether, chloroform, chloral hydrate, and morphin.

During these experiments it was found that a short narcosis produced by ether did not entirely destroy the bactericidal power of the lungs. The course of infection was shorter, however, when the narcosis was continued for a longer period. The bactericidal action of the lungs was restored soon after the narcosis was discontinued. Similar results were obtained from the use of chloroform, chloral hydrate, and morphin. In order to test the direct action of ether and chloroform upon anthrax bacilli, a comparative experiment was made, during which it was found that white mice inoculated with anthrax bacilli died within 24 hours, while mice inoculated with cultures which had been subjected to ether or chloroform fumes for 4 hours lived for periods ranging from 46 to 70 hours.

The author believes as a result of these experiments that the influence of narcosis is sufficient to bring about the death of infected animals as a result of the temporary destruction of the bactericidal power of the lungs.

The morphological processes in infection and immunity, A. WOLFF (*Berlin. Klin. Wchnschr., 40 (1903), Nos. 17, pp. 387–391; 18, p. 414; 19, pp. 434–436; 20, pp. 456–459*).—The author describes in detail the results of his study and observations on this problem. It was found that the leucocytes were sensitive to the action of iodin during infectious processes. There is no causal connection between iodin reaction and the phenomena of leucocytosis. These results are believed to militate against Metschnikoff's theory of immunity. In the peritoneal exudate of normal guinea pigs the leucocytes were often entirely absent.

The author's hypothesis concerning the cause of death in infectious diseases is that death takes place as a result of the absorption of bacterial products in the process of

bacteriolysis. It is believed that the appearance of leucocytes is merely a symptom which indicates the existence of a pronounced disintegration of cells or bacteria.

Annual report of the State Board of Live Stock Commissioners of Ohio, P. FISHER and W. W. MILLER (*Columbus, O.: State Bd. Live Stock Comrs., 1902, pp. 29*).—Notes are given on the prevalence of glanders, hog cholera, swine plague, tuberculosis, infectious keratitis, blackleg, anthrax, actinomycosis, and sheep scab. Copies are presented of various State laws and rules covering animal diseases and shipment of live stock.

Report of the chief inspector of stock for the year 1902, T. A. TABART (*Tasmania: Govt. Printer, 1903, pp. 1–8*).—Brief notes are given on sheep scab, dipping methods, quarantine, wool sales, anthrax and its treatment, and septic pleuro-pneumonia in calves.

Report of the government veterinarian, J. D. STEWART (*New South Wales, Dept. Mines and Agr., Stock and Brands Branch Rpt. 1902, pp. 25*).—Notes are presented on the inspection work during the year 1902 and on the prevalence of animal diseases. It was found during the progress of this work that the chief diseases of horses were ophthalmia, influenza, glanders, and troubles from infestation with botflies. In cattle the most important diseases were anthrax, actinomycosis, tuberculosis, Texas fever, and pleuro-pneumonia. Notes are also given on anthrax, scab, and flukeworms in sheep, and on the work of the veterinary department in the destruction of noxious animals.

Report of the chief inspector of stock and brands for the year 1902, P. R. GORDON (*Queensland Agr. Jour., 13 (1903), No. 5, pp. 483–487*).—Notes are given on Texas fever and other diseases of animals which prevailed during the year, together with notes on the work of destroying injurious marsupials and other animals.

Notes from practice, R. SCHMIDT (*Berlin. Tierärztl. Wchnschr., 1903, No. 19, pp. 302–304*).—The author presents detailed notes on results obtained in the use of various Vasogen preparations in the treatment of different diseases. A combination of iodin and Vasogen was used successfully in the treatment of actinomycosis. In 6 cases this combination was more effective than a mixture of iodoform and Vasogen. The remedy was applied externally upon the actinomycotic wounds after they had been opened by surgical interference. Notes are also given on the use of this and other related remedies in the treatment of various diseases.

Animal and human tuberculosis, A. CIPOLLINA (*Berlin. Klin. Wchnschr., 40 (1903), No. 8, pp. 163, 164*).—The author carried on an experiment in feeding apes with tuberculous cows' milk. A culture of tubercle bacilli was obtained and 2 cc. of this material was mixed with 100 cc. of milk as a feed for apes used in the experiment. The feeding experiment was carried on for 1 month. After a period of 1½ months an ape showed symptoms of infection and died at the end of 3 months.

An autopsy showed the presence of serous peritonitis with numerous tubercles on the omentum. The mesenteric glands were enlarged and caseous and many other abdominal structures were involved. No lesions were found in the walls of the alimentary tract. The author concludes from these experiments that apes may be infected with tuberculosis through the walls of the alimentary tract without the production of primary lesions in that structure.

The identity of bovine and human tuberculosis, TROJE (*Deut. Med. Wchnschr., 29 (1903), No. 11, pp. 190–192*).—The author describes a number of cases of tuberculosis in man acquired by infection with bovine tubercle bacilli through accidental wounds. Notes are also given on cases of ingestion tuberculosis in man, with evidence of bovine origin of such cases. During the examination of these cases by way of comparison with other cases of human origin, the author found it was impossible to distinguish between the lesions formed in the human skin and lymphatic glands after infection with bovine tubercle bacilli and the lesions of ordinary lupus. It is

argued, therefore, that these cases furnish fresh proof of the identity of human and bovine tuberculosis and indicate the possibility of morphological variation in the bacillus during the process of adaptation.

Experimental demonstration of the unity of tuberculosis, S. ARLOING (*Jour. Méd. Vét. et Zootech., 5. ser., 7 (1903), May, pp. 257–278*).—An extensive series of experiments is reported, during which 46 animals were inoculated with tubercle bacilli. Of this number, 33 received human tubercle bacilli and 13 bacilli of bovine origin. The bacilli of human origin came from 5 cases of tuberculosis. During these experiments asses, goats, cattle, sheep, and hogs were inoculated with human tubercle bacilli, cattle, sheep, and goats with bovine tubercle bacilli, and cattle, sheep, and goats with equine tubercle bacilli.

The results were positive in every case, and the author concludes, therefore, that tuberculosis in man is transmissible to cattle and causes characteristic tuberculous lesions. The human tubercle bacillus is not always of the same virulence; in some cases it appears almost entirely to have lost its virulence, while in others it is fully as virulent as the bovine tubercle bacillus. It is believed that the variability in the virulence of the human tubercle bacillus is sufficient to account for the negative results obtained by Koch and Schütz.

Experiments in inoculating cattle with tubercle bacilli of different origin, H. KOSSEL (*Ztschr. Fleisch- u. Milchhyg., 13 (1903), No. 11, pp. 329–337*).—The experiments reported in this article were undertaken for the purpose of testing the foundation of Koch's assertion of the nonidentity of human and bovine tuberculosis.

During these experiments cattle inoculated with tubercle bacilli of bovine origin showed an enlargement of the prescapular lymphatic glands within from 8 to 10 days, and this swelling was preceded by the formation of an infiltration at the point of inoculation. About 10 days after inoculation a high fever developed, which persisted until the death of the animals in all acute cases. Infection with bovine tubercle bacilli, however, did not always produce an acute infection. The results obtained from inoculation of cattle with human tubercle bacilli showed that cultures of human origin are less virulent.

Cultures were obtained from 19 cases of pulmonary tuberculosis in man, and were inoculated hypodermically into cattle. An infiltration was formed at the point of inoculation, and the prescapular glands became enlarged within 8 to 14 days. When the animals were killed, 4 weeks after inoculation, living tubercle bacilli were found in the caseous masses at the point of inoculation, but the prescapular glands in the majority of cases had regained their normal size and appearance. In a few cases, however, caseous foci were still found in these glands.

The author also investigated 7 cases of primary intestinal tuberculosis in man, and from 39 cultures thus obtained cattle were inoculated for the purpose of determining the virulence of these bacilli. Four out of these 39 cultures were found to produce generalized tuberculosis in cattle. As a rule, however, the bacilli obtained from man were far less virulent than the bovine organism.

Ingestion tuberculosis, D. VON HANSEMANN (*Berlin. Klin. Wchnschr., 40 (1903), Nos. 7, pp. 141–144; 8, pp. 170–172*).—Notes are given on 25 cases of intestinal tuberculosis in man with special reference to the origin of these cases. The tubercle bacilli concerned in the production of these cases were of animal origin. Brief notes are given on ingestion tuberculosis in animals by way of comparison with data obtained in the study of human tuberculosis. The author believes that in both man and animals infection may take place through the healthy mucous membrane of the alimentary tract, without causing any lesion in that structure. As a rule, however, it is believed that infection takes place only during the presence of some other disease or when the resisting power of the mucous membrane is otherwise lowered.

The permeability of the young gastroenteric mucous lining for tubercle bacilli, DISSE (*Berlin. Klin. Wchnschr., 40 (1903), No. 1, pp. 4–7, figs. 4*).—From the

author's study of the structure of the mucous membranes in young animals it is concluded that this membrane in the stomach of new-born animals is comparatively thin and increases in thickness as age advances. The mucous lining of the intestines, on the other hand, is about as thick in the young as in the adult animal. The author describes the microscopic features of the mucous membrane in so far as they are related to the permeability of this membrane by tubercle bacilli.

Combating tuberculosis, E. VON BEHRING (*Berlin. Klin. Wchnschr., 40 (1903), No. 11, pp. 233–238*).—The author describes his method of immunization by means of attenuated cultures of tubercle bacilli, and presents notes on the effect of repeated injections of tuberculin in tuberculous animals.

Pulmonary tuberculosis and means of combating this disease, E. VON BEHRING (*Deut. Med. Wchnschr., 29 (1903), No. 39, pp. 689–697*).—The author discusses in a general way the ordinary means of transmission of tuberculosis in both animals and man, attributing the chief source of pulmonary tuberculosis in man to the milk used during infancy, which is likewise believed to be the chief source of tuberculosis in animals.

It is suggested that a great improvement would be made in the sanitary control of milk if it were pasteurized at the point of production and before being sent to distributing centers. The resulting product would thus be obtained in a better condition, both for feeding calves and other young domesticated animals, and as food for children. The author argues that the danger from feeding tuberculous milk to young children or animals can not be exaggerated. The possibility of extending the immunization processes devised by the author for cattle and man is also suggested.

Vaccination against tuberculosis in cattle according to the method of E. von Behring, G. REGNÉR and O. STENSTRÖM (*Meddel. K. Landtbr. Styr. [Sweden], 1903, No. 88, pp. 36*).—A detailed account is given of a method of immunization as applied to cattle by E. von Behring in Marburg. The results thus far obtained indicate that the method is practicable and satisfactory.

Immunization against tuberculosis, F. NEUFELD (*Deut. Med. Wchnschr., 29 (1903), No. 37, pp. 653–656*).—The author's experiments were made on 46 goats, 9 asses, and numerous cattle. The method of procedure was based on the assumption of the nonidentity of human and bovine tuberculosis, the idea being to immunize species of animals which are susceptible only to the one kind of virus, by a previous treatment with the other kind. The general plan of immunization was to treat the animals first with preparations of dead tubercle bacilli, then with increasing doses of living cultures, first of human tuberculosis and finally of bovine tuberculosis.

The results show that it is possible to immunize goats, asses, and cattle by intravenous injections of living human tubercle bacilli so that these animals resist subsequent infection with doses of virulent bovine cultures which would be fatal to untreated animals.

The immunization of the organism against tuberculosis, E. MARAGLIANO (*Berlin. Klin. Wchnschr., 40 (1903), Nos. 25, pp. 563–567; 26, pp. 593–596*).—The author believes that in the process of agglutination by the serum of tuberculous animals, substances present in the blood play an important rôle and exercise a specific action upon the tubercle bacillus. The agglutinative action of the serum of animals is therefore considered as a proof of resisting power on the part of the animal. In addition to the substances which are normally present in the blood to protect the animal against infection, new substances develop after infection with pathogenic bacilli.

The author describes a number of his experiments in immunization of animals against tuberculosis, which it is stated were begun in 1895. He has succeeded in immunizing cattle, horses, asses, goats, sheep, and dogs against tuberculosis. In one case success was had in immunizing a rabbit against this disease. Some of the animals have been under observation for 5 years and the immunization is believed to

be complete. The author maintains that immunization can be brought about either by the use of active cultures of tubercle bacilli, or with dead and desiccated bacilli. It is also held that it is not necessary to make intravenous inoculations in order to obtain immunity.

Attention is called to the possibility of applying this method of immunization in the treatment of human tuberculosis. During the author's experiments it was found possible to prepare a vaccine material which produced a tuberculous inflammation when injected hypodermically, and immunity resulted from the substances developed at the point of injection.

The cause of error in diagnosing tubercle bacilli in blood clots, F. Bezançon et al. (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 5, pp. 203, 204*).—The authors allude to the fact that in the examination of clotted blood from tuberculous animals organisms may sometimes be observed in colonies and may resemble in all essential respects the bacillus of tuberculosis. This resemblance may include the staining reaction, acid-fast condition, and other characters. The authors maintain that it is frequently necessary to resort to experimentation in the laboratory in order to determine definitely whether one is dealing with tubercle bacilli or other acid-fast bacilli.

The legal requirement for the determination of tuberculosis in all living animals, Thiro (*Berlin. Tierärztl. Wchnschr., 1903, No. 17, pp. 279–282*).—Attention is called to the extreme difficulty met with in attempting to diagnose tuberculosis ante-mortem. Such diagnoses must depend upon a physical examination, bacteriological examination of sputum, and of the superficial lymphatic glands, etc. In the opinion of the author it is in many cases absolutely impossible to give a correct diagnosis from an examination of the living animal, and it is urged that the legal requirement of a positive diagnosis will lead to many faulty diagnoses and to loss of reputation on the part of veterinarians.

The action of dead tubercle bacilli and the toxins of tubercle bacilli, V. Klingmüller (*Berlin. Klin. Wchnschr., 40 (1903), No. 34, pp. 778–780*).—In order to determine the cause of swellings and pathological changes at the point of injection of tuberculin, the author made a careful study of these tissues. It was found that in numerous cases typical tuberculous formations were present with epithelioid and giant cells. It appears, therefore, that tubercle bacilli in some form may be present in the tuberculin.

During the author's investigation 10 samples of tuberculin were examined, and in 4 samples tubercle bacilli and disintegrated fragments were found. After subjecting these samples to live steam at a temperature of 105° C. for 1 hour and filtering through moist cotton batting, bacilli were still present, and were only removed after filtration through clay filters. Inoculation experiments showed that the tubercle bacilli in samples of tuberculin were not alive and were not capable of producing tuberculosis. It is believed, therefore, that the alterations caused at the point of injection of tuberculin are due to the presence of dead tubercle bacilli. The toxins of the tubercle bacillus are thus capable of producing tuberculous alterations in the tissue.

Generalized tuberculosis in hogs, K. Müller (*Ztschr. Fleisch- u. Milchhyg., 13 (1903), No. 11, pp. 350, 351*).—Notes are given on the lesions and pathological anatomy in cases of generalized tuberculosis in hogs. In 1 case, which is described in detail, it was found that the hog had received large quantities of raw milk as food.

The diagnosis of anthrax and blackleg, R. Ostertag (*Ztschr. Fleisch- u. Milchhyg., 13 (1903), No. 7, pp. 213–216*).—The author agrees with the contentions of certain veterinarians that the requirement of a bacteriological diagnosis of anthrax and blackleg is unnecessary and sometimes unreliable. It is argued, however, that as a rule the bacteriological test gives reliable results and it is urged that the law does not work any excessive hardship upon veterinarians.

Verification of the diagnosis of anthrax and blackleg, Tillmann (*Deut. Tierärztl. Wchnschr., 11 (1903), No. 11, pp. 97-100*).—The author takes the position that the obligatory bacteriological verification of the diagnosis of anthrax and blackleg has no good scientific basis and should be discontinued, both on the ground of being dangerous and also because it is unsatisfactory. It is recommended that such verification of a clinical diagnosis be left to the discretion of the district veterinarians and similar officials.

The action of iodin on the virus of anthrax and blackleg, and the possibility of transforming either virus into vaccine by the addition of Lugol's solution, V. Galtier (*Jour. Méd. Vét. et Zootech., 5. ser., 7 (1903), Aug., pp. 462-467*).—The author made a number of experiments in inoculating rabbits and guinea pigs with anthrax and blackleg cultures, after these had been treated with iodin and Lugol's solution.

As a result of these experiments it was found that the addition of 2 cc. of Lugol's solution to each 1 cc. of a sporulated anthrax culture at the time of inoculation was sufficient to prevent an infection with anthrax in rabbits and guinea pigs and to change the virus into a vaccine which produced considerable immunity in the experimental animals. Similar results were obtained in experiments with blackleg virus. This virus was rendered harmless for guinea pigs when mixed with large doses of Lugol's solution, or when exposed for a considerable time to a small dose of iodin.

A new method of vaccination for blackleg, Baer (*Berlin. Tierärztl. Wchnschr., 1903, No. 12, pp. 194, 195, fig. 1*).—Notes are given on a needle especially designed for use in vaccinating cattle against blackleg by means of the so called "Blacklegine" threads.

Report to the Minister of Education concerning investigations on foot-and-mouth disease, Löffler (*Berlin. Tierärztl. Wchnschr., 1903, No. 13, pp. 209-215*).—A mixture was made of immune serum and attenuated lymph, and large numbers of animals were vaccinated with this mixture to test its efficacy in checking foot-and-mouth disease. Animals treated with this mixture were allowed to reenter infected premises within from 10 days to 3 weeks after treatment. It was found that the majority of animals thus treated had developed an immunity sufficient to resist natural infection after a period of 3 weeks.

In practical tests of this method it was found that vaccinated animals developed an immunity while remaining in constant association with infected animals. The method used by the author has been found effective in immunizing cattle, hogs, and sheep against foot-and-mouth disease. The use of a mixture of a horse serum and serum from cattle which had recovered from the disease was very effective in producing immunity in healthy cattle. A number of cattle were immunized by the administration of increasing doses of lymph. In numerous experiments carried out by the author young pigs were found to be the most suitable animals for the continuous cultivation of an immunizing lymph for general use.

The method of Baccelli applied in the treatment of cattle affected with foot-and-mouth disease, I. Sacchini (*Clin. Vet., 26 (1903), Nos. 3, pp. 13-16; 5, pp. 25-28; 7, pp. 39-43; 9, pp. 53-57; 11, pp. 63-67; 13, pp. 75-79; 15, pp. 89-92; 17, pp. 101-104*).—The author made a study of the method proposed by Baccelli, viz, intravenous inoculations with corrosive sublimate in the treatment of foot-and-mouth disease in cattle. Three injections were given at intervals of 2 or 3 days, the corrosive sublimate being administered intravenously in doses of 5 cgm. from a solution containing 100 parts water, 1 part corrosive sublimate, 1 part sodium chlorid.

During these experiments the author found that cattle could receive 9 cgm. of corrosive sublimate without suffering any harm and that doses of 5 cgm. lowered the temperature and relieved the symptoms of the disease, even where the hoofs and mouth were badly affected, and in general led to a comparatively rapid recovery from the disease with cicatrization of the old lesions.

Texas fever, A. R. Ward (*California Sta. Circ. 1, pp. 7*).—Brief notes are given on the symptoms, post-mortem lesions, etiology, and means of transmission of this disease. Methods of controlling the disease are also outlined.

How can we exterminate the cattle tick? H. A. Morgan (*Proc. Louisiana State Agr. Soc. and Stockbreeders' Assoc. 1903, pp. 77–79*).—The necessity for improving the beef and dairy herds of the South involves strict sanitary measures in controlling Texas fever. While immunity can be produced in susceptible animals by inoculation with the blood of animals which have recovered from Texas fever, it seems desirable to adopt measures looking toward the destruction of the tick. The author maintains, however, that no success can be hoped for from any method of tick extermination without cooperation among the farmers.

Some experiments in inoculation for redwater, E. B. Maclean (*Transvaal Agr. Jour., 2 (1903), No. 5, pp. 58–60*).—During the author's first experiments in inoculation for this disease, from 10 to 20 per cent of the inoculated animals died within 3 weeks after inoculation. In these experiments more than 6,000 cattle were inoculated, and at last the loss from inoculation was reduced to from 2 to 3 per cent. The doses of defibrinated blood used in these experiments were 5 and 6 cc.

Rhodesian tick fever, S. B. Woollatt (*Agr. Jour. and Min. Rec. [Natal], 6 (1903), No. 19, pp. 704–709*).—From experiments and observations thus far made the author believes that this disease is undoubtedly carried by ticks, which leave the cattle during the larval and again during the nymph stage, but it is only in the adult condition that they are virulent. The symptoms and post-mortem appearances of Rhodesian fever are described in detail.

Cause of the cornstalk disease in cattle, R. E. Buchanan (*Iowa Agr., 4 (1903), No. 1, pp. 24, 25*).—Brief mention is made of the various theories which have been proposed in explanation of the cause of cornstalk disease. These theories have explained the etiology of the disease by reference to poisonous weeds, impaction of the stomach, corn smut, prussic acid, saltpeter, and the organism which causes the bacterial disease of corn. This account is largely based on the results obtained during the investigation of the subject by the Nebraska Experiment Station.

Hemorrhagic septicemia, Krueger (*Berlin. Tierärztl. Wchnschr., 1903, No. 16, pp. 261–264*).—The author had occasion to observe this disease in 118 cattle, horses, and hogs. The disease assumed several forms, including pectoral, exanthematic, and intestinal. Detailed notes are given on the symptoms observed in this disease. A large number of cases of croupous pneumonia in cattle are believed to have been caused by the organism of hemorrhagic septicemia, and attention is also called to the close resemblance between hemorrhagic septicemia and anthrax in hogs.

The author does not believe that any great danger exists of infection in man from handling animals affected with this disease. It is recommended, however, that as a rule animals affected with hemorrhagic septicemia be treated in the same manner as those affected with anthrax.

Puerperal metritis, A. Rodrigo (*Gac. Med. Zool., 27 (1903), No. 9, pp. 148, 149*).—Notes are given on the symptoms, course, and etiology of this disease.

Tetanus in cows, Burgeon (*Jour. Méd. Vét. et Zootech., 5. ser., 7 (1903), May, pp. 280–282*).—A case of traumatic tetanus was treated with antitetanus serum without success. The animal received 110 cc. of serum.

The antitoxin treatment of tetanus, E. von Behring (*Deut. Med. Wchnschr., 29 (1903), No. 35, pp. 617–621*).—The author presents a general discussion of the results which have thus far been obtained in the use of antitoxin in cases of tetanus. The rate of mortality without the antitoxin treatment is shown to be about 88 per cent, while with the antitoxin treatment it has been reduced to from 40 to 45 per cent. Numerous experiments were made on mice for the purpose of determining the proper strength of the serum for use in vaccination.

Cattle poisons of the Transvaal, J. B. Davy (*Transvaal Agr. Jour., 2 (1903), No. 5, pp. 96–101*).—The Transvaal department of agriculture has begun the study of

poisonous plants, and preliminary notes are given on the symptoms produced by a number of these plants and on the remedies which have been found effective. The greatest amount of poisoning from plants occurs in early spring before the grass has started up. Some of the more important species of poisonous plants are *Dichapetalum cymosum*, species of Moræa, *Datura stramonium*, *D. tatula*, and oleander. Notes are also given on poisoning from sorghum and Kafir corn.

Bacillus pyogenes suis, B. pyogenes bovis, and the bacteriological findings in chronic mammitis of milch cows, F. Glage (*Ztschr. Fleisch- u. Milchhyg., 13 (1903), No. 6, pp. 166–175*).—A study was made of the organisms mentioned in the title of this article, with special reference to the etiology of chronic mammitis with abscesses. The morphological and biological characters of the organisms are compared in detail. The author concludes that *B. pyogenes suis*, *B. pyogenes bovis*, and the bacillus found in chronic mammitis are all identical, and that this organism is the most common pyogenic bacillus of the hog and cattle. The organism was frequently found in suppurative mammitis and it is believed that it may be transmitted from cattle to hogs in the milk of diseased cows.

The etiology of swine plague, W. Grips (*Deut. Tierärztl. Wchnschr., 11 (1903), No. 20, pp. 185, 186*).—In the author's opinion the appearance of small yellow or gray necrotic areas in the lungs of hogs affected with swine plague is not a constant symptom of the disease. During a study of this disease, *Bacillus pyogenes suis* was found in the lungs of hogs and the disease was transmitted to healthy hogs by inoculation with this organism and feeding experiments during which the same bacillus was employed. The author believes therefore that this organism is the cause of swine plague and that the micro-organism described by Löffler and Schütz is not connetced with the disease in a causal manner.

The etiology of swine plague, R. Ostertag (*Deut. Tierärztl. Wchnschr., 11 (1903), No. 21, pp. 193, 194*).—Referring to an article on the same subject by W. Grips, the author agrees with a statement of Grips that small yellow or gray necrotic areas are not always present in cases of swine plague. It is believed, however, that the Löffler-Schütz organism is the cause of the disease and that *Bacillus pyogenes suis* is associated with this organism in a number of cases of swine plague. The author urges that the production of pneumonia in hogs by inoculation with *B. pyogenes suis* does not prove that this organism is the cause of swine plague, but simply that in common with other bacteria belonging to the same group, it is capable of setting up a process of suppuration.

The vaccine material for swine erysipelas prepared by the Jenner-Pasteur Institute at Budapest, L. Detre-Deutsch (*Berlin. Tierärztl. Wchnschr., 1903, No. 16, pp. 265, 266*).—The method of serum vaccination used by the Jenner-Pasteur Institute at Budapest requires 2 inoculations at intervals of about 12 days. This method has been used chiefly in the control of swine erysipelas and has been tested in 9,250 animals. In this number of animals not a single case developed swine erysipelas after vaccination. The treatment appears therefore to be perfectly safe and effective.

The most convenient position of hogs for vaccination, K. Müller (*Berlin. Tierärztl. Wchnschr., 1903, No. 17, pp. 278, 279*).—For holding hogs during vaccination the author recommends the use of a strong cord which is inserted in the mouth and fastened over the head. As a rule 1 man is able to restrain hogs of ordinary weight by this method during vaccination.

Paralysis of young colts, Zwicker (*Berlin. Tierärztl. Wchnschr., 1903, No. 12, pp. 197, 198*).—While the term lameness or paralysis of young colts has been used to include all the more pronounced functional disturbances in the extremities, it is quite apparent that a considerable number of diseases bring about symptoms of lameness. One of these is infectious omphalitis, with secondary pyemic inflammation of the joints.

The author's attention was devoted largely to forms of articular lameness or paralysis due to improper diet and unsanitary surroundings during early life. In the treatment of this form of the disease good results were obtained from blood letting and from rubbing the affected joints with a mixture of sulphuric acid and rectified spirits in the proportion of 1:6. This remedy applied twice daily was sufficient to bring about a cure in cases of not too acute nature.

The army horse in accident and disease, A. PLUMMER and R. H. POWER ([*U. S. War Department*] *1903, pp. 91*).—A brief discussion of the conformation of horses and external diseases; stable management; administration of medicines; anatomy; wounds, sprains, and bruises; diseases of the respiratory, digestive, urinary, nervous, and lymphatic systems; miscellaneous diseases; diseases of the skin, eye, feet, and bones; detection of lameness; and the action and uses of medicines used in the treatment of diseases of the horse.

Diseases and disorders of the horse, A. THEILER (*Transvaal Agr. Jour., 1 (1903), No. 2, pp. 30–39*).—A brief account of "through the water," strangles, lampas, stomatitis, colic, mange, etc. The author mentions the symptoms, pathological alterations, and treatment for each disease.

The transmission of horse distemper by coitus, A. GRIMME (*Deut. Tierärztl. Wchnschr., 11 (1903), No. 12, pp. 109–111*).—The author found during an outbreak of this disease that stallions which have once been infected may retain the virus in the body for at least 14 weeks and are capable of transmitting the disease in a large percentage of cases in coitus.

Data on petechial fever in horses, J. J. IBARS (*Gac. Med. Zool., 27 (1903), No. 20, pp. 328–330*).—The symptoms of this disease are described by way of comparison with those of other related diseases and a brief account is given of the etiology of the disease.

Epizootic lymphangitis, A. THEILER (*Transvaal Agr. Jour., 2 (1903), No. 5, pp. 52–55*).—A description is given of the yeast fungus which causes this disease. The species concerned is believed to be *Saccharomyces farciminosus*. The disease occurs most commonly in horses and mules, but occasionally attacks cattle. Notes are given on the symptoms and pathological lesions of the disease. The author used a mallein test on horses affected with the disease, but obtained a reaction in only 2 cases. Treatment is believed to be without results except in mild cases and when applied during the early stages.

Poisoning from moldy clover, BANSSE (*Jour. Méd. Vét. et Zootech., 5. ser., 7 (1903), Feb., pp. 93–96*).—The symptoms of poisoning in a horse, resulting from the ingestion of moldy clover, are described in detail. The case was subjected to medicinal treatment without good results, and finally died. An autopsy was made and it was found that quite pronounced lesions were present in the kidneys and liver, both organs being congested and somewhat infiltrated.

Intestinal coccidiosis in fowls, ECKARDT (*Berlin. Tierärztl. Wchnschr., 1903, No. 11, pp. 177–180*).—During a comparative study, which was made for the purpose of determining whether fowl plague and fowl cholera were identical or not, the author found a large number of fowls to be suffering from coccidiosis of the intestines.

The blood of fowls affected with this disease when used in inoculation experiments with other fowls proved to be noninfectious. Feeding experiments with portions of infected intestines, however, reproduced the disease in nearly all cases with fatal results in a large proportion of the experiments. The disease was transmitted in feeding experiments to chickens and fowls of all ages. The symptoms produced during an infection were swelling and reddening of the intestinal membrane and the development of a greenish color in the intestinal contents. The prevalence of this disease seems to be immediately connected with unsanitary conditions in large poultry establishments. The disease prevails most extensively from May to July.

A study of the nature of fowl plagues, D. CALAMIDA (*Centbl. Bakt. u. Par., 1.*

Abt., Orig., 35 (1903), No. 1, pp. 37–42).—The author investigated an outbreak of disease among chickens in Turin. The combs, lungs, liver, spleen, and kidneys appeared perfectly normal while the alimentary tract was affected in various ways, according to the duration of the disease. A microscopic and bacteriological investigation failed to reveal the presence of any micro-organism, but the author believes that the disease is due to an organism sufficiently small to pass through a porcelain filter. Inoculation experiments with animals showed that the virus was pathogenic for chickens but not for rabbits.

Parasitological notes, B. GALLI-VALERIO (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1903), No. 1, pp. 81–91, figs. 4*).—Brief notes on various plant and animal parasites, including the organisms of favus and herpes; various protozoan parasites of guinea pigs, rats, lizards, etc.; the infestation of dogs with *Bothriocephalus latus;* and *Ankylostoma duodenale* as affected by bisulphate of soda in a 2 per cent solution.

The beef measle worm in the slaughterhouse of Trieste, J. SPADIGLIERI (*Ztschr. Fleisch- u. Milchhyg., 13 (1903), No. 5, pp. 136–139*).—The examination of beef during the ordinary meat inspection in the slaughterhouse at Trieste yielded valuable data on the occurrence of the beef measle worm and its relative distribution in various muscles. This parasite is found most extensively in the internal and external muscles of mastication.

Trichinosis and heredity, A. O. DE LANDÁZURI (*Gac. Med. Zool., 27 (1903), No. 16, pp. 261–264*).—Attention is called to the possibility of intrauterine infestation by trichina in hogs, and a few cases are cited in which such a method of infestation appeared to be demonstrated. In such cases it was urged that the public should be warned against the use of the meat of young pigs.

AGRICULTURAL ENGINEERING.

Irrigation engineering, H. M. WILSON (*New York: John Wiley & Sons; London: Chapman & Hall, Ltd. (1903), 4. ed., rev. and enl., pp. XXIII+573, pls. 41, figs. 142*).—This is the fourth revised and enlarged edition of this work. While the revision has been thorough it has involved no radical changes, although many important corrections and additions have been made, especially in part 3, which relates to storage reservoirs.

Murray waters and irrigation, R. T. MCKAY (*Agr. Gaz. New South Wales, 14 (1903), Nos. 7, pp. 611–626, figs. 17; 11, pp. 1088–1101, figs. 13*).—A continuation of the preceding article (E. S. R., 14, p. 1055), giving additional information regarding irrigation in the Murray basin.

Water supply, R. E. MIDDLETON (*London: Charles Griffin & Co., Ltd. (1903), pp. IX+168*).

Windmill irrigation in Kansas, P. EASTMAN (*Amer. Mo. Rev. of Reviews, 29 (1904), No. 2, pp. 183–187, figs. 8*).—A description of the system and results of irrigation with water pumped by means of windmills in the subarid region of western Kansas, especially around Garden City.

Windmills, M. RINGELMANN (*Jour. Agr. Prat., n. ser., 6 (1903), No. 49, pp. 737–740, fig. 1*).—A note on the report of Courtney and Shaw on the exhibit of windmills under the auspices of the Royal Agricultural Society of England at the Royal Park in March and April, 1903.

The practical working of trench excavating machinery, E. MCCULLOUGH (*Engineer. News, 50 (1903), No. 26, pp. 562–564, figs. 2*).

Trial stations for machinery, implements, and tools used in agriculture and dairying, F. WITTING (*Queensland Agr. Jour., 13 (1903), No. 6, pp. 524–528*).—This is a brief account of the history of the establishment of such stations in Sweden, one in connection with the agricultural college at Alnarp, southern Sweden, and the other in connection with the college at Ultuna, central Sweden. The character and value of the tests made are also explained.

German and English agricultural machine industry, G. KÜHNE (*Mitt. Deut. Landw. Gesell., 18 (1903), Nos. 45, pp. 253–255; 46, pp. 258–260; 47, pp. 262–264*).—A general review.

Steam plowing a success, J. H. CONNELL (*Texas Farm and Ranch, 23 (1904), No. 2, pp. 1, 2, figs. 5*).—The conditions under which steam plowing may be successful and the cost of operating such plows are discussed, and satisfactory experience of a number of farmers is reported.

Electricity in agriculture, E. GUARINI (*Jour. Soc. Cent. Agr. Belg., 51 (1903), No. 1, pp. 18–29*).—This is a review of the progress which has been made in the application of electricity to various agricultural processes and operations, including its use as a motive power, for promoting the growth of plants directly and by means of electric lights, the purification of water, etc. The possibilities of the Cooper-Hewitt mercury-vapor lamp are briefly referred to.

Alcohol motor cars for agricultural purposes, A. OSCHMANN (*Arb. Deut. Landw. Gesell., 1903, No. 86, pp. 84, figs. 86*).—This is a report of tests made during 1903 by the agricultural implements section of the German Agricultural Society, and includes a discussion of motor cars in general, details of construction of such cars, and the results of tests of (1) a motor freight train, (2) an express wagon, and (3) a milk wagon, furnished by 3 different firms.

Reinforced concrete and its applications, P. CHRISTOPHE (*Le béton armé et ses applications. Paris and Liége: Ch. Béranger, 1902, pp. XIX + 755, figs. 847*).—This is a second revised and enlarged edition of this work, the first appearing in 1899.

The story of refrigeration, R. CROWE (*Jour. Dept. Agr. Victoria, 2 (1903), No. 2, pp. 129–136*).—A general discussion of the subject of refrigeration with special reference to conditions and experience in Victoria. The special topics discussed are practical application of refrigeration, ripening of cheese in cold storage, and cold storage of eggs.

Report of the committee on rural engineering of the Association of American Agricultural Colleges and Experiment Stations, W. E. STONE ET AL. (*U. S. Dept. Agr., Office of Experiment Stations Circ. 53, pp. 10*).—This report reviews the present status of instruction and research in rural engineering in this country and points out the necessity for improvement along these lines. It recommends the creation of separate departments of rural engineering in the agricultural colleges and commends the efforts of the Secretary of Agriculture to extend work of this character in his Department.

MISCELLANEOUS.

Growth and management of American agriculture, F. T. CARLTON (*Ann. Amer. Acad. Polit. and Soc. Sci., 22 (1903), No. 3, pp. 79–91*).—A discussion based upon the statistics of the last census. Attention is especially called to the following conditions indicated by an analysis of these statistics: The readjustment and localization of production as a result of better transportation facilities; and concentration of population in cities and decline of small towns and villages, accompanied by unhealthy unrest in the former and idleness in the latter. It is suggested that long-distance transmission of electrical power will do much to remedy this condition by reviving small industries and providing local markets.

Improved educational facilities in the country, it is believed, will do much to check the influx of rural population into the cities. The advantage of country training over city training in developing the power of adaptability is pointed out, and it is urged that rural schools should always keep in view the training of men and women for farm duties.

Annual Reports of the Department of Agriculture, 1903 (*U. S. Dept. Agr. Rpts. 1903, pp. 560*).—This includes the report of the Secretary and the reports of

the heads of the different bureaus and divisions. The report of the Secretary, which is also published separately as Report No. 76, has been reviewed editorially (E. S. R., 15, p. 317).

Organization of Department of Agriculture, 1903-4 (*U. S. Dept. Agr., Division of Publications Circ. 1, rev. ed., pp. 23*).

Organization lists of the agricultural colleges and experiment stations in the United States (*U. S. Dept. Agr., Office of Experiment Stations Bul. 137, pp. 100*).

Sixteenth Annual Report of Kansas Station, 1903 (*Kansas Sta. Rpt. 1903, pp. XXIX*).—This includes the organization list of the station; a financial statement for the fiscal year ended June 30, 1903; a report of the council on the staff, publications, and different lines of station work during the year; a subject list of all the bulletins issued by the station; and an index to Bulletins 111-118 issued during the year.

Annual Report of South Dakota Station, 1902 (*South Dakota Sta. Rpt. 1902, pp. 10-23*).—This includes a report of the director and departmental reports covering, in a general way, the work of the station during the year. A financial statement is included.

Annual Report of South Dakota Station, 1903 (*South Dakota Sta. Rpt. 1903, pp. 7-19*).—A report of the work of the station during 1903, similar in character to the report noted above.

Press Bulletins Nos. 71 to 124 (*Kansas Sta. Bul. 119, pp. 86*).—This is the third bulletin of this nature issued by the station, and consists of reprints of press bulletins published during the period from July 1, 1900, to June 30, 1903. The subjects are as follows: Experience in soiling and pasturing cows, 1899; fattening steers without hogs; cultivated blue grasses; some interesting climbers for the veranda; the races of corn; sugar beets in Kansas, 1900; honeysuckles at the Kansas Station; Johnson grass; a digestion experiment with buffalo-grass hay; notes on plums; soy beans in Kansas in 1900; disking alfalfa; clovers; tests of soy beans by Kansas farmers in 1900; roots for Kansas farmers; Kafir corn versus good butter; when to cut alfalfa; condimental stock food for dairy cows; shelled corn compared with corn chop for young calves; dried blood as a tonic for young calves; the clover-hay worm; cowpeas as a second crop; baby beef; three ways of feeding milk to calves; skim milk calves in the feed lot; feeding wheat; inquiries concerning prairie dogs and gophers; feeding farm animals; fall seeding of alfalfa; sorghum pasture for dairy cows; the Hessian fly; maintenance ration for cattle; grain weevils; cattle distemper; sore mouth of cattle; profit in maintaining the milk flow; cerebritis or "staggers" in horses; destroying prairie dogs—a preliminary report; destroying pocket gophers; corn improvement; onion notes; pneumonia in cattle; pasture weeds—their prevention and eradication; whole Kafir corn compared with ground Kafir corn for young calves; contagious sore eyes in cattle; glanders and farcy; ergotism; scab or itch in cattle; poison for prairie dogs and pocket gophers; better-bred grain and corn for Kansas; fistulous withers and poll evil; pasture for hogs; a test of hand separators; and late crops.

Wages of farm labor in the United States, J. H. BLODGETT (*U. S. Dept. Agr., Bureau of Statistics Bul. 26, pp. 62*).—This bulletin adds the results of the twelfth investigation to the results of the previous investigations published in Bulletin 22 of the Division of Statistics (E. S. R., 13, p. 597). This report is similar in character to the one preceding.

Crop Reporter (*U. S. Dept. Agr., Bureau of Statistics Crop Reporter, vol. 5, Nos. 7, pp. 49-56; 8, pp. 57-60; 8, Sup., pp. 61-68; 9, pp. 69-76*).—These numbers for November and December, 1903, and January, 1904, contain the usual statistical reports on the crops in the United States and foreign countries.

NOTES.

Idaho Station.—G. A. Crosthwait, formerly of the Illinois Station, has been appointed agronomist.

Illinois University and Station.—Three new buildings will be erected in the spring, one for beef cattle costing $25,000, another for horticulture costing approximately $12,500, and a storage building for agronomy costing a similar amount.

Iowa College.—An organization of alumni and ex-students, known as the Iowa Agricultural Union, has been formed with similar aims and purposes to the unions connected with several other agricultural colleges. A pamphlet of 16 pages, outlining experiments in animal husbandry, agronomy, horticulture, and similar lines has been issued. The secretary of the union is G. I. Christie, of Ames.

Kentucky Station.—The following members of the governing board have been appointed by the governor and approved by the State senate: D. F. Frazee, Lexington, to succeed himself; F. A. Hopkins, Prestonburg, to succeed himself; R. L. Stout, Versailles, vice L. N. Lindsay, Frankfort; B. M. Brooks, Slaughtersville, vice W. T. Fowler, Hopkinsville; and Charles Nichols, Lexington, vice R. C. Stoll, Lexington.

Louisiana Stations.—Three assistant chemists have been appointed at the Sugar Station, including J. E. Halligan, formerly connected with the Massachusetts Station.

Missouri University and Station.—C. H. Eckles has been granted a year's leave of absence, beginning in June, and will spend the time abroad in study relating to dairy husbandry.

Nebraska University and Station.—The legislature of 1902–3 appropriated $100,000 for buildings for the agricultural college and experiment station. The February issue of *Agriculture*, published by the students of the college, gives a description of two of these buildings, viz, a horticultural building and a new dairy barn which have been practically completed. Both are located at the university farm. The horticultural building is 40 by 44 ft. and 2 stories in height, with a cellar and 2 greenhouses extending to the south. The first floor contains a large laboratory and the office of the professor of horticulture. The second floor has a large class room and 2 storerooms. One of the greenhouses will be used especially for the germination of seeds, propagation of cuttings, and grafting and potting of plants; the other for growing garden vegetables and small shrubs. The greenhouses and laboratory have cement floors and are heated by steam and lighted by electricity.

For several years the dairy herd has occupied the north wing of the horse barn. The new dairy building now completed—with an appropriation of $10,000—consists of a main part and 2 wings. The main portion is 40 by 80 ft., and 38 ft. high; the 2 wings are 40 and 44 ft. wide, respectively, by 60 ft. long and 28 ft. in height. The first floor of the main portion includes 3 bull stalls, 2 hospital stalls, grain bins, scales for weighing animals, toilet and bathroom, and an office. On the second floor are a seed room, grain bins, and considerable room for storing hay. The wing used for milch cows is well lighted and ventilated, has a cement floor, and is fitted with the Drown iron stall. The other wing is used as a stock-judging pavilion. The barn has a capacity of 77 head, furnishing stall room for 42 milch cows. A silo with a capacity of 120 tons is provided.

Ohio University.—The building occupied by the departments of chemistry, pharmacy, metallurgy, and mining engineering was destroyed by fire the latter part of February, resulting in a total loss estimated at $100,000.

Rhode Island Station.—A. W. Bosworth, first assistant chemist, has resigned.

South Carolina College.—The general assembly has provided 124 scholarships of $100 each for students in the agricultural department of the college. These will be available to students entering next fall. The new agricultural hall will be ready for occupancy in August.

Texas College.—The last session of the State legislature appropriated $50,000 for the purpose of establishing a school of textile engineering, and this sum was turned over to the college. The erection of a textile building was begun in January, and it is expected to be finished early in August. The building will be a model cotton factory, and is designed by one of the best known cotton-mill architects in the country. It is 174 ft. long by 54 ft. wide and 2 stories in height, with a basement under one-third of the building. The walls will be of hard brick. About one-third of the space on each floor will be devoted to offices, class rooms, laboratories, etc., and the remainder to the machinery. The latter will be of the most approved patterns, and will be operated by electricity. Two courses in textile engineering are offered, one of 2 years, intended for practical cotton spinners, and one of 4 years for the regular students, intended to fit them for the details of construction and management of a large cotton and woolen factory. A number of students have already registered for the new courses which promise to be among the most important in the college.

Virginia College and Station.—The State legislature has appropriated $165,000 for buildings, equipment, and improvements. An agricultural building is planned for under this appropriation.

Wisconsin University and Station.—The two weeks farmers' course which began February 5 was successful beyond all expectation. Despite the comparatively short notice and the fact that only persons over 25 years of age were admitted to the course, 166 farmers registered, many of whom were over 50 years of age, and 2 over 60 years old. There were only two lectures of one hour each a day, the remainder of the time being occupied in corn judging, live-stock judging, and demonstrations. Those in attendance showed the keenest appreciation of the instruction, and it is believed that much good will result from the course from the fact that the farmers were brought in touch with the agricultural course and had opportunity to learn of its many possible advantages. W. J. Carson, instructor in dairying and lecturer on dairy chemistry at the Kingston (Ontario) Dairy School, has been elected instructor in dairying at the university, vice U. S. Baer, who has resigned to take the important position of assistant State dairy and food commissioner. Mr. Carson is a practical cheese maker of large experience, and for two seasons has served as traveling dairy instructor in the Province of Ontario. G. N. Knapp, assistant in agricultural engineering, entered upon his college duties March 1.

Wyoming University and Station.—A short course was given at the university from March 1 to 12. The first week was devoted to irrigation matters, and the second to live-stock management and judging. This was the first short course given in the State. A monthly publication has been started under the name of *The Ranchman's Reminder*. The paper is edited by the professor of agriculture and director, and will serve to announce short courses, give items of general interest to ranchmen in the State, and call attention to station publications and other investigations not sufficiently large or complete for bulletins. E. E. Sigman, farm foreman, resigned to take effect in March. It is planned to appoint a head farmer who will look after the general work, and an assistant who will have charge of the notes and records of the station.

Philippine Bureau of Agriculture.—The present organization of the bureau is as follows: F. Lamson-Scribner, chief; W. C. Welborn, assistant chief; H. H. Dell, director of animal industry; H. T. Edwards, fiber expert; William S. Lyon, in charge

of seed and plant introduction; J. M. de Marcaida, assistant to expert in seed and plant introduction; Alfred M. Sanchez, soil physicist; A. J. Washburn, manager of stock farm on the island of Culion; Thomas L. Richmond, superintendent of Malate experiment station; George M. Havice, in charge of San Ramón government farm; James H. Shipley, expert in plant culture, in charge of experiment station work in Batangas; Thomas Hanley, expert in tropical agriculture, in charge of experiments in Benguet Province; C. E. Miles, in charge of rice farm at Murcia, Tarlac Province. The position of director of the agricultural college and experiment station in Western Negros was made vacant at the beginning of the year by the resignation of A. P. Hayne, who has engaged in private work. The botanical work in charge of E. D. Merrill was transferred to the Bureau of Government Laboratories last July. Prof. F. Lamson-Scribner, who organized the Bureau of Agriculture and has been for the past two years its chief, has returned to this country on leave of absence.

New agricultural institutions for India.—Mention was made some months since of an endowment for agricultural work in India which had been given by Mr. Henry Phipps, of Pittsburg. The travel letters of William E. Curtis give a more detailed account of the plan of organization. It appears that Mr. Phipps placed at the disposal of Lord Curzon $100,000, to which he has since added $50,000, to be devoted to whatever object of public utility in the direction of scientific research the viceroy might consider most useful and expedient. The council of state took the subject in hand and have arranged for the organization of an agricultural institution at Pusa, which will include a central research station, a high-grade agricultural college, an experimental farm, and a cattle-breeding farm. Whatever funds are necessary to carry out the project, in addition to Mr. Phipps's donation, will be supplied from the imperial treasury.

A Mr. Coventry, a planter of experience, who came to India in 1880 as manager of a large estate in Southern Bengal, has been selected as director. Other members of the staff are now being selected, and so far as possible natives will be secured to fill these positions. It is proposed to place the agricultural college upon a higher grade than has been reached by any of the agricultural schools in India, the object being not only to provide for the reform of the agricultural methods of the country, but also to furnish a model for and raise the standard of the provincial schools. It is proposed to have a course of 5 years for the training of teachers for other institutions and specialists needed in the various branches of science connected with the agricultural department, who are now usually imported from Europe. For young men who desire only to train themselves for the management of estates a three-years' course will be offered, with practical work upon the farm and in the stable.

The draft horse in action.—The American Museum of Natural History, in New York City, is fitting up an alcove showing the evolution of the horse. This will consist of two series of mounted specimens, the first of fossil horses and of the wild horses, asses, and zebras so far as they can be secured, to show the evolution of the horse in a state of nature; the second of the domesticated horse, showing the modifications of the skeleton as brought about by the artificial selection of man. The three types selected to show the varieties of the domesticated horse are the Percheron, to illustrate the draft horse; the race horse, to show the swiftest form, and the Shetland pony, to show the smallest and least powerful. The expense of preparing the exhibits in this alcove has been borne by the late William C. Whitney, who was a trustee of the museum, and much interested in this subject.

The latest addition to the alcove is the skeleton of a Percheron horse which in life weighed 2,160 pounds, and was 5 feet 6½ inches in height at the withers. The skeleton was mounted by S. H. Chubb, and illustrates the position in drawing a heavy load. Preparatory to the mounting, Mr. Chubb took a large series of photographs of the side, front, and rear views of similar horses hauling heavy loads, in order to ascertain as nearly as possible the position of every part of the skeleton when the

animal is at work. The result, as shown in the mounted skeleton, is considered a complete success, and illustrations of the skeleton from the side and from above and behind, as given in *The American Museum Journal* for January, 1904, are highly interesting. In the side view the exact position of each of the limbs is shown and the flexure of the various joints. The view from above and behind is still more striking, showing the relative position of the parts of the body and the curvature of the backbone as the animal steps. The skeleton of the Shetland pony, showing the animal in the act of grazing, is now in preparation. A mount of a rearing horse held in check by a man is nearly ready for exhibition. The race horse will be mounted as running at full speed.

"The skeleton of an animal is popularly considered its least interesting part; but this method of illustrating its adaptation for special purposes, by representing it in various kinds of action, immediately transforms the skeleton into a subject of the greatest interest. In fact, the wonderful evolution of the horse as it will be shown in the fossil series can only be thoroughly understood when taken in connection with the special motions and actions of the living horse."

Personal Mention.—Dr. E. A. de Schweinitz, in charge of the biochemic laboratory of the Bureau of Animal Industry of this Department, and dean of the medical department of Columbian University, died in Washington February 15, at the age of 38. Dr. de Schweinitz was born at Salem, N. C., and received his education at the universities of North Carolina, Virginia, Berlin, and Göttingen, and also at the Columbian University. He received an appointment in the Bureau of Animal Industry as chemist on January 1, 1890, and was made chief of the biochemic division upon its organization. The investigations for which he is chiefly noted were made in the field of the chemistry and biology of bacteria. He was one of the first to suggest the possibility of the production of immunity toward tuberculosis by inoculation with attenuated cultures of the tubercle bacillus. During the past few years his attention was devoted chiefly to a study of tuberculosis and hog cholera; and his experiments and investigations contributed greatly to the proof of the identity of human and bovine tuberculosis. He also discovered many interesting facts concerning the chemical nature of tubercle bacilli and the changes produced in nutrient media by the growth of these organisms. Dr. de Schweinitz devoted much attention also to the preparation of an efficient antitoxin for the treatment and prevention of hog cholera. Recently his investigations along this line brought to light the existence of a new infectious disease of swine closely related to hog cholera. Dr. de Schweinitz was a member of many American and foreign scientific societies, and was repeatedly chosen as a delegate to international congresses on hygiene, tuberculosis, and medicine.

A. W. Harris, director of The Jacob Tome Institute, has definitely declined the presidency of Boston University.

F. S. Earle, of the New York Botanic Gardens, formerly connected with this Department, has gone to Cuba to consider the offer of an appointment under the Cuban government as chief of agricultural investigations. The development of work in the interest of agriculture in that country, including the establishment of one or more experiment stations, is under consideration.

W. C. Sturgis, formerly botanist at the Connecticut State Station, has been appointed lecturer on botany in Colorado College, at Colorado Springs.

H. S. Grindley, of the University of Illinois, who for several years past has conducted investigations, in cooperation with this Office, on the cooking of meats, has been awarded a second grant of $250 from the Elizabeth Thompson Science Fund to continue his investigations upon the proteids of meats.

A. D. Hall, director of the Rothamsted Experiment Station, delivered a series of three lectures at the Royal Institution in February on Recent Research in Agriculture.

Albert C. Crawford has been appointed expert in pharmacology in the Bureau of Plant Industry, this Department.

George W. Curtis, formerly director of the Texas Station, has been appointed special agent in the Bureau of Plant Industry. He will be connected with demonstration work which is to be carried on upon a large number of private farms under the appropriation for the cotton-boll weevil investigations.

Charles W. Walker, recently connected with the office of the State entomologist of New York, has been appointed assistant in the Division of Entomology, and will take part in the work in Texas against the cotton-boll weevil.

Matthew Steel, of the New Mexico Agricultural College, has been appointed a scientific aid in this Office.

Miscellaneous.—We note from *Science* that the University of Michigan has received from Arthur Hill, of Saginaw, a tract of 80 acres of land near Ann Arbor, to serve as an experiment farm for the forestry department, to be known as the Saginaw Forest Farm. It will provide for an arboretum of all useful forest trees suited to Michigan, demonstration areas for seed-bed and nursery stock, model plantations of forest trees, and special experiments in forestry.

The *American Agriculturist* has begun the publication of a series of articles on the work and results of the experiment stations, with a view to calling attention to the great work which these institutions have been and are doing for the advancement of agriculture and the improvement of farm practice, as well as in contributing to the scientific basis of agriculture.

A $100,000 cassava starch factory is to be built at Lake City, Fla., by a Chicago firm. The citizens of the town provided the site and subscribed for a large block of stock. The mill will have a daily capacity of 120 tons of raw material, and is expected to be a great aid to farmers in the locality by furnishing a market for cassava roots.

The French committee of the International Dairy Association at a meeting in November, 1903, elected M. Legludic honorary president of an international dairy congress to be held in Paris in 1905. The programme of the congress will provide for five sections, as follows: Production of milk; dairy technology (milk, butter, cheese, derivatives, and by-products); dairy hygiene; examination of milk (scientific researches, analyses, adulterations, etc.), and dairy economics (commerce, transportation, and legislation). Declarations of membership, accompanied by a membership fee of 10 francs, should be made to the Comité Français de la Fédération Internationale, 61 Boulevard Barbès, Paris.

The supreme court of New Jersey has issued a mandamus directing the State to pay to Rutgers College the sum of $80,000. This is rendered in connection with the decision of the constitutionality of a law enacted by the State establishing scholarships in the scientific school, which includes the agricultural course. These scholarships have remained unpaid for some time on the contention that the legislative act was unconstitutional.

By the terms of the will of Hudson Hoagland, who died in New York on January 30, the Hampton Normal and Agricultural Institute, of Hampton, Virginia, is to receive a fund of $100,000.

In a recent number of *Gardeners' Chronicle*, it is stated that the new potato Eldorado has been sold at the rate of $1,000 per pound. This potato was recently originated by a large seed firm at Essex, England, and is supposed to be very resistant to certain potato diseases prevalent in England.

The government of New Brunswick, through its Department of Agriculture, is preparing to operate a model orchard in each one of the counties of that province. Apples will be chiefly grown and some plums. These orchards will be located on private farms and cultivated by farmers under the direction of the Department of Agriculture. It appears that this kind of orchard work has been successfully introduced into Nova Scotia, and it is believed that much good to the fruit-growing industry will result from it in New Brunswick.

A new journal of entomology, entitled *Redia*, has recently been established under the editorship of A. Berlese. The journal is published in Portici, Italy, and is designed to include original works on Arthropods, especially on the anatomy, biology, physiology, and classification of insects.

At the jubilee meeting of the Royal Scottish Arboricultural Society, held in Edinburgh last month, a resolution was agreed to, according to a note in *Nature*, expressing the opinion that the Board of Agriculture should now take steps to give effect to the recommendation of the Departmental Committee on Forestry so far as Scotland was concerned, by providing an estate to serve as a state forest demonstration area, and also by providing experimental plats in connection with Edinburgh University. The resolution also expressed the view that education in forestry in that country would not be adequately provided for until these facilities were supplied and a thoroughly equipped forestry school was established in Scotland.

The agricultural college for women founded by Lady Warwick about five years ago, and since conducted at Reading, is reported in *Mark Lane Express* to be about to acquire a new location at Studley Castle, Warwickshire. The new location will afford ample accommodation for 60 students, and suitable rooms for lecture rooms and laboratories. A park of 360 acres surrounds the house, while immediately attached to the castle are large gardens of every description, with a pinetum, orangery, rock garden, and about 600 ft. of glass. The grounds are well suited for poultry keeping; and fruit preserving rooms, laundry, workshop, marketing office, etc., can be fitted up in some of the numerous outbuildings. It is the object of the founder to make the college second to none in the country for the training of women in carrying out the lighter branches of agriculture, such as the production of butter, cheese, poultry, eggs, vegetables, fruit, and flowers.

We note from the London *Times*, through *Science*, that the British Board of Agriculture has asked the governors of the Southeastern Agricultural College at Wye, Kent, to consider a scheme for establishing local field stations for experiments and for providing special courses of training in the processes of agriculture. The board has also suggested the appointment of an instructor in poultry-raising for the counties of Kent and Surrey. A scheme for establishing school gardens throughout the county of Kent is already under consideration. This, it is understood, has the approval of the Board of Agriculture, and no difficulty in obtaining their sanction for the expenditure of the necessary money is anticipated. The technical education funds of the county will bear the cost of the experiment.

Nature states that the Municipal Council of Paris has adopted a proposal of M. Bussat for the foundation of a laboratory of applied physiology. The scheme outlined by M. Bussat for the work to be undertaken in such a laboratory includes studies of the nutritive value of foods, muscular work, intoxication, etc.

It is learned from the same source that a horticultural and gardening exhibition is to be held in June under the auspices of the Royal Botanic Society in the new exhibition grounds of the society in Regents Park, London. The plan of the exhibition includes horticulture, forestry, botany, educational methods, nature study, and colonial products. Arrangements are being made for lectures and conferences to be held in connection with the exhibition.

O

EXPERIMENT STATION RECORD.

Vol. XV. April, 1904 No. 8.

The record of respiration experiments abstracted in this issue is a matter worthy of more than passing notice, both on account of the unique character of the apparatus used and the evidence presented of its application in fundamental studies on animal nutrition. It marks a decided advancement in the method and facilities for such investigation, and it may be said to represent the combined result of experience in that important field.

The respiration calorimeter itself, in its present form, is an American product. As is generally known, the Armsby-Fries apparatus follows the Atwater-Rosa apparatus for experiments with man in its main features of construction. In adapting the latter to experiments with large animals, however, it was necessary not only to increase the size of the respiration chamber but to introduce a considerable number of special features, so that the operations of feeding, weighing, collecting the excreta, etc., could be performed from without. The cooperation of the subject within the chamber could not be counted on, as in the case of experiments with man. Among the most interesting of these special features are the devices for weighing the heat absorbers from the outside, the air lock for introducing feed and water without allowing the air in the respiration chamber to escape, and similar devices for the collection of the liquid and solid excretory products. As shown by the results of check experiments, the apparatus is very accurate, the measured heat being practically identical with the theoretical amount produced by burning alcohol in the respiration chamber.

In ordinary metabolism experiments the amounts and composition of the food and of the urine and feces are the factors considered. Using this apparatus the amount and composition of the respiratory products, the fuel value of the food, and the energy output of the body are also ascertained, and it is possible to determine the total income and outgo of both matter and energy. The sufficiency of the ration and its digestibility are thus necessarily brought into account, while the other data recorded make it possible to judge of the changes going on in the body much more satisfactorily than by any method hitherto available.

These things make the apparatus specially adapted to studies of such questions as the energy required to digest and assimilate different classes of feeding stuffs. It is obvious that more energy will be used up in assimilating the nutritive material from a feed like timothy hay, containing relatively large amounts of crude fiber and woody substances, than from a concentrated feed like corn meal, and that this factor will affect the net value of the feed for the nutrition of the animal. Such differences are not taken account of in ordinary studies of the composition and digestibility of feeds. Hitherto they have been studied very largely by Zuntz's method of observing the variations in the respiratory quotient; that is, the ratio of oxygen consumed to the carbon dioxid excreted. Dr. Armsby's apparatus furnishes another way of approaching such problems and one in which it is possible to control the experimental conditions and judge of the changes going on in the body more accurately.

That the first series of experiments with this apparatus should have given results of so much interest, both in their scientific aspects and from a practical standpoint, is especially gratifying. The conclusion reached that a maintenance ration is not a constant quantity, but a variable one depending upon the kind of food used, is of fundamental importance, as are also the closely related deductions which have to do with the replacing value of nutrients. There is indication that Rubner's law regarding the replacing value of nutrients, which has been held for so many years, is subject to certain limitations and will need modification in the light of the energy requirements for digestion and assimilation. Indeed, Rubner's original conception in regard to this matter has been considerably modified in his recent book.

The apparatus affords an opportunity for following up a great variety of important lines of investigation and for checking the results secured by the more practical methods of feeding experiments. The difference found in the above experiment between the energy used up by the animal when standing and when lying down suggests the importance of reducing muscular activity to a minimum during the fattening period. Furthermore, the fact that on a maintenance ration and when closely confined the steer produced more heat than was required to maintain the body temperature has a bearing on the contested point as to whether steers should be fattened out of doors or in stables in cold weather. It seems evident from Dr. Armsby's data that steers on heavy or fattening rations are really developing an excess of heat, and hence would not need to draw upon their food for any increased supply when fed out of doors. This supports and explains Waters's conclusions of several years ago. Some of the observations already made also have a decided bearing on the problem of stable hygiene and ventilation; and, in a word, it is true of this as of the Atwater-Rosa apparatus that the possible lines of investigation range from the most practical to the most technical subjects.

The development and operation of this apparatus is one of those large undertakings which belong appropriately to the General Government to foster. It is a necessarily expensive line of research and requires a corps of specially trained men. Few of the individual experiment stations are in position to enter upon it, but all can profit alike by its findings, wherever they are made, for in general they are of as much interest and application in Maine as in California. It is a matter for congratulation, therefore, that the National Department of Agriculture, through its Bureau of Animal Industry, has seen fit to contribute its funds to the development and subsequent operation of this apparatus, and it is earnestly to be hoped that no lack of public funds will prevent the continuation of this cooperation on a liberal basis.

Rural economics as a subject of undergraduate study has received comparatively little attention in American agricultural colleges. Some phases of the subject, such as the history of agriculture, farm management, and farm law, have been taught from time to time, but as yet there has been no adequate provision for well-rounded courses in rural economy in any of the agricultural colleges. Attention was called to this subject in the fifth report of the committee on methods of teaching agriculture in 1900, and a tentative course in rural economics was outlined.[a] Since then the faculties of our agricultural colleges have manifested a somewhat greater interest in the subject, with the result that a few institutions have begun to develop definite courses of instruction along these lines.

The College of Agriculture of the Ohio State University includes in its faculty a professor of rural economy, and offers a course on the history of agriculture and rural economics consisting of "lectures and recitations upon the history of agriculture, agricultural methods in various countries, cost and relative profits, and various farm operations and systems." A course in "agricultural economics" at the College of Agriculture of the University of Minnesota includes farm management, systems of farming, planning farms, field crops, stock, labor, finances, soils, prices, agricultural statistics, production, exports, wages, land laws, ownership, taxes, and organizations. In the reorganized programme for courses of instruction in the College of Agriculture of Cornell University rural economy is given as one of the main branches of agriculture, and courses are offered in farm accounting and the economics and history of agriculture. Special attention is given to this subject at the Rhode Island College, where courses in farm management and rural economics are offered.

At the University of Wisconsin the instructor in commerce gives a course in agricultural economics which "treats of those principles

[a] U. S. Dept. of Agr., Office of Experiment Stations Bul. 99, p. 91.

which underlie the prosperity of the farmer and of all other classes in so far as they are dependent upon agriculture. The subject is divided into two parts. Part one considers the point of view of the farmer and those economic principles which underlie the management of a farm in such a manner as will make it yield the largest net return. Part two discusses the point of view of the nation as a whole and those principles which should guide the statesman in his efforts to regulate and improve the agriculture of the country."

The annual report of this Office, now in press, contains an article on Agricultural Economics as a Subject of Study in the Agricultural College, with a syllabus of a college course. The article is by President K. L. Butterfield, of Rhode Island, who has made this subject one of special study for some time.

President Butterfield takes the ground that the course in rural economy should be something more than the study of farm management: that "farm management discusses the aspects of agriculture as a business and approaches agriculture from the standpoint of the individual farmer, while agriculture is something more than a business; it is an industry. And because agriculture is an industry, and indeed ranks among the leading industries, it is related to all other industries and must be considered in those relations. It is not an isolated occupation. It is subject to economic laws. It prospers or lags, not merely because of its internal phases, so to speak, but also because of its external relations. It should therefore be studied as an industry as well as an art and a business and approached from an economic standpoint." Agricultural economics "is a discussion of agriculture in the light of the principles of political economy."

With this provisional definition in mind, President Butterfield outlines a short lecture course in agricultural economics under the following general heads: (1) Characteristics of the agricultural industry; (2) History of the agricultural industry; (3) Present status of the farming industry; (4) The agricultural market; (5) Business cooperation in agriculture; (6) Agriculture and legislation; and (7) Some current problems—agricultural labor, machinery and agriculture, interest (rates, indebtedness, etc.), tenant farming, business methods, immigration and agriculture.

The recent action of the Carnegie Institution in establishing a department of economics and sociology in charge of Carroll D. Wright is of interest in this connection. This department has undertaken the preparation of an economic history of the United States, embracing eleven subjects. The second of these subjects, concerning the history and status of the economic and social relations of agriculture in the United States, has been assigned to President Butterfield, who is planning to bring to his aid a number of experts in different branches of agriculture. Owing to the scarcity of available

material which has been put into pedagogical form, those interested in the development of courses in rural economy in our agricultural colleges will await the appearance of reports from President Butterfield and his collaborators with interest.

In European countries much more attention has been given to the formulation of courses in rural economy than in the United States. According to a somewhat detailed outline of the subject as taught in a number of the principal countries of Europe, which is included in a review of progress in agricultural education in the forthcoming report of this Office, some of the agricultural institutions of Germany have been conducting such courses for thirty or more years, and practically all of the agricultural institutions of France, from the Institute Nationale Agronomique down to the grammar schools, give attention to rural economics.

In the higher agricultural schools of France the lectures on rural economy include the elements of political economy, rural economy, and agricultural legislation. Political economy as taught in this course comprises a consideration of the production, circulation, distribution, and consumption of wealth. Rural economy includes the study of the character and history of the subject, as preliminary to a more detailed consideration of the production, circulation, distribution, and consumption of agricultural wealth, and of credit and agricultural accounts. The lectures on rural legislation present a study of civil, administrative, and commercial laws, together with other legislation of agricultural interest. The class work is supplemented by excursions to different estates for the purpose of inspecting and studying their management.

Prof. Étienne Jouzier, of the National School of Agriculture at Rennes, has recently contributed to the Encyclopédie Agricole a text-book on Économie Rurale, which constitutes one of the first pedagogical treatises on this subject that has come to our attention. After giving consideration to the place that rural economy should occupy among agricultural sciences and defining the subject, Professor Jouzier takes up the consideration of social environment or external factors, such as population, the State, associations, charitable institutions, and exports. This is followed by chapters on elements of production, or internal factors, including capital, labor, and land, and on credit, vegetable production, animal production, and cultural methods. Finally a few pages are devoted to comparative economics and the organization and management of an enterprise.

This little volume is especially valuable because it embodies the experience which has been had in teaching this subject abroad, and particularly in France where it has been brought into pedagogical form.

The outline followed in the higher institutions of France serves also

in the practical schools of agriculture, but the work is naturally more elementary. In such of the grammar schools as include courses in agriculture some consideration is given to divisions of the land, societies and meetings, large, medium, and small farms, methods of farm management, agricultural credit, agricultural institutions and organizations, and the distribution of agricultural products.

In some of the Belgian agricultural institutions social, political, and rural economy were formerly taught as one subject, but at present rural economy is considered as a separate branch. At the Agricultural Institute at Gembloux lectures on rural economy are given during the third year of the college course, and include consideration of factors instrumental in agricultural production, the soil, capital, labor, elements necessary or favorable to production, plant production, animal production, and agricultural technology. The lectures are supplemented by practicums devoted to exercises in estimating land values, capital required for running expenses, quantities of feed consumed, management of the farm, and labor requirements.

In the agricultural institutions of Great Britain some attention is given to courses in rural economy, but these are far from uniform. In many cases the courses are nothing more than lectures on farm management. However, some attention is given to the consideration of broader subjects, such as the food supply of the United Kingdom, foreign competition, effects of appreciation of gold and depreciation of silver, and the laws of landed estates.

In Austria courses in rural economy are preceded by courses in civil government, political economy, political economy applied to agricultural statistics, and labor and social reform. The subject of rural economy is taught in the course in agronomy and includes the consideration of such factors of agricultural production as the soil, capital, labor, methods of management, organization of an agricultural estate, and taxation.

The Royal Agricultural High School in Berlin teaches rural economy by means of lectures in the class room and by deliberations and discussions in the economic seminar. This seminar was organized in 1889, and has grown steadily in its influence and numerical strength, its membership comprising both undergraduate and graduate students, as well as persons making special investigations in political economy, philosophy, history, and other subjects. Each student is required to write a dissertation on some subject, usually of his own choice, and to lecture on the same before the seminar, after which the subject is thoroughly discussed by the other members. This work is supplemented by excursions to institutions possessing economic, social, and political interest.

In nearly all of the German universities courses in rural economy are maintained. These vary considerably, but in general include lectures on the elements of political economy, and on capital, labor, land, and farm management, together with some instruction in rural legislation. At Göttingen these lectures were started in 1875, and at Hohenheim in 1873. In some of the agricultural winter schools also lectures on economics are given, which include such subjects as agricultural societies, factors affecting agricultural pursuits, cost of agricultural production, systems of farming, crop rotations, and agricultural law.

This is far from being an exhaustive review of the present status of instruction in rural economy, but it is sufficient to show that with respect to this branch of the science of agriculture the agricultural institutions of Europe are far ahead of our own, both in the extent of the instruction given and in the definite formulation of courses. In the United States scarce a half dozen of our leading agricultural colleges offer courses in rural economy, while in Europe not only do the agricultural colleges quite generally give attention to this subject, but many of the secondary and primary agricultural schools also include it in their curricula. In general, the subject is considered quite broadly, not alone as farm management from the point of view of the individual farmer, but also as a branch of economic science, in which the external factors related to agriculture as an industry are viewed from the standpoint of the economist.

23461—No. 8—04——2

SUBJECT LIST OF ABSTRACTS.

CHEMISTRY.

The determination of citric-acid soluble phosphoric acid in Thomas slag, O. Böttcher (*Chem. Ztg., 27 (1903), No. 100, p. 1225*).—A method of testing the citric acid extract of Thomas slag for silicic acid is described as follows: To 100 cc. of the extract in a 200 cc. flask add 75 cc. of ammoniacal citrate solution, boil over the direct flame, and allow to stand for 5 to 10 minutes. If no precipitate soluble in hydrochloric acid separates out, silicic acid is not present in sufficient amount to interfere with the accuracy of the determination, and phosphoric acid may be determined directly in 50 cc. of the extract. If a flocculent precipitate of silicic acid is formed the solution is acidified with dilute hydrochloric acid, cooled, and filtered. To 100 cc. of the filtrate 20 cc. of magnesia mixture is added, the mixture shaken one-half hour, and the operation continued in the usual way.

The inapplicability of the so-called Maercker-Bühring solution to the determination of total phosphoric acid in Thomas slag, H. Svoboda (*Chem. Ztg., 27 (1903), No. 98, pp. 1203–1205*).—Comparative tests of the Maercker-Bühring solution (1,500 gm. of citric acid and 5 liters of ammonia of 0.91 sp. gr. made to a volume of 15 liters) with the old method of separate addition of citric acid and ammonia are reported. The results by the new method were as a rule higher than those by the old. This is attributed to the presence in the precipitate of silicic acid dissolved from the glass vessels in which the solution was kept.

A table for the calculation of phosphoric acid from magnesium pyrophosphate, T. Kämpfer (*Ztschr. Analyt. Chem., 43 (1904), No. 1, App., pp. 25*).

The organic matter in soils and subsoils, F. K. Cameron and J. F. Breazeale (*Jour. Amer. Chem. Soc., 26 (1904), No 1, pp. 29–45*).—Of the 3 methods in common use for the determination of organic matter in soils, those based on loss on ignition and humus content are condemned as unsatisfactory, and the third or combustion method, which consists in burning the organic matter either in a tube in a furnace or by powerful oxidizing agents, such as chromic acid or potassium permanganate, and collecting and determining the carbon dioxid liberated, is considered most accurate and reliable.

In the method recommended "a sample of the soil, usually about 10 gm., is carefully weighed and brought into the combustion flask. If the sample be rich in organic matter, it has been found advisable to introduce also some sand, previously ignited before the blast, and in an amount dependent roughly upon the apparent quantity of organic matter in the soil. From 5 to 10 gm. of pulverized potassium bicromate are then added, and the whole mixed thoroughly by shaking, care being taken to prevent any of the mixture adhering to the sides of the flask above the level of the mixture. The flask is closed securely by the stopper, and a gentle stream of air drawn through the whole apparatus by means of the aspirator.

"When this stream of air has been passing for about 10 minutes, concentrated sulphuric acid (sp. gr. about 1.83) is slowly and cautiously run in by means of the

dropping funnel until the tip of the glass tube, for the introduction of air, is covered. When this point has been reached, and if no very vigorous action is taking place, the combination flask is slowly heated until the sulphuric acid commences to give off fumes. It is held at this temperature for from 5 to 10 minutes, and then allowed to cool slowly, unless there is reason to believe combustion has not been complete, in which case the temperature is again raised. Care must be exercised to see that a steady current of air be kept passing through the apparatus, and that the mixture in the flask be not forced back toward the wash-bottles."

In case of soils containing chlorids this method of procedure may result in the generation of chlorin gas, which will vitiate the results. This, it is claimed, may be obviated by dissolving the potassium bichromate in the concentrated sulphuric acid and slowly and cautiously running the solution in upon the soil with no attempt to heat the mixture until the reaction in the flask has proceeded for some time. By proceeding in this manner "no hydrochloric acid, chlorin, nor chromyl chlorid gas is generated, or in but very small amounts. The procedure thus modified has been used a large number of times with artificial mixtures and natural soils, and has proved satisfactory, although no explanation is obvious why hydrochloric acid should not be formed and oxidized under these conditions." The method is claimed to be fairly rapid, a combustion requiring on the average about 40 minutes.

As a result of a large number of determinations, it is stated that the organic matter in a subsoil rarely equals or exceeds that contained in the corresponding soil. "The facts presented here would suggest that the humus determination is of even more uncertain value than is usually believed. There is not sufficient ground as yet for advocating the use of any other factor than the usually accepted one [0.471] for the calculation of the organic matter from the carbon dioxid obtained in the combustion."

A number of determinations are reported which show an average of 42 per cent of carbon in humus instead of 56 per cent, as reported by other investigators.

On the determination of assimilable plant food by extraction of soils with very dilute acids, H. G. Söderbaum (*K. Landt. Akad. Handl. och Tidskr., 42 (1903), pp. 103–106; abs. in Centbl. Agr. Chem., 32 (1903), No. 12, pp. 795–798*).—This is an account of pot experiments during 1900 and 1901 with barley growing on loam and humus soils which had been extracted for 48 hours at ordinary temperatures with 2 per cent hydrochloric acid. The extracted soils without addition of any fertilizing material proved practically sterile. The application of lime as carbonate, however, resulted in a partial restoration of the productive capacity, and with applications of lime and 2 of the essential fertilizing constituents (either potash or phosphoric acid) the yield was very little less than that on unextracted soil. Apparently assimilable nitrogen was the element most completely removed by the extraction, but in no case did the treatment remove all of the assimilable plant food present in the soil.

A contribution to soil analysis, O. Förster (*Chem. Ztg., 28 (1904), No. 4, pp. 36–38*).—A method of procedure is described which is intended to obviate as far as possible the difficulties encountered in securing complete removal of solution from the insoluble residue of acid digestion, and also the separation of potassium and alkaline earths from the voluminous iron and alumina precipitates.

The solution is prepared by treating 100 to 200 gm. of the air-dry soil for 3 hours on a water bath with 10 per cent hydrochloric acid at the rate of 2 cc. of acid to each gram of soil. The solution after cooling is diluted with water at the rate of 1,000 cc. for each 100 gm. of soil, and an aliquot part of the solution is evaporated to dryness with 5 to 10 cc. of nitric acid to remove silicic acid. The residue is taken up in dilute hydrochloric acid and the solution diluted to such a volume that each 100 cc. corresponds to 40 to 50 gm. of soil. Aliquots corresponding to from 20 to 50 gm. of soil are used for the determination of phosphoric acid, potash, lime, and magnesia by methods which are described in detail.

Methods of physical and chemical soil analysis, E. W. HILGARD (*California Sta. Circ. 6, pp. 23, fig. 1*).—A revision of methods given in Bulletin 38 of the Bureau of Chemistry of this Department (E. S. R., 5, p. 510), reprinted for the use of students in the college of agriculture of the University of California.

A rapid gravimetric method of estimating lime, F. B. GUTHRIE and C. R. BARKER (*Jour. and Proc. Roy. Soc. New South Wales, 36 (1902), pp. 132-134*).—In order to secure complete and rapid oxidation of the calcium oxalate precipitate it is recommended that it be mixed with ammonium nitrate before ignition.

On the determination of calcium in the form of oxalate, J. VAN DORMAEL (*Rev. Gén. Agron.* [*Louvain*], *12 (1903), No. 11, pp. 495, 496*).—Experimental data are reported which indicate that the method proposed by Paguiref (E. S. R., 14, p. 737) does not possess any advantage as regards accuracy over the ordinary method of determination and is slower.

Some recent methods of technical water analysis, H. R. PROCTER (*Jour. Soc. Chem. Ind., 23 (1904), No. 1, pp. 8-11*).—A brief review of the progress of investigation along this line, showing the advantages from a technical standpoint of the more exact methods of titration, such as those proposed by Hehner and Pfeiffer and Wartha, over the old soap solution method. The author describes these methods, calling attention especially to some of the sources of error in working with such dilute solutions as most waters present and suggesting means of avoiding errors.

The separation and determination of iron and phosphoric acid in waters, H. CAUSSE (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 18, pp. 708-710; Bul. Soc. Chim. Paris, 3. ser., 29 (1903), No. 24, p. 1229*).—The author recommends that the iron and phosphoric acid be precipitated in 2 to 3 liters of the filtered water by the addition of 0.6 to 0.8 gm. per liter of chloromercurate of sodium p-amidobenzinsulphonate, the precipitate being allowed to settle for 24 to 36 hours, collected on a filter, and dissolved in hydrochloric acid. The hydrochloric acid solution is evaporated to dryness and the residue fused with pure sodium carbonate. The fusion is moistened with nitric acid, dried, and calcined. On treatment with water the phosphoric acid is dissolved and the iron is left as oxid, which may be collected on a filter.

The direct estimation of free carbonic acid in natural waters, A. McGILL (*Jour. Amer. Chem. Soc., 26 (1904), No. 2, pp. 183-186*).—The apparatus used by the author for this purpose is described.

The determination of hardness in waters, P. DRAWE (*Chem. Ztg., 27 (1903), No. 99, p. 1219*).—This is a discussion of results obtained by means of Pfeiffer's modification of Wartha's method[a] on alkaline waters, in which the temporary hardness was occasionally greater than the permanent hardness. The author ascribes the permanent alkalinity observed in such waters after boiling to sodium carbonate and not to magnesium carbonate as Pfeiffer claims.

In the Pfeiffer-Wartha method temporary hardness is determined by titration with tenth-normal hydrochloric acid, using alizarin as indicator and completing the titration in boiling solution in a Jena flask. The permanent hardness is determined by adding an excess of a tenth-normal mixture of sodium hydroxid and carbonates, boiling and partially evaporating in a Jena flask, allowing to cool and settle, or filtering, and titrating the excess of alkali solution with tenth-normal hydrochloric acid in an aliquot part of the solution, using alizarin as indicator. Pfeiffer employs the water which has been used for the determination of temporary hardness instead of the original water.

Determination of hardness in waters, E. BASCH (*Chem. Ztg., 28 (1904), No. 3, p. 31*).—A brief discussion of recent investigations on this subject, including a reference to the article by Drawe noted above. Results of examinations by the author

---

[a] Ztschr. Angew. Chem., 15 (1902), p. 198.

of two waters are reported. These bear out Drawe's conclusion that the alkalinity after boiling is due entirely to sodium carbonate, but they also indicate that magnesium carbonate remains in solution, the latter carbonate presenting a neutral reaction.

The determination of hardness in waters, F. AUERBACH (*Chem. Ztg., 28 (1904), No. 2, p. 16*).—Referring to a previous article by Drawe, the author questions whether the permanent alkalinity is not in part at least due to magnesium carbonate as first pointed out by Pfeiffer.

Modifications of the Pelouze-Fresenius method of determining nitric acid, L. DEBOURDEAUX (*Bul. Soc. Chim. Paris, 3. ser., 31 (1904), No. 1, pp. 1–3*).—In the modification proposed the Fresenius apparatus is used with the addition of a cooling device to prevent loss of nitric acid. The air is driven from the flask containing the nitrate by means of carbon dioxid. The ferrous solution is introduced through the tube carrying the gas by means of a 100 cc. pipette, care being taken to do this and to heat the solution so that a regular evolution of gas occurs. After washing the tubes with boiled distilled water the excess of ferrous chlorid in the solution is titrated with potassium permanganate.

On a new volumetric method of determining nitric acid, L. DEBOURDEAUX (*Bul. Soc. Chim. Paris, 3. ser., 31 (1904), No. 1, pp. 3–6*).—Previously noted from another source (E. S. R., 15, p. 224).

On the dissociation of alkaline carbonates, P. LEBEAU (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 26, pp. 1255–1257*).

Composition of commercial alkalis ("concentrated lye"), G. E. COLBY (*California Sta. Rpt. 1902–3, p. 92*).—The sodium hydroxid in 5 samples of soda lyes examined was respectively 97.6, 92.2, 87.5, 82.4, and 68.5 per cent. The potassium hydroxid in 2 samples of potash lyes was respectively 71.4 and 69.1 per cent.

The conversion of calcium oxalate to the sulphate, A. N. CLARK (*Jour. Amer. Chem. Soc., 26 (1904), No. 1, pp. 110, 111*).—In the method proposed the platinum crucible containing the oxalate saturated as usual with sulphuric acid is partially embedded in asbestos or calcium sulphate contained in a porcelain crucible about ½ in. larger in diameter than the platinum crucible. "The top portion of the platinum crucible is heated first and remains hotter than the bottom so that the excess of sulphuric acid boils out from the top of the precipitate, instead of from the bottom. The excess of acid is driven off in about one minute; the platinum crucible is then removed from the porcelain crucible and set over the flame until it is brought to a red heat."

The determination of alkalis, especially in plant substances, H. NEUBAUER (*Ztschr. Analyt. Chem., 43 (1904), No. 1, pp. 14–36*).—To the coarsely ground material add a mixture of nitric acid of 1.4 sp. gr. and concentrated sulphuric acid (30 cc. of nitric acid for 5 gm. of seeds, 40 cc. for 5 gm. other materials) and allow to stand 1 hour without heating. Then apply heat cautiously and digest until the solution becomes almost colorless. Allow to cool slightly, add about ½ cc. of concentrated nitric acid, and heat again. Repeat the treatment with nitric acid to complete the oxidation. Cool, add at least an equal volume of water, and warm to expel nitrous fumes. Evaporate to dryness in a platinum dish and heat to redness. Take up in warm water acidified with hydrochloric acid and evaporate to dryness to expel hydrochloric acid. Add phenolphthalein and freshly prepared milk of lime until a saturated solution of calcium hydroxid (shown by a strong red color) is obtained. Make to definite volume (125 cc. for example), mix, allow to stand ½ hour, and filter.

In an aliquot of the filtrate precipitate lime by adding first oxalic acid and then ammonia, taking special care to secure neutrality and complete precipitation without a great excess of ammonium oxalate. Filter through a small filter into a platinum dish, wash with cold water containing a little ammonium oxalate, evaporate to dryness, and drive off ammonium compounds. Take up in hot water, add ammonia,

and again evaporate to dryness. To insure conversion of bisulphates which may be present add ammonium carbonate and heat to redness, repeating this operation until a constant weight is obtained. This gives the sum of the weights of the sodium and potassium sulphates plus a small error due to magnesium sulphate.

The sulphates are dissolved in dilute hydrochloric acid and the potash determined by the author's method already described (E. S. R., 14, p. 631).

Determine magnesia by precipitation with sodium phosphate and ammonia in the hot alcoholic filtrate from the potassium-platinum chlorid, dissolving the precipitate in hot dilute hydrochloric acid and evaporating to dryness, and heating slowly with sodium carbonate until the dish glows. Take up in water and hydrochloric acid and determine magnesia in the usual way, using the results to correct the combined weights of potassium and sodium sulphate.

Coal ash, J. W. Cobb (*Jour. Soc. Chem. Ind., 23 (1904), No. 1, pp. 11–13, fig. 1*).—Methods of determining the ash in coal and of analyzing the ash are discussed.

Concerning fats, A. Partheil and F. Ferié (*Arch. Pharm., 241 (1903), Nos. 7, pp. 545–560; 8, pp. 561–569, figs. 2, dgms. 2*).—The author studied especially lithium salts of some of the higher fatty acids, and a method of separating these acids by means of their lithium salts is proposed. This depends on the fact that stearic and palmitic acid are precipitated quantitatively by lithium acetate, and myristic acid very nearly so, and with the aid of this reagent these acids may be separated from lauric and oleic acids. Experiments are also reported on the estimation of acids of the linoleic series and their separation from oleic acid by means of barium salts. The method of procedure in fat analysis is outlined and results are reported of analyses of butter, lard, and human fat.

Concerning the constituents of unripe St. John's bread, L. Rosenthaler (*Arch. Pharm., 241 (1903), No. 8, p. 616*).—A brief note on the material obtained by extracting the fruit of St. John's bread (*Ceratonia siliqua*) with boiling alcohol.

The analysis of hexon bases, A. Kossel and A. J. Patten (*Ztschr. Physiol. Chem., 38 (1903), No. 1–2, pp. 39–45*).—A modified method of estimating histidin is recommended, which depends on the fact that this body is completely precipitated by mercury sulphate even in the presence of a certain amount of free sulphuric acid. With the help of this reagent the authors found that it was possible to separate histidin, aspartic acid, and other monoamido acids. For the separation of histidin and arginin Kossel and Kutscher's method is considered the best, the mercury sulphate being used to purify the histidin after it is separated from the arginin as a silver compound. By using modified methods, the authors determined the hexon bases in crystallized edistin.

The chemistry of wheat gluten, G. G. Nasmith (*Trans. Canad. Inst., 7 (1903); Univ. Toronto Studies, Physiol. Ser. (1903), No. 4, pp. 22*).—The work of other investigators on the nitrogenous constituents of wheat is critically discussed and the results of a number of experiments reported. According to the author, "gliadin and glutenin do not come from the same parent substance, nor are they of the same composition. Gliadin has not a definite coagulation point, while glutenin has. Gliadin is obtained from rye, barley, and maize, and from the bran and shorts of wheat, while glutenin can not be obtained from these. By chemical or other means one has as yet not been transformed into anything at all resembling the other.

"The substance between the aleurone grains seems to be chiefly gliadin, and contains inorganic iron, calcium salts, and phosphorous-holding compounds.

"Gliadin is distributed throughout the endosperm, especially toward the periphery, where the small proteid granules are much thicker and the starch granules they inclose smaller. It is also contained in bran, and probably in aleurone cells as part of the packing between the aleurone grains, for both bran and shorts yield gliadin to dilute alcohol."

The author found that gliadin was precipitated with an excess of acid and is of the

opinion that this property has not been hitherto noted. He states further that it is not entirely insoluble in dilute salt solutions.

"Both gliadin and glutenin invariably give the reactions for organic iron and phosphorus, but are not nucleo-proteids. Under the microscope the gluten matrix in thin sections of wheat does not show any indication of iron or phosphorus, and it must, therefore, be concluded that the organic iron and phosphorus found in gluten are due to nucleins or nucleic acid derived from the nuclei of the large endosperm cells. Probably part is derived from nuclei of the aleurone cells, or of the embryo cells, or from the nucleins present in the cytoplasm of the embryo cells.

"With the exception of the rapidly dividing cells such as those of the radicle and plumule, iron is found in the nuclei only of the various cells of the wheat grain.

"Phosphorus is more widely distributed, appearing between the aleurone grains; in fine grains in the radicle and plumule cells; in the foam-like mesh work of another type of embryo cell; in the very distinct large granules just described, and in the nuclei of all these cells. From the various ways in which these different cells stain and the several methods of phosphorus distribution in them, one may conclude that there are probably several nucleins present.

"Gliadin exists as such in the wheat grain, and the theory of its formation by means of ferment action is not justifiable. Strong alcohol mixed with flour and then diluted with water to a 70 per cent solution extracts gliadin from it; boiling alcohol also extracts gliadin from flour or bran.

"Glutenin exists as such in the wheat grain; any manipulation that will destroy the hypothetical ferment will coagulate glutenin, thus making gluten formation impossible.

"Gluten formation is not merely a mechanical mixture of gliadin with glutenin, but a definite physical state of the two mixing substances is necessary. Coagulated glutenin with gliadin does not form gluten.

"There are probably several nucleins or nucleo-proteids in wheat as shown in the various ways phosphorus is distributed in the different types of embryo cells. Organic iron is found only in the nuclei of the endosperm, aleurone, and embryo cells, and in the cytoplasm of the absorption layer, plumule and radicle cells. The proteid between the aleurone grains shows the presence of organic phosphorus only."

A bibliography of the subject is appended.

Proteids: A contribution to the subject, II, F. Kutscher (*Ztschr. Physiol. Chem., 38 (1903), No. 1–2, pp. 111–134*).—With a view to securing data regarding the structure of proteids, the author studied the cleavage products of gluten casein, gluten fibrin, gliadin, mucedin, zein, and thymushiston, the cleavage being induced by heating with dilute sulphuric acid. The method of separating the different cleavage products is described and the results reported in detail. The following table summarizes the percentage amount of different cleavage products found:

Cleavage products of a number of proteids.

Kind of proteid.	Ammonia.	Histidin.	Arginin.	Lysin.	Tyrosin.	Glutamic acid.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Gluten casein	2.64	1.56	4.54	2.0	2.75	9.00
Gluten fibrin	3.89	1.53	3.05		4.43	13.07
Gliadin	4.10	1.20	2.75		2.09	18.54
Mucedin	4.23	.44	3.13		2.35	19.81
Zein	2.56	.81	1.82		10.06	10.00
Thymushiston	1.66	1.21	14.36	7.7	6.31	3.66

The results obtained with the first 4 proteids included in the table are discussed with special reference to the composition of wheat gluten. Gliadin and mucedin are regarded as identical, and the author proposes that they be grouped together under

the name gliadin. Wheat gluten he considers to be made up, therefore, of 3 distinct proteids well characterized by their cleavage products, namely, gluten casein, insoluble in alcohol; gluten fibrin, slightly soluble in cold 60° alcohol; and gliadin, readily soluble in this reagent.

Concerning the precipitation of pure glycogen, Z. Gatin-Gružewska (*Arch. Physiol.* [*Pflüger*], *100* (*1903*), *No. 11–12, pp. 634, 635*).—A preliminary communication in which the author notes that pure glycogen prepared from horseflesh is precipitated by alcohol from an aqueous solution in two different forms, viz, spheres and rods. The character of the precipitate, in his opinion, affords a means of judging of the purity of the glycogen.

On a new product of the autodigestion of pancreas, F. Baum (*Beitr. Chem. Physiol. u. Pathol.*, *3* (*1903*), *pp. 439–441; abs. in Bul. Soc. Chim. Paris, 3. ser.*, *30* (*1903*), *No. 23, p. 1289*).—The autodigestion of pancreas was continued from 5 to 6 weeks at a temperature of 37° C. A new product was isolated, for which the author proposes the name "scatosine" because of its probable relations to skatol.

New studies on scatosine, R. E. Swain (*Beitr. Chem. Physiol. u. Pathol.*, *3* (*1903*), *pp. 442–445; abs. in Bul. Soc. Chim. Paris, 3. ser.*, *30* (*1903*), *No. 23, p. 1289*).—A chemical study of the scatosine mentioned above.

Loss of nitrogen from urine by evaporation, Bürki (*Schweiz. Landw. Ztschr.*, *31* (*1903*), *No. 39, p. 938; abs. in Centbl. Agr. Chem.*, *32* (*1903*), *No. 12, p. 846*).—In evaporating to dryness the nitrogen of a sample of urine declined from about 0.8 per cent to 0.08 per cent.

Further notes on the phosphorous constitutent of plant seeds, E. Schulze and E. Winterstein (*Ztschr. Physiol. Chem.*, *40* (*1903*), *No. 1–2, pp. 120–122*).—A chemical study of a phosphorous body in the seeds of *Sinapis nigra*.

Concerning the lecithins prepared from plants, I, E. Schulze and E. Winterstein (*Ztschr. Physiol. Chem.*, *40* (*1903*), *No. 1–2, pp. 101–119*).—The authors prepared and studied lecithin from lupines and from vetch, paying especial attention to the portion of the lecithin which is difficultly soluble in alcohol.

Investigation of the seeds of Polygala apopetala, E. W. Hilgard (*California Sta. Rpt. 1902–3, pp. 102, 103*).—The possibility of using for oil-making the seeds of *Polygala apopetala*, which is a native of the lower region of California, is discussed, and analyses (by G. E. Colby) of seed and partial analyses of the roots are reported. The seeds were found to contain over 56 per cent of oil, which when extracted by ether was found to have a strong flavor of saponin. The cold-pressed oil was of a lighter color than olive oil. When washed with water, dried with calcium chlorid, and filtered, the taste of saponin disappeared and the oil was bland. Comparative tests showed that the oil is more liquid and less drying than olive oil.

The author does not regard it probable that *P. apopetala* can be grown with profit as an oil-producing plant unless the oil is found to possess some special merits or have uses not now known.

Miscellaneous analyses, G. E. Colby (*California Sta. Rpt. 1902–3, pp. 98, 99*).—Brief statements are made regarding the examination of a number of samples of oranges, wines, olive oils, gluten foods, poisoned foods, etc.

Report of the Agricultural Chemical Institute at Bern, 1902 (*Landw. Jahrb. Schweiz*, *17* (*1903*), *No. 10, pp. 543–553*).—Analyses were made during the year of 2,299 samples of fertilizers, 1,247 of feeding stuffs, 199 of soils, and 139 of miscellaneous substances. The results of the analytical and inspection work during the year are summarized and a brief outline is given of the experimental work conducted.

Report of the Agricultural Chemical Institute at Zurich, 1902 (*Landw. Jahrb. Schweiz*, *17* (*1903*), *No. 10, pp. 554–569*).—This is an extract from the annual report of the institute and consists of a summary of the results of analyses of 1,801 samples of fertilizers, 1,043 samples of feeding stuffs, and 283 of miscellaneous materials.

Annual Report of the Agricultural Experiment Station of Mauritius, 1902 (*Rap. An. Sta. Agron.* [*Mauritius*], *1902, pp. 53*).—This report contains summaries of meteorological observations during the year (see p. 756); accounts of laboratory work, including analyses of fertilizers, barnyard manure, bagasse, coal and coal ashes, and miscellaneous notes; and a discussion of the relative fertilizing value of sodium nitrate and ammonium sulphate.

A laboratory manual of physiological chemistry, R. W. WEBSTER and W. KOCH (*Chicago: The University of Chicago Press, 1903, pp. VII+107, pls. 21*).—The chapters in this volume include the chemistry of the cell and of tissues, the chemistry of foods and of digestion, the chemical and sanitary examination of milk, and the chemistry of the excretions. In the arrangement of the subject-matter "an attempt has been made to bring physiological chemistry into closer touch with the biological sciences, without unduly sacrificing connection with the clinical branches; and this manual represents the laboratory course which is given to students [at the University of Chicago] who wish general instruction in the subject, which shall be not too remote from its practical applications." The volume contains an introduction by A. P. Mathews.

Directions for laboratory work in physiological chemistry, H. C. JACKSON (*New York: John Wiley & Sons, 1903, 2. ed., pp. VI+148*).—A revised and enlarged edition of this laboratory manual designed for use in medical schools.

A back-pressure valve for use with filter pumps, R. N. KOFOID (*Jour. Amer. Chem. Soc., 26* (*1904*), *No. 1, p. 110*).—"The body of the valve is constructed of 2 pieces of glass tubing of fairly heavy gauge. . . . The valve itself is an improvement on the old Bunsen valve, with a glass rod of slightly smaller diameter than the rubber tubing, wired on, to prevent collapse. Soft rubber tubing works best. The device has given excellent service, and can be made at little expense of time and material. It was originally devised for use with condensers in a laboratory where the water pressure sometimes gave out and the water ran back. It gives equally good service for both purposes."

BOTANY.

Economic botany, H. M. HALL (*California Sta. Rpt. 1902–3, pp. 127–140*).—As in the previous reports the author gives an account of the various lines of investigation carried on by the assistant botanist at the station. These include identification of plants and reply to inquiries concerning them, the care of an economic herbarium, collection and preparation of seeds, a study of the weeds and poisonous plants of the State, and studies and investigations in economic botany. Notes are given on a number of the economic plants that have been under investigation, and lists are given of the identifications made during the period covered by the report.

Distribution of seeds, plants, and cuttings, E. J. WICKSON (*California Sta. Rpt. 1902–3, pp. 141–153*).—A synopsis is given of the distribution of seeds and plants carried on by the station for 18 years. Notes are also given on various seeds and plants which have been distributed, their economic uses being indicated.

The economic garden, A. V. STUBENRAUCH (*California Sta. Rpt. 1902–3, pp. 153–160*).—A tabular report is given showing the results of test plat cultures made with various grasses and other forage plants.

Relation of soil to the distribution of vegetation in the pine region of Michigan, E. B. LIVINGSTON (*Abs. in Science, n. ser., 19* (*1904*), *No. 474, pp. 167, 168*).—A study is reported of 15 townships of Michigan, the soils being classed as clay, clay loam, sandy, loam, and sand. The region is glacial and consists of ridges and plains, the former being usually gravelly and sandy, while the latter are loamy sand, clay, or nearly pure sand. The vegetation on the different portions is divided

into upland and lowland types. In general, the upland types follow in their distribution the distribution of soils, the hard wood occuring on low clay plains, on swamp margins in loamy soil, and on certain plains of loam which are well covered with humus.

The white pine occurs on ridges of clay loam, clay, and also on swamp margins in loam and clay. The Norway pine type was found on loamy sand plains and on ridges of sand and gravelly loam, while the jack pine type occupies exclusively the well-washed sand plains. The only complicating factors in this distribution are the effect of humus, which seems to be able to make rather poor sand support hard woods. According to the author, the real factor which determines the distribution is the power of the soil to hold water, and this increases with the fineness of particles or the presence of humus.

The taxonomic value of the spermogonium, J. C. ARTHUR (*Abs. in Science, n. ser., 19 (1904), No. 474, pp. 171, 172*).—The physiological significance of the spermogonium is as yet unknown, although it is assumed to be associated with the sexual reproduction of the organism. The author claims that among the Uredineæ are 2 classes of spores, the teleutospores which are doubtless of sexual character, and the conidia, which are either æcidia or uredospores. The spermogonium always appears in the life cycle as the first fruiting structure. If the first subsequent spore structure is the uredo, there is no æcidium in the cycle. If it is a teleutospore, there is neither æcidium nor uredo. The presence of the spermogonium, therefore, furnishes important information regarding the extent of the life cycle of the fungus. The form, size, and origin furnish minor diagnostic characters.

Pot experiments to determine the limits of endurance of different farm crops for certain injurious substances, F. B. GUTHRIE and R. HELMS (*Jour. and Proc. Roy. Soc. New South Wales, 36 (1902), pp. 191–200*).—Noted from another source (E. S. R., 14, p. 945).

The enzym-secreting cells in the seedlings of maize and dates, H. S. REED (*Abs. in Science, n. ser., 19 (1904), No. 474, p. 175*).—During the process of germination seedlings of maize and dates produce an enzym for the solution of endosperm. According to the author, this enzym is secreted from a differentiated layer of cells, which show continuous morphological changes during the time the enzym is being secreted. When the secretion begins these cells are full of fine proteid granules, but as the secretion progresses they constantly disappear.

In the early stages of secretion the nuclei of the secreting cells of maize are found in the basal end of the cell. In the latter stages they are in the apical end next the endosperm layer. As the secretion progresses there is a continuous increase in the amount of chromatin in the nuclei of the secreting cells. At the same time the nucleoli decrease in size and staining properties, and at the end of the process the protoplasm of the secreting cells breaks down and the products of disintegration disappear.

The histology of insect galls, M. T. COOK (*Abs. in Science, n. ser., 19 (1904), No. 474, p. 174*).—The author says that the function of the gall is to furnish nutrition and protection for larvæ. The simplest form of galls shows only 2 zones, the inner nutritive one and the outer protective zone. In the most highly developed galls 4 zones are shown, the inner zone being nutritive and the others protective. In the simplest galls where there are only 2 zones the inner layer is rich in protoplasm, starch, etc., until the insect has become nearly mature, while the other zones furnish tannin. A separation of the second and third zones, which occurs in some of the more highly developed galls, is believed to be a protective device.

Symbiosis in Lolium, E. M. FREEMAN (*Abs. in Science, n. ser., 19 (1904), No. 474, pp. 172, 173*).—In a previous paper (E. S. R., 14, p. 842) the author has described the life cycle of the fungus of *Lolium temulentum* and other species. Further experiments show that the fungus does not produce spores and that there are 2 races of

each species of grass, one with and one without the fungus symbiont. Of these the race associated with the fungus is slightly the more vigorous. The present state of knowledge seems to indicate that the fungus belongs to the Ustilagineæ, which has lost the power of spore formation.

On a culture of buckwheat in the presence of a mixture of algæ and bacteria, Bouilhac and Giustiniani (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 26, pp. 1274–1276*).—Experiments are reported which show that *Nostoc punctiforme* and Anabœna covered with bacteria grow rapidly on a soil entirely free of organic matter and increase its content of nitrogen. The experiments showed further that a plant like buckwheat thrives and develops normally in such a soil as a result of the action of these micro-organisms.

The chemical stimulation of algæ, E. B. Livingston (*Abs. in Science, n. ser., 19 (1904), No. 474, pp. 173, 174*).—A study is reported with the polymorphic alga Stigeoclonium, in which it is shown that with relatively high osmotic pressure the alga produce only spherical cells, while with low osmotic pressure it grows out in long, branching filaments. Zoospores are formed only with a low pressure and, upon germination, they form filaments. If filaments are placed in a medium of high pressure they break up into round cells or form groups of round cells.

When the solution of low osmotic pressure had added to it a trace of poison such as nitric or sulphuric acid, copper sulphate, silver nitrate, etc., the alga took upon itself the Palmella form as though the pressure were high. If the poison was still more diluted, there was a stimulation of zoospore production, though their germination was checked. Nitrates and sulphates were used, and it appeared that the cations had the effect of producing the Palmella form in a solution whose osmotic pressure is far too low to bring about this result.

The effect of chemical irritation upon the respiration of fungi, Ada Watterson (*Abs. in Science, n. ser., 19 (1904), No. 474, p. 178*).—Experiments were conducted with *Sterigmatocystis nigra* and *Penicillium glaucum*, the irritants used being zinc sulphate, iron sulphate, and lithium chlorid. The results obtained show that, although the economic coefficient of the sugar was increased, the carbon dioxid respired remained proportionally the same.

ZOOLOGY.

Index generum mammalium: A list of the genera and families of mammals, T. S. Palmer (*U. S. Dept. Agr., Division of Biological Survey, North American Fauna No. 23, pp. 984*).—In this number of North American Fauna the author presents an alphabetical index of the genera of mammals, an alphabetical index of families and subfamilies, and an index of genera arranged according to orders and families. A detailed index of genera is appended to the bulletin. In an introduction the author outlines the purpose of the publication, which has been in course of preparation for a period of 12 years. An attempt is made to furnish not only the accurate name of each genus, with the name of the originator of the generic name and the date, but also other notes regarding synonymy and similar information of value to the student of systematic zoology.

Wonder horses and Mendelism, C. B. Davenport (*Science, n. ser., 19 (1904), No. 473, pp. 151–153*).—From a discussion of several recorded cases of the transmission of abnormalities, the author concludes that "while Mendelian principles seem applicable to some cases of crosses between sports and the normal species, there seem to be others where neither Mendel's nor Galton's law of inheritance holds."

The feeding habits of Sorex vulgaris, G. Röric (*Arb. K. Gesundheitsamte, Biol. Abt., 4 (1903), No. 1, pp. 121, 122*).—Observations were made on the feeding habits of this species of shrew. The animals were kept in confinement where they could be readily observed, and the data obtained are presented in a tabular form.

Rats in Martinique, P. des Grottes (*Jour. Agr. Trop.*, *3* (*1903*), *No. 29*, *pp. 330–332*).—In Martinique perhaps the most important animal enemies of sugar cane are rats. Notes are given on the habits of these animals and means which have been found more or less effective in preventing their ravages.

Experiments in destroying mice in barns and mows by means of the organism isolated from susliks, S. S. Mereshkowsky (*Centbl. Bakt. u. Par.*, *1 Abt.*, *Orig.*, *35* (*1903*), *No. 1*, *pp. 25–36*).—The destruction of mice in barns and haymows is considered to be in some respects more difficult than the control of these animals in the field. The author's experiments have been continued since 1894, and consist in placing dough infected with cultures of an organism which he obtained from susliks in the runways of mice about barns and in haymows. In all the experiments dead mice were found in considerable numbers within a few days after the exposure of the infected dough, and the mice continued to die rapidly for a period of about 1 week.

In the case of 4 haymows which were infected in the manner just described and thoroughly examined 10 days after infection, the extent of mortality was found to vary from 79 to 95 per cent. The species of mice chiefly concerned were *Mus domesticus* and *M. musculus*. The author believes that this method is practical and exceedingly effective under such conditions.

Studies on the economic importance of insectivorous birds, G. Rörig (*Arb. K. Gesundheitsamte, Biol. Abt.*, *4* (*1903*), *No. 1*, *pp. 1–50*, *figs. 8*).—The author discusses in all its bearings the general problem of the economic relations of birds. In order to obtain a clear conception of the value of birds, it is considered necessary to determine what insects are beneficial and to what extent; the quantity of food, especially injurious insects, consumed by insectivorous birds; and the species of insects which serve chiefly as the food of these birds. The author discusses in great detail the question of what insects may be considered beneficial, and concludes that the value of parasitic and predaceous insects to the farmer has been greatly overestimated.

The agency of insects in fertilizing flowers is noted and conclusions reached that insects are of more benefit in this regard than in any other. While about 3,000 species are known as constant visitors of flowers, the number which are really of importance in the pollination of flowers is much smaller. The most important families are bees, wasps, Muscidæ, Bombylidæ, and Syrphidæ. None of these species, however, possess a power of flight which would insure them against the attacks of insectivorous birds, but as a rule the beneficial insects appear to be fully as well if not better protected from destruction by birds than are injurious species. The author states emphatically his belief, based upon numerous experiments and personal observations, that parasitic and predaceous insects can not be depended upon to control any injurious species, or even greatly to reduce its numbers.

In order to determine the amount and kind of food of insectivorous birds the author carried on a number of feeding experiments in large aviaries in gardens. The birds employed in these experiments included a number of species fed various kinds of food, including beneficial and injurious insects. The behavior of the different species and their economic value are discussed in detail. The author concludes from these experiments that the destruction of insects by insectivorous birds may be so extensive as to greatly reduce the numbers of injurious species in any locality. The author's experiments in determining the preferred food of various insectivorous birds are presented in detail and indicate the importance of continuing experimental work in this line, and also support the author's conclusion regarding the value of insectivorous birds.

The relation of insectivorous birds to fruit growing, J. P. Fort (*Proc. Georgia State Hort. Soc.*, *27* (*1903*), *pp. 70–75*).—Attention is called to the insectivorous habits of a large number of common birds, and to the value of these birds to the farmer.

The economic value of our native birds, H. A. SURFACE (*Pennsylvania State Dept. Agr., Zool. Quart. Bul. 1 (1903), No. 3, pp. 32*).—Brief popular notes on the habits and economic relations of vultures and hawks.

Studies on the food of our native birds with special reference to hawks and owls, G. RÖRIG (*Arb. K. Gesundheitsamte, Biol. Abt., 4 (1903), No. 1, pp. 51–120, pls. 3, fig. 1*).—A detailed discussion of the food and feeding habits of various species of hawks and owls found in the German Empire, and also certain species of crows, woodpeckers, cuckoos, pigeons, grouse, stork, etc. Data obtained from an examination of the stomach contents and from field observations are presented in tabular form. Special attention was devoted to a study of the pellets cast up by owls.

Report of the A. O. U. committee on the protection of North American birds, W. DUTCHER (*Auk, 21 (1904), No. 1, pp. 97–208, pls. 7, figs. 2*).—In this report an account is given of the work of the committee of the American Ornithological Union on the protection of birds, and also of the National Committee of Audubon Societies. The work of these societies in various States is briefly outlined, and notes are given on the legislation regarding bird protection in various States and Territories.

METEOROLOGY—CLIMATOLOGY.

Climatology of California, A. G. MCADIE (*U. S. Dept. Agr., Weather Bureau Bul. L, pp. 270, pls. 19, figs. 21*).—The available data relating to pressure, temperature—including frost, precipitation—including snowfall and fog, thunderstorms, and earthquakes for different sections of the State (north, central, and southern coast, great valley, and Santa Clara Valley), and for various localities are summarized in tables, charts, diagrams, etc.

"The general climatic conditions of the Pacific coast, and particularly the climate of California, may be said to be controlled by four great factors. These are:

"(1) The movements of the great continental and oceanic pressure areas—the so-called permanent 'highs' and 'lows.' Under this head we include also the most active factor in climatic development, namely, the movements of individual pressure areas, since there is now good ground for believing that the paths of these individual disturbances—large-sized whirls and counter whirls—are largely determined by the general relations of the permanent pressure areas.

"(2) The prevailing drift of the atmosphere in temperate latitudes from west to east.

"(3) The proximity of the Pacific Ocean with a mean annual temperature near the coast line of about 13° C. (55° F.), a great natural conservator of heat, and to which is chiefly due the moderate range of temperature along the coast from San Diego even to Tatoosh Island.

"(4) The exceedingly diversified topography of the country for a distance of 200 miles from the coast inland."

These factors are discussed in detail.

Climatic conditions at California substations, A. V. STUBENRAUCH (*California Sta. Rpt. 1902–3, pp. 162, 175, 179, 186, 198*).—Monthly summaries are given of observations on temperature, rainfall, and cloudiness during the period from January 1, 1902, to June 30, 1903, at the Foothill, Southern Coast Range, San Joaquin Valley, Southern California, and Santa Monica substations. A summary of seasonal (September to May) rainfall at Paso Robles from 1897 to 1903 is also given.

Meteorological observations, A. O. LEUSCHNER ET AL. (*California Sta. Rpt. 1902–3, folders opp. p. 160*).—This is a synopsis of observations at Berkeley on atmospheric pressure, temperature, precipitation, relative humidity, cloudiness, and direction of the wind during the 2 years ended June 30, 1903.

Meteorological observations at the Michigan Agricultural College for 1902 (*Michigan Sta. Rpt. 1903, pp. 98–121*).—Tabulated daily and monthly sum-

maries of observations during 1902 on temperature, pressure, precipitation, humidity, cloudiness, wind movement, etc.

Meteorological records for 1902 (*New York State Sta. Rpt. 1902, pp. 448-456*).—Tables are given which show the average monthly temperature and precipitation since 1882; the daily wind record for each month of 1902; a monthly summary of the direction of the wind from January to May, inclusive; tridaily readings of the standard air thermometer during each month of the year; a monthly summary of maximum, minimum, and standard thermometer readings; and daily readings of maximum and minimum thermometers at 5 and 6 p. m. for each month of the year.

Meteorology (*Rap. An. Sta. Agron.* [*Mauritius*], *1902, pp. 1-9*).—Observations on pressure, temperature, and rainfall at Mauritius during 1902 are summarized and compared in part with similar data for 1901. The mean temperature of 1902 was 22° C.; the maximum 30°, in November; the minimum 11°, in August. The rainfall was 1,736.5 mm. (68.22 in.), of which 968.4 mm. fell during the night. The heaviest rainfall occurred during December, January, February, and March, varying from 3.53 in. in March to 11.79 in. in December. For the rest of the year the monthly rainfall varied from 1.46 in. in April to 2.64 in. in October and November, averaging something over 2 in.

Variations in the transparency of the atmosphere (*Science, n. ser., 19* (*1904*), *No. 476, p. 274*).—In a brief summary of the report of the secretary of the Smithsonian Institution to the board of regents attention is called to observations with the bolograph which showed "a notable variation of atmospheric transparency which is likely to have affected climate and the growth of vegetation over a considerable part of the earth's surface . . . so that there seems renewed promise of progress toward the goal 'for telling by such means those remoter changes of weather which affect harvests.'"

Forests considered in their relation to rainfall and the conservation of moisture, J. H. Maiden (*Jour. and Proc. Roy. Soc. New South Wales, 36* (*1902*), *pp. 211-240*).—This is a discussion of the subject from the standpoints of (1) the effect of forests and other vegetation in increasing the rainfall, and (2) their effects in conserving moisture. As a result of his experience of Australian forestry, the author states that "taking an extensive territory, it appears to be indisputably proved that forests do not increase rainfall; it is fully as well proved that they conserve the rain that falls, and therefore every effort should be made to save them from unnecessary destruction."

WATER—SOILS.

Analyses of waters, G. E. Colby (*California Sta. Rpt. 1902-3, pp. 66-83*).—The results of analyses of 275 samples of water examined with reference to their fitness for domestic and irrigation purposes are reported. A general summary of the results is given in the following table:

Number and character of samples of water examined.

Source.	Total number of waters examined.	Suitable for domestic or irrigation purposes.	Of doubtful use.	Not suitable for domestic or irrigation purposes.
Lakes and streams	19	15	2	2
Springs	70	41	12	17
Common wells	153	101	10	42
Artesian wells	19	14	2	3
Reservoirs and irrigation ditches	14	14		
Total	275	185	26	64

On investigations on drinking water, O. von Czadek (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 12, pp. 797–807, fig. 1*).—This article discusses methods of bacteriological and chemical examination of water, describes a device for taking samples with precautions to be observed in the operation, and reports analyses of 22 samples of water.

Notes on the water supplies in the Black Hills of South Dakota and vicinity, Ellen H. Richards (*Tech. Quart., 16 (1903), No. 4, pp. 309–312*).—Sanitary analyses of 14 samples of water from this region are reported.

The water supplies of southeastern Alaska, Ellen H. Richards (*Tech. Quart., 16 (1903), No. 4, pp. 304–308*).—Sanitary analyses of 17 samples of water from different localities in southeastern Alaska are reported. The author concludes that, "on the whole, the country seems to be well provided with good soft water fairly accessible."

The industrial uses of water, H. de la Coux, trans. and rev. by A. Morris (*London, 1903, pp. 364, ill.*).

Water supply, drainage, and epidemics, K. A. Widegren (*Agr. Jour. Cape Good Hope, 24 (1904), No. 1, pp. 72–80*).—The author shows the close connection of a great number of infectious diseases with drainage and water supply, and the importance of securing a proper drainage scheme and a water supply which is protected from all chance of infection.

Definition of physiological analysis of the soil, H. Vanderyst (*Rev. Gén. Agron. [Louvain], 11 (1902), Nos. 9, pp. 410–421; 10, pp. 437–462; 12, pp. 552–559; 12 (1903), Nos. 1, pp. 23–30; 2, pp. 65–72; 3, pp. 115–120; 4, pp. 172–180; 5, pp. 218–221; 6, pp. 273–276; 7–8, pp. 289–293*).—A detailed discussion of this subject summarizing fully the author's views and extensive experience, and including extracts from various other authorities. The expression "analysis of the soil by the plant," as opposed to chemical analysis of the soil, was first used by Ville; later the expression "physiological analysis of the soil" was substituted for it. These two phrases designate in a general way various methods, more or less analogous, used to determine the fertility and productive capacity of soils, and including pot, box, and plat experiments on different plants with various fertilizing materials. As the author points out, these methods of experimentation are synthetic rather than analytic, because they give at best only indications of the composition of the soil.

The development of this method in Europe for experimental purposes was due very largely to the work of Ville, Joulie, Proost, the author, and others. The disappointing results which had been yielded by chemical analysis caused the method to be welcomed with enthusiasm, and following the lead of Ville extravagant claims were made for it as a reliable and accurate means of determining the fertilizer requirements of soils for both scientific and practical purposes. The method appealed especially to the practical man and served a useful purpose in encouraging experiments on the fertilizer requirements of soils. The author was among the first to recognize the serious limitations of the method, and to attempt to perfect it so that it would yield reliable and useful results. His first studies along this line were made in 1887. Similar studies of the method were afterwards taken up by Smets and Schreiber, the object being to develop a suitable method for determining, with reasonable accuracy, the fertilizer requirements of the soils of Belgium for use in the preparation of agronomic charts. In this article the author attempts to point out the limitations of the method and to indicate the means by which it may be made stable, definite, and rational.

At the outset the author sharply differentiates between physiological analysis of the soil and mere fertilizer experiments. The first to be of scientific value must include only experiments with simple and chemically pure fertilizing materials under clearly defined conditions as regards every detail, and has for its object the determination of the fertilizer requirements of a given soil for a particular plant. Such

experiments require as much skill as laboratory methods, and are too complicated for the average farmer to undertake. Fertilizer experiments are the logical supplement of physiological analysis, since their object is to determine which of the various commercial fertilizing materials available will most efficiently and economically supply the fertilizer requirements indicated by the physiological analysis. Such experiments may be made with advantage by farmers.

Modern investigators clearly recognize the fact that the simple methods advocated by Ville and others are entirely unreliable, and that it is not possible to deduce from the results of such experiments by a simple calculation the exact quantities of fertilizer to be restored in practice. Reliable results can be obtained, and these results can be properly interpreted only when the numerous possible sources of error, both of execution and of interpretation, are taken into account and precautions taken to eliminate them as far as possible. The author enumerates the following points:

(1) In the first place the law of minimum on which the method so largely rests is by no means absolute as applied to such experiments—i. e., the fertilizing constituents are more or less replaceable or interchangeable, and the mineral composition of the plant varies to a considerable extent with the excess or deficiency of certain elements of plant food. Then again certain fertilizing constituents may improve only the quality and not affect the quantity of the product.

(2) A disturbing factor is also introduced by the fact that even in the simplest fertilizing material the constituent under investigation is necessarily combined with other constituents, and it is often difficult to tell how far the particular effect observed is due to the form of combination or to the associated constituents.

(3) Moreover, certain fertilizers do not serve simply as sources of plant food, but also modify the physical conditions in the soil, act as solvent and diffusing agents, correct acidity and other unfavorable conditions, aid nitrification, etc.

(4) The soil renders certain of the fertilizing constituents applied unavailable. If, for example, by analysis by the plant of a soil rich in organic matter a lack of phosphoric acid is found, one must not conclude *à priori* that restitution of phosphates is necessary. This soil may be rich in unavailable phosphoric acid, and in that case it would be of greater advantage to destroy the excess of humus by liming, harrowing, etc.

(5) Account must also be taken of the fact that some fertilizers are more soluble and diffusible than others and are less readily absorbed by soils.

(6) With an abundant supply of water in the soil and free transpiration from the plant a smaller amount of plant food in the soil may suffice for the needs of the plant than if the reverse were the condition. In other words, fertilizers are most effective when the water conditions are favorable.

(7) The behavior of the plant during growth as well as the final weights must be recorded, because the two are sometimes contradictory.

(8) In experiments with mixed herbage there is a special source of error due to the fact that a form of fertilizer which favors one plant of the mixture may be injurious to another.

(9) There is always the injury due to birds, insects, and fungus diseases, etc., to be guarded against and taken into account.

The results of physiological analysis of a soil vary with the species, variety, and sometimes the individuality of the plant, the quality of the seed, the physical conditions of the soil and air, and the form in which the fertilizers are applied. The results of experiments in pots and boxes are not strictly applicable to field conditions, nor those of one year to another. From a physiological analysis made by means of oats we may not legitimately conclude that sugar beets, potatoes, clover, etc., would behave in the same manner in the same soil and under the same conditions of environment. Such an analysis would have a considerable relative and indirect value

for all other cultivated plants if we knew more of the specific rôles of the different elements of plant food and the comparative needs of plants in this respect. The usefulness of the method, however, is greatly impaired by lack of exact knowledge of the physiological needs and functions of plants.

It is evident that useful results can be obtained by the method only when it is employed under well-defined conditions, and the author offers the following general definition: Physiological analysis of soil consists of two or more comparative synthetic cultural experiments, executed systematically with one or more species of cultivated plants, in a soil modified in various suitable ways by simple and chemically pure fertilizers, with the object of determining, on the basis of the examination of the plants and the quantity, quality, and mineral composition of the crops produced the one or more necessary or useful fertilizing elements which are required by the one or more species of plants experimented with, under the conditions of environment in which the experiment is made.

The author explains in detail how the conditions imposed by this definition may be secured in experimental work. He classes experiments as complete and incomplete. The most simple incomplete analysis consists of two cultures, the one with complete fertilizer, the other with the same fertilizer minus a single element, necessary and indispensable or useful, to the experimental plant. The physiological analysis is complete when it comprehends at least the following cultures: (1) Complete fertilizer, (2) complete fertilizer without phosphoric acid, (3) complete fertilizer without nitrogen, (4) complete fertilizer without potash, (5) complete fertilizer without lime, (6) complete fertilizer without magnesium, (7) complete fertilizer without iron, (8) complete fertilizer without sulphuric acid, (9) complete fertilizer without common salt. For purposes of comparison a culture without fertilizer is generally added. Properly speaking, the latter is not at all a part of physiological analysis.

It is not only necessary to experiment with different kinds of plants, but to use as large a number as practicable of individuals of the same kind. Comparison is made in all cases with the culture receiving a fertilizer which is complete with reference to the needs of the plant and the character of the soil, all the other cultures receiving identically the same fertilizer, absolutely or relatively complete, with the exception of a single fertilizing element. The importance of using only simple and chemically pure fertilizers is strongly emphasized.

The experiments must as far as possible be so made that the results may be interpreted in strict conformity to the method of difference. This, however, is an ideal condition not realized in practice under present conditions of knowledge. The conclusions as to the effect of the fertilizers experimented with must be based upon (1) the general aspect of the crops—height, color, resistance to parasites, to tendency to lodge, etc.; (2) their quantity; (3) their quality—richness in sugar or starch, flavor, palatability to animals, etc.; and (4) their mineral composition—content of phosphoric acid, potash, etc.

In discussing the value of chemical and physical examination as a means of studying the productive capacity of soils, and as an adjunct to the method of physiological analysis, the author says that, as a general rule, up to the commencement of the nineteenth century the most advanced agronomists occupied themselves almost exclusively with the physical properties of soils. The biological laws, which control the growth of plants, were for the most part unknown, and inexact, erroneous, or false ideas were current regarding the causes which determine the fertility of soils. On this point Liebig made the following observation in 1840:

"It is very singular that our most distinguished, most capable agronomists have taken so much trouble the last sixteen years to demonstrate that the soil conserves all its fertility even when the fixed principles which it has lost are not restored to it.

They teach that a fertile field is inexhaustible in regard to the fixed substances which plants contain, and consequently can never become deficient."

In the author's opinion agronomists imbued with such prejudices could not attach any real importance to chemical analysis of the soil. It should be stated, moreover, that the methods of chemical analysis were very imperfect at that time. In fact, the earlier methods of chemical analysis of soil were so unreliable and therefore came into such disrepute that many eminent chemists, including Fresenius, Müntz, Risler, Colomb-Pradel, Schloesing, Berthelot and André, Petermann, Grandeau, and Wolff, devoted a great deal of attention to studies having as their object the improvement of these methods. As a result of this activity, however, chemical methods were made so complicated and tedious as to become impracticable, while at the same time they did not show in a precise manner the influence of the soil on the growth of plants.

Chemical analysis is capable of showing with great accuracy, and with close agreement in the hands of independent analysts, the percentage composition of soils, but can not be relied upon to show the form of combination or the availability of the constituents, nor does it furnish a reliable basis upon which to estimate the amounts of plant food which may be rendered available during the growth of a crop by the physical, chemical, and biological agencies constantly at work in the soil.

Even with the most complete information furnished by a complete chemical analysis of soil, no one can deduce from it, with any certainty, the results which will be obtained by analysis of the soil by the plant. The chemist can, however, instruct us upon the nature and the total quantity of elements necessary, useful, indifferent, or injurious to vegetation which the soil contains; and such precise knowledge of the chemical composition of the soil, as well as of its mineralogical, geological, and physical characteristics, is essential to the proper interpretation of the results of physiological analysis.

The water-soluble potash of the soil and its utilization by plants, T. Schloesing, Jr. (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 26, pp. 1206–1209; abs. in Rev. Sci.* [*Paris*], *5. ser., 1 (1904), No. 2, p. 55*).—In earlier experiments plants grown in artificial soils of pure quartz were able to derive their potash from solutions applied to the soil which contained only from 1.8 mg. to 7.5 mg. of potash per liter (E. S. R., 12, p. 36).

Further experiments were made by the same method followed in similar studies on water-soluble phosphoric acid in the soil (E. S. R., 14, p. 341), to determine whether plants are able to derive their potash from such dilute solutions as occur in natural soils. Samples of 4 different soils used in 2 series of experiments, in one of which plants were grown and in the other the soil was kept bare, were exhausted by continuous extraction with water and the potash so removed from the cropped and uncropped soils determined. The proportion of potash so removed was in all cases smaller on the cropped soil than on the uncropped soil, the difference between the 2 varying from 65 to 123 mg. per kilogram of dry soil and approximating quite closely in every case the amounts of potash found by chemical analysis in the crop grown.

On the influence of the relative proportions of lime and magnesia in soils on the yield, O. Loew (*Chem. Ztg., 27 (1903), No. 100, pp. 1225, 1226*).—Referring to a recent article by Gössel (E. S. R., 15, p. 564) containing conclusions not in accord with Loew's theory of a necessary relation between lime and magnesia in soils, the author points out that, while the details of Gössel's experiments are not reported, the disagreement of his results with those of Loew and his associates may be explained by the fact that Gössel used secondary potassium phosphate in his experiments, while in the other experiments primary potassium phosphate was used. It has been shown that the secondary phosphate greatly reduces the injurious effect of an excess of magnesium salts in water cultures.

In conclusion the author cites numerous authorities for the conclusions that (1) magnesia salts and calcined magnesia in certain amounts act injuriously on plants; (2) a moderate liming is beneficial to many soils, but excessive liming may reduce the yield; (3) calcium salts reduce the injurious effect of an excess of magnesia, and in presence of a sufficient amount of lime the magnesia may play an important rôle as plant food. The majority of the experiments which have heretofore been made have indicated that for cereals as a rule the best ratio of lime and magnesia is 1 to 1. For other plants, and especially leafy plants, the amount of lime should be two or three times as great as that of magnesia.

Examination of soils, R. H. LOUGHRIDGE, E. W. HILGARD, ET AL. (*California Sta. Rpt. 1902–3, pp. 23–37*).—This includes descriptions and analyses of samples of soils from the northeastern lava bed region and the coast range region of California, Sacramento Valley, and southern California, with a discussion of the humus content of the soils of the humid and arid regions of Oregon. The analyses of the Oregon soils show that those of the arid region of that State contain a low percentage of humus, which is rich in nitrogen, while those from the humid region contain a high percentage of humus poor in nitrogen.

The chemical nature of the soils of New South Wales, with special reference to irrigation, F. B. GUTHRIE (*Agr. Gaz. New South Wales, 14 (1903), No. 11, pp. 1078–1087*).—Mechanical and chemical analyses of typical soils of the semiarid parts of New South Wales are reported and discussed with reference to their adaptability to irrigation. The average composition of 19 such soils is as follows: Capacity for water, 40 per cent; volatile matter, 5.7 per cent; nitrogen, 0.08 per cent; lime, 0.44 per cent; potash, 0.33 per cent; phosphoric acid, 0.21 per cent. These averages are compared with those of a large number of analyses of soils from different parts of the world. "From the chemical point of view discussed in this paper there is no room for doubt that the soils of our arid districts are admirably adapted for cultivation by means of irrigation, abundance of water, properly applied, being the only thing necessary to render them extraordinarily fertile."

Two years' field work of the chemical branch, F. J. HOWELL (*Jour. Dept. Agr. Victoria, 2 (1903), Nos. 1, pp. 5–14; 2, pp. 177–186, pl. 1*).—A discussion of the soil requirements of the different districts of Victoria.

"Bleisand" and "Orstein," A. MAYER (*Landw. Vers. Stat., 58 (1903), No. 3–4, pp. 161–192; abs. in Centbl. Agr. Chem., 32 (1903), No. 12, pp. 798, 799*).—These two substances, which are found associated with each other in humus soils, are defined and described. The first is a metallic-gray sand impregnated with humic acid, the second is a slightly coherent chocolate-brown sand strongly impregnated with humates of iron and aluminum mixed with more or less clay. The conditions essential to the formation of the two substances are explained.

On the influence of the assimilable nitric nitrogen in cultivated soils on the action of tubercle bacteria, F. NOBBE and L. RICHTER (*Landw. Vers. Stat., 59 (1903), pp. 167–174; abs. in Chem. Ztg., 28 (1904), No. 3, Repert. No. 1, p. 6*).—Pot experiment during 1895, 1897, and 1898, on the influence of an abundance of nitric nitrogen in the soil on the activity of tubercle bacteria of hairy vetch are reported. The results show that the inoculated soils produced much larger crops, which were richer in nitrogen than the uninoculated soils. The nitrogen assimilation of the inoculated over the uninoculated soil increased as the nitric nitrogen in the soil declined, i. e., it was least the first year (1895) following applications of potassium nitrate (500 and 1,000 mg. of nitrogen to each 4.5 liter pots of soil which already contained 0.4 per cent of nitrogen); greater the second year (1897) when no nitrate, but a large amount of garden soil was added, which increased the soil nitrogen to 0.59 per cent; and still greater the third year (1898) when no fertilizing material was added and the soil nitrogen was only 0.38 per cent.

The after-effect of soil inoculation for leguminous plants on other crops, F. Nobbe and L. Richter (*Landw. Vers. Stat., 59 (1903), No. 3-4, pp. 175-177*).—Oats grown in soil which had been used the previous year in the inoculation experiments referred to above were largely increased in yield as an after-effect of the inoculation. This increase is attributed to the larger amounts of nitrogen furnished by the roots of the leguminous crop in the inoculated soil.

Notes on nitrification, H. H. Cousins (*Bul. Dept. Agr. Jamaica, 2 (1904), No. 1, pp. 1-9*).—A general discussion of this subject.

The life conditions of nitrate bacteria, H. Buhlert (*Fühling's Landw. Ztg., 53 (1904), No. 1, pp. 29-34*).—A general discussion of conditions favorable to nitrification.

On denitrification in cultivated soil, G. Ampola and C. Ulpiani (*Gaz. Chim. Ital., 33 (1903), II, p. 125; abs. in Chem. Ztg., 27 (1903), No. 99, Repert. No. 22, p. 315*).—Investigations are reported which show that under ordinary conditions calcium nitrate, which is the natural product of nitrification, is not readily acted upon by the denitrifying organisms. In order to prevent loss of nitrogen it is necessary to abstain from applications of fresh coarse manure to the soil while nitrification is in progress, and in order that sodium nitrate may be of the greatest benefit it must be applied only after the manure has undergone very complete decomposition.

Alkali and alkali lands, R. H. Loughridge et al. (*California Sta. Rpt. 1902-3, pp. 37-56*).—This includes a statement with reference to the history of investigations relating to this subject with a list of publications treating of alkali lands which have been issued either by the California Station or elsewhere by the present director of the station; and analyses of alkali soils from different parts of the State with reference to geographic distribution and distribution in different depths of soil. Observations on the latter subject at the San Joaquin Substation have shown that—

"(1) Alkali of similar strengths or similar composition is not continuous over an area of more than a few feet, and may vary very materially even at nearer points.

"(2) There is a very great difference and variability in the composition of each of the several salts in adjoining soil columns, being within danger limits in one and below the danger point for cultures in the other. Thus a culture sensitive to carbonate of soda and not to common salt might grow at a point 16 ft. east of the center line with its 1,160 lbs. of carbonate, while it would suffer if planted 16 ft. to either side, where the carbonate is 1,600 or 1,900 lbs. And similarly with reference to common salt on adjacent spots. This effect of varying amounts of an injurious salt is often felt in orchards and is marked by the suffering of single trees here and there.

"(3) The rise of alkali toward the surface is seen in the accumulation of the several salts within the upper 2 ft. in each soil column, and in the progressive diminution downward from foot to foot; but the irregularity in rise is apparent when we take each salt in the column into consideration.

The benefits of drainage, E. W. Hilgard (*California Sta. Rpt. 1902-3, pp. 64, 65*).—A brief general statement of the benefits of drainage, particularly in connection with irrigation and where alkali occurs.

Experiments in washing salt land, E. Gelé (*Jour. Khediv. Agr. Soc. and School Agr., 5 (1903), No. 3, pp. 83-90*).

The sanitary relations of the soil, H. B. Bashore (*Sanitarian, 52 (1904), No. 410, pp. 42-44*).—A brief discussion.

FERTILIZERS.

Annual report on the working of the sewage farm at Mánjri for 1902-3, P. R. Mehta and J. W. Leather (*Bombay, 1903, pp. 11, chart 1*).—Comparative tests on sugar cane, onions, peanuts, yams, and other crops of the effluent from a septic tank and of the same effluent after passage through the contact beds are reported. The

former was found to be much more effective as a fertilizer. This is due to the higher percentage of nitrogen in the effluent. The average nitrogen content of the crude sewage at different periods was as follows:

Nitrogen content of crude sewage during different months.

[Parts per 100,000.]

	Total nitrogen.	Ammonia nitrogen.	Organic nitrogen.
December	4.35	2.36	1.99
January	3.99	1.63	2.36
February	3.69	1.51	2.18
March (16-30)	9.53	2.60	6.93

The richer sewage in March was due to addition of night soil. In the septic tank the sewage lost 3 per cent of its nitrogen during the first 16 hours, and 4 per cent more in the next 8 hours during December; 10 per cent and 4 per cent, respectively, during January; and 19 and 3 per cent, respectively, in February. With the stronger sewage of March the loss of nitrogen amounted to 22 per cent during the half month. Similar losses occurred when the effluent from the septic tank was passed through contact beds, varying from 5 to 40 per cent of the original nitrogen of the sewage. The average composition of the sewage as it left the septic tank was as follows:

Fertilizing constituents in effluent from septic tank.

[Parts per 100,000.]

	December.	January.
Nitrogen	4.07	3.42
Phosphoric acid	1.92	1.72
Potash	1.47	1.37

"If the irrigation rate be assumed as 4,000 gal. per acre per day this sewage would supply 1.5 lbs. nitrogen, 0.73 lb. phosphoric acid, and 0.57 lb. potash."

Influence of the nature of the exterior medium on the mineral composition of plants, A. Hébert and G. Truffaut (*Bul. Soc. Chim. Paris, 3. ser., 29 (1903), No. 24, pp. 1235-1239*).—The authors have already reported investigations (E. S. R., 9, pp. 451, 755; 12, p. 851) from which they concluded that a rational basis for fertilizing was furnished by chemical analysis of typical plants grown under normal conditions and the determination of the fertilizing constituents furnished by the soil. They here report ash analyses of dracæna, chrysanthemum, cyclamen, and mint grown on fertilized and unfertilized soil, which seem to bear out this conclusion in that the mineral composition of the fertilized plants was not as a rule appreciably different from that of the unfertilized plants.

The authors therefore conclude that for a given species of plant grown on a given soil the use of a complete fertilizer increases the yield but does not affect the mineral composition. However, a special fertilizer like sodium chlorid or nitrate may increase the assimilation of the principal element which the compounds contain without disturbing to any great extent the relative proportions of the other mineral constituents.

Influence of the nature of the exterior medium on the organic composition of plants, A. Hébert and E. Charabot (*Bul. Soc. Chim. Paris, 3. ser., 29 (1903), No. 24, pp. 1239-1247*).—Experiments similar to those noted above were made to determine the influence of various salts of sodium, potassium, iron, and manganese

on the organic composition of peppermint. The results show that with the exception of nitrogen the relative proportions of the organic constituents were but slightly affected, the only marked effect of the fertilizers applied being either to increase or decrease the yield.

Fixation of atmospheric nitrogen by dead forest leaves, E. HENRY (*Ann. Sci. Agron., 2. ser., 1902–3, II, Nos. 2, pp. 313–320; 3, pp. 321–327*).—Observations are recorded from which the conclusion is drawn that dead forest leaves, either alone or mixed with soil, have the power when resting upon a moist substratum of soil to fix the free nitrogen of the air. The dead leaves of forests growing on poor dry soils do not fix nitrogen at all or only in insignificant amounts.

On the decomposition of dead leaves in forests, E. HENRY (*Ann. Sci. Agron., 2. ser., 1902–3, II, No. 3, pp. 328–333*).—The observations recorded show that in case of leaves kept in zinc boxes the salts of this metal formed retarded decomposition of the leaves to a marked extent. Decomposition was most rapid in summer and almost ceased in winter. Leaves of the oak (*Quercus robur*), which are tough and rich in tannin, were decomposed more slowly than the leaves of hornbeam (*Carpinus betulus*).

Fertilizers for new land, C. A. MOOERS (*Univ. Tennessee Record, 7 (1904), No. 1, pp. 31, 32*).—In field experiments with potatoes, beans, peas, cucumbers, tomatoes, and radishes on naturally fertile and durable new land containing more than the average amounts of phosphoric acid and nitrogen for East Tennessee soils, it was found nevertheless that applications of quickly available phosphoric acid and nitrogen gave profitable returns. The nitrates increased the vigor of the plants, while the phosphoric acid hastened maturity.

On the phosphoric acid of Thomas slag, T. KNÖSEL (*Chem. Ztg., 28 (1904), No. 4, pp. 38, 39*).—The author explains the merits of his patented process for the treatment of Thomas slag with concentrated sulphite solution.

Florida phosphate trade (*Engineer and Min. Jour., 77 (1904), No. 7, p. 285*).—Statistics of exports of Florida phosphate during 1903 are given. These amounted to 617,981 long tons.

Perchlorate in nitrate of soda, A. VERWEIJ (*Chem. Weekblad, 1 (1903), pp. 155–159; abs. in Chem. Centbl., 1904, I, No. 3, pp. 206, 207*).—The author claims that it is not established that the injurious effect observed from time to time in case of plants fertilized with nitrate of soda is due to perchlorate. He claims that nitrates containing large amounts of perchlorate have often been used without injurious effect, while on the other hand the use of nitrate practically free from perchlorate has in some cases resulted in serious injury.

On the action of perchlorate in nitrate of soda, B. SJOLLEMA (*Chem. Weekblad, 1 (1903), pp. 125–129; abs. in Chem. Centbl., 1904, I, No. 3, p. 206*).—A reply to the article by Verweij noted above.

FIELD CROPS.

The culture substations, A. V. STUBENRAUCH (*California Sta. Rpt. 1902–3, pp. 161–194*).—The field work of the California substations for the season of 1901–2 is summarized (for that in horticulture see p. 773).

At the Foothill Substation near Jackson fertilizer experiments were conducted with oats, wheat, and barley grown as hay crops. The most profitable returns were obtained on granite soil from the use of 80 lbs. per acre of nitrate of soda applied alone. Lime proved unprofitable. On red soil an application of 800 lbs. of Thomas phosphate and 160 lbs. of nitrate of soda per acre gave a profit of $11.70, which was second to the returns for nitrate of soda alone. In this experiment half of the nitrate was applied in January and the other half in March.

Brief notes are given on a number of saltbushes and grasses grown at the Southern

Coast Range Substation at Paso Robles. A number of saltbushes, especially *Rhagodia spinescens inermis*, *Atriplex cachiyuyum*, *A. pamparum*, and *A. nummularia*, grew very well without irrigation during the summer and withstood the rather severe winter frosts. The plants formed compact bushes from 3 to 4 ft. high and seemed to prove valuable as browsing plants for both summer and winter.

Among the different plants tested at the Southern California Substation, *Lupinus albus* seemed promising for green manuring purposes. The results with berseem (*Trifolium alexandrinum*), indicated that it is not as valuable as alfalfa. The one-flowered lentil (*Ervum monanthos*), obtained through this Department, made a good growth in 1901 but suffered from drought in 1902.

Report of the agriculturist, E. R. LLOYD (*Mississippi Sta. Rpt. 1903, p. 11*).—In 1902 24 varieties of corn were grown on poor red hill soil, with yields varying from less than 1 bu. to 20 bu. per acre.

Eighteen varieties of cotton grown on upland soil made an average yield of 954 lbs. of seed cotton per acre, with the yields of the individual varieties varying from 700 to 1,260 lbs. In a fertilizer test on poor upland the largest yield of seed cotton per acre, 1,000 lbs., was obtained from a plat receiving 125 lbs. each of cotton-seed meal and kainit per acre, and the smallest yield, 240 lbs., from a plat fertilized with 250 lbs. of cotton-seed meal per acre. The cotton on a plat where 250 lbs. of kainit per acre was applied was practically free from rust, and plats receiving liberal applications of barnyard manure were only slightly affected. The unmanured plats and those on which cotton-seed meal and acid phosphate were used, separately or in combination, were badly rusted.

The Woburn field experiments, 1901, J. A. VOELCKER (*Jour. Roy. Agr. Soc. England, 63 (1902), pp. 308–330, figs. 3*).—The data presented for the experiments in continuous growing of wheat and barley represent the twenty-fifth season (E. S. R., 14, p. 27). Street Imperial wheat was grown with different fertilizer applications. Nitrate of soda throughout gave better results than ammonia salts, either used alone or with mineral fertilizers. The plats receiving ammonia salts, alone or with minerals but without lime, showed signs of failing. The improvement due to 2 tons of lime per acre applied in 1897 with ammonia salts containing 50 lbs. of ammonia was still perceptible. Rape cake furnishing 100 lbs. of ammonia per acre gave a crop equal to that from $3\frac{1}{2}$ cwt. of superphosphate of lime, 200 lbs. sulphate of potash, 100 lbs. sulphate of soda, 100 lbs. of sulphate of magnesia, and $2\frac{1}{2}$ cwt. of nitrate of soda. The best yield in grain and straw was obtained on the plat treated with barnyard manure supplying 200 lbs. of ammonia per acre. As in former seasons, nitrate of soda gave the lowest weight per bushel.

The experiments with barley were made with the Standwell variety. Mineral fertilizers gave an increase of over 2 bu. per acre, and barnyard manure, as in the case of wheat, gave the best returns. Rape cake furnishing 100 lbs. ammonia per acre, applied annually since 1890, also gave good returns. The beneficial influence of lime was manifest wherever it had been used. Barley plants on unlimed distinctly acid soil were stunted in growth with their roots poorly developed, while plants on limed soil were healthy and well developed with plenty of rootlets. Nitrate of soda used alone produced the lightest grain and the largest proportion of small kernels, with the lowest value per bushel.

Mustard, rape, and tares were plowed under for green manuring, and followed by wheat. One-half of each plat received superphosphate and kainit, but no apparent advantage resulted from this application. The best quality of grain was produced after rape and mustard.

In a variety test with barley, Goldthorpe, Burton Malting, and Golden Melon ranked in the order given in the production of grain and straw. Standwell and Burton Malting ripened earliest. The results for 3 years show no advantage from kiln-drying the seed before sowing.

Sandy, Potato, and Tartar King oats yielded 30.2, 61.6, and 36 bu. per acre, respectively.

Wheat on heavy and light soils gave the best yields when sown at the rate of 8 pks., as compared with 7, 9, 10, and 13 pks. per acre.

The experiments with alfalfa plainly showed the superiority of the plats receiving potash in the fertilizer application. English Giant sainfoin ranked above French Common, English Common, and French Giant in the production of green forage. A total yield of 4 tons, 698 lbs. of green fodder per acre, was obtained from *Lathyrus sylvestris.*

The results of experiments on pasture indicated a general improvement of feeding over mowing the grass. Including rye grass in the seed mixture gave a marked increase in the hay crop. The thickly-seeded plats continued to give the heavier yields. The use of lime produced a marked effect on the yield and general appearance of the plats. In another experiment 5 cwt. of mineral superphosphate per acre gave a heavier yield of hay than 8 cwt. of basic slag. There was no apparent increase in the clover where basic slag was used.

Cooperative field trials (*Univ. Ext. Col. Reading, Agr. Dept., Ann. Rpt. Field Trials and Expts. 1903, pp. 21–39*).—The results of cooperative trials are briefly reported. The yield of mangels, the quantity of important constituents produced per acre, and the percentage of water contained in the roots are shown in the following table:

Results of a variety test with mangels at Burghfield in 1902.

Varieties.	Yield of roots.	Water.	Dry matter.	Ash.	Organic matter. Total.	Organic matter. Nitrogenous.	Organic matter. Nonnitrogenous.
	Tons.	*Per cent.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*
White Sugar	23	86.30	7,091	316	6,785	357	6,428
Red Sugar	22¼	84.50	7,725	314	7,411	339	7,072
Golden Tankard	22	86.12	6,773	386	6,387	478	5,909
Prizewinner	24½	88.50	6,284	470	5,811	437	5,374

In a fertilizer test with mangels, carried out at West Wycombe, a plat receiving 2 cwt. of nitrate of soda and 4 cwt. each of superphosphate and kainit per acre, yielded 26 tons per acre, being the best yield in the test. A plat receiving 2 cwt. of common salt in addition to this application gave the same yield, while the plats receiving no manure or incomplete applications produced considerably less.

Experiments were also made with different quantities of seed and different widths of drilling barley and oats. In both tests the drills were 7⅓ and 11 in. apart. Barley was sown on 6 plats at rates ranging from 1 to 3½ bu. per acre, making a difference of ½ bu. of seed between each 2 contiguous plats in the series. The yield of barley was practically the same on both series of plats, but the wider drilling produced the most straw. The proportion of small kernels as well as the average weight per bushel was greatest on the narrow drilled plats. On the wide drilled plats the largest yields were obtained from the use of 2 bu. of seed per acre. The weight per bushel in both distance tests was greatest from the smaller quantities of seed.

In the experiments with oats the seed used ranged from 2½ to 5 bu. per acre, also making a difference of ½ bu. between any plat and the next one to it in the series. The total yield of grain and straw was the best on the narrow-drilled plats. The largest quantity of good grain was obtained from the narrow drilling, and from 2½ bu. of seed per acre. Good results were also secured where from 4 to 5 bu. of seed were used.

Tests at Burghfield of fertilizers for hay on clay loam soil with very stiff clay subsoil illustrated the lasting effect of basic slag, superphosphate, and kainit, these fer-

tilizers having been applied 5 years before. The results of this season not only showed increased yields as compared with the check tests, but also an improvement in the quality of the herbage.

Fertilizer experiments were also conducted on old pasture with clay soil of a brick-earth character and a red-clay subsoil. Barnyard manure and an application of 10 cwt. basic slag, 6 cwt. kainit, and 1 cwt. nitrate of soda per acre gave about the same increase over the unmanured plat, but the use of barnyard manure was the most expensive. Basic slag was not very effective on this soil, but kainit produced a very marked increase in the yield of grass.

Field and other experiments, 1902, D. A. Gilchrist (*County Councils Cumberland, Durham, and Northumberland Rpt. 1902, pp. 129*).—This publication is a compilation of the results of cooperative experiments with fertilizers and seed mixtures for hay and pasture, together with other fertilizer and rotation tests. Cooperative experiments with fertilizer applications for permanent meadows have been in progress for a number of years, and the results are here tabulated and discussed in detail. In each locality the experiments were conducted on different kinds of soils.

Of a number of seed mixtures for hay and pasture in one of the tests a mixture consisting of 9.3 lbs. of *Lolium perenne*, 4.9 lbs. of *Dactylis glomerata*, 3.1 lbs. of *Phleum pratense*, 13 lbs. of *Festuca pratensis*, 0.9 lb. of *Poa trivialis*, 2.3 lb. of *Trifolium pratense*, 2.1 lbs. of *T. hybridum*, 5.6 lbs. of *T. repens*, and 0.3 lb. of *Achillea millefolium* per acre gave the best results.

An application of 12 tons of barnyard manure with 1 cwt. nitrate of soda, 1 cwt. sulphate of ammonia per acre, with another hundredweight nitrate of soda as a top-dressing after thinning, is recommended for mangels. The results obtained in these experiments are considered as confirming the general opinion as to manuring the mangel crop. In a test with swedes Fell Bronze Top and Arctic surpassed the others in content of dry matter. Considerable differences in the percentage of dry matter were presented by the same varieties of swedes grown on different farms. The individual root appeared to be the greatest cause of the difference, while such factors as variety, season, and soil are regarded as secondary.

Experiments at the County Demonstration Farm, Morpeth (*County of Northumberland, Education Com. Rpt. 1902–3, pp. 19–41*).—A summary of experiments on meadows in progress for 6 years shows that the annual application of 8 tons of barnyard manure, $\frac{5}{16}$ cwt. of sulphate of ammonia, $\frac{7}{16}$ cwt. of nitrate of soda, $\frac{7}{8}$ cwt. of superphosphate, 75 lbs. of slag, and 50 lbs. of sulphate of potash per acre gave the best returns, being followed by the use of 8 tons of barnyard manure alone, with a yield of 5 cwt. per acre less. Complete applications of commercial fertilizers also gave good and profitable results, and giving $\frac{1}{2}$ of the nitrogen in the form of nitrate of soda showed an advantage over sulphate of ammonia as the only source of this element. When potash was omitted the yield was not decreased, but the quality of the hay was considerably better when it formed part of the application. The omission of nitrogenous fertilizers reduced the yield of hay about 5 cwt. per acre.

The results of two 4-year rotations on the same land with different fertilizer applications are given in tables. Turnips, oats, hay and oats were grown in the first rotation, and swedes, barley, hay and oats in the second. Barnyard manure wherever used in the first rotation gave good returns, and these were best when the manure was applied to the root crop. The highest returns were obtained from the plat on which roots received 20 tons of barnyard manure per acre. Practically the same profits were secured from a plat upon which the root crop received a standard application of 1 cwt. of sulphate of ammonia, 5 cwt. superphosphate, and 1.25 cwt. of muriate of potash per acre, and where in addition another similar application was divided between the last 2 crops of the course and half of the crop of roots eaten on the land by sheep. The profits as here reported represent the total returns for

the 4 years. Ten tons of barnyard manure for the root crop and a standard application of commercial fertilizers for the hay also gave good results. Where potash was withheld the total value of the crops for the entire course was reduced. Barnyard manure alone was more satisfactory than the use of commercial fertilizers alone.

In the second rotation the quantity of muriate of potash in the standard applica-cation was reduced to 1 cwt. A very marked reduction in the yield took place when potash was omitted. Doubling the standard application for swedes did not benefit the crop, but resulted in an increase of 4½ bu. per acre in the yield of the succeeding barley crop. The use of 3 times the standard application for the hay crop was not profitable, but 1 cwt. sulphate of ammonia applied to each of the cereals in addition to the double standard dressing gave a marked increase in yield and thereby proved useful in extracting the residues of large quantities of commercial fertilizers previously given. As in the first rotation, 10 tons of barnyard manure gave better results than any application of commercial fertilizers.

Among 9 varieties of oats Siberian, Banner, Waverly, and Yellow Lentewitz, in the order given, produced the best yields. Waverly, although not the heaviest yielder, produced the greatest weight of kernel per acre. The straw of the Tam Finlay variety is considered the best for fodder.

Sutton Prize Winner Yellow Globe mangel produced heavier crops of roots and total solid matter than the Carter variety. In connection with this test an application of 12 tons of barnyard manure, ⅞ cwt. of sulphate of ammonia, 4½ cwt. of superphosphate, ⅓ cwt. of muriate of potash, and 2¼ cwt. of nitrate of soda after thinning gave better results than the use of 20 tons of barnyard manure and 1⅛ cwt. of nitrate of soda applied after singling. The results of another fertilizer test with mangels showed that nitrogen is the most important element for the crop, and that on light sandy soil potash is much more needed than phosphoric acid. A complete application of commercial fertilizers in addition to 12 tons of barnyard manure gave a large increase in yield over the manure alone. On this same kind of soil swedes receiving 12 tons of barnyard manure and a complete application of commercial fertilizers in addition were but slightly benefited as compared with the use of manure only.

Fertilizer experiments with potatoes on this soil also showed the special need of potash. Withholding nitrogen caused a marked reduction in the yield of good tubers, while the omission of phosphoric acid lowered the yield but little as compared with the complete application of commercial fertilizers. Twelve tons of barnyard manure increased the salable potatoes by more than 7½ tons per acre over the check plat, and where the complete application of commercial fertilizers was added this increase amounted to over 9½ tons.

Of what value is the stooling capacity of grains? W. LIPPOLDES (*Inaug. Diss., Univ. Jena, 1903, pp. 91*).—The work and views of Schribaux and Rimpau on the value of the stooling capacity of cereals are discussed, and data obtained for the purpose of demonstrating the value of the first stem produced by the plant, as compared with subsequent stems, are given. Previous articles on the work by Schribaux have been noted (E. S. R., 12, pp. 850, 941; and 15, p. 247).

The data here presented comprise the weight and number of grains per head, the weight per thousand grains, and the weight, length, and thickness of the stems of varieties of rye, wheat, and barley. The rank of the earlier appearing stems with reference to these different points is pointed out, and the principal conclusions are summarized. The acceptance of the rule laid down by Schribaux that the yielding capacity of cereals is inversely proportional to their stooling capacity is not regarded as warranted, on account of the numerous exceptions. The initial stems were not found to be regularly superior to the other stems of the plant. The study of a number of plants showed that almost without exception the initial stem was the heaviest and its head contained the largest quantity of grain by weight, while the number of grains and the thickness were also generally in its favor. In length and in the

weight per thousand grains it was frequently surpassed by the stems of later growth. The average value of the first 3 stems was found superior to the average value of the first 6 in all the points determined. No regular differences between the initial stems of plants with small and large stools were discerned.

Mineral matter in the lower part of the stems of cereals in its relation to lodging, D. Lienau (*Inaug. Diss., Univ. Königsberg, 1903, pp. 91, pls. 4, dgm. 1*).—Strube Schlanstedt oats, a variety which stands up well, was grown with different fertilizer applications in field and pot experiments, for the purpose of obtaining material for observation. The results obtained point to a relation between the mineral matter furnished in the fertilizer and the thickness of the cell wall, as well as the content of the stems in total ash, phosphoric acid, lime, potash, and crude fiber. A summary of the results and conclusions is here given.

It was found that phosphoric acid produced the most marked thickening of the cell wall, and that this influence is very much retarded by a large proportion of potash or lime applied at the same time. A heavy application of potash increased the size of the cell lumen, and large quantities of nitrogen, in addition to a like effect, reduced the thickness of the cell wall. This action of these 2 plant-food elements was neutralized when a proportionally large quantity of phosphoric acid was applied simultaneously. Ammonia nitrogen weakened the stems less than nitrate nitrogen. The plants on limed soil also showed weaker cell walls and larger cell lumen than those on unlimed soil, and this result with lime was strikingly apparent on the plats heavily fertilized with phosphoric acid. The weakening of the stems did not proceed beyond a certain point, even when several factors with such a tendency were active at the same time.

The data further show a constant analogy between the total ash of the stems and their potash content, the one rising and falling with the other. When large quantities of potash, nitrogen, and lime were used the stems contained more total ash and potash than when only small quantities were given. The increase in these substances through lime was particularly heavy on the plat receiving ammonium sulphate. A liberal use of phosphoric acid decreased the total ash and potash content of the stems in a number of instances. A definite maximum in the content of total ash and potash was never surpassed, even when several favorable factors were working in conjunction.

The quantity of phosphoric acid in the stems showed no connection with the quantity applied in the fertilizers, and the results apparently indicate that the liberal use of potash, nitrogen, and lime further the absorption of phosphoric acid by this part of the plant.

On the nitrate-of-soda plats a connection between the phosphoric acid given in the fertilizer application and the lime content of the stems was observed. The plats heavily fertilized with phosphoric acid produced plants with considerably less lime in the stems than the plants receiving little or no lime. On the ammonium-sulphate plat heavy applications of potash and nitrogen increased the quantity of lime taken up by the stems. The silicic acid, iron, and sodium in the stems showed no connection with the fertilizers applied. The crude fiber appeared to be increased in the straw by heavy applications of phosphoric acid, and, in case of insufficient plant food, also by the use of lime.

An anatomical study of the plants under observation showed that fertilizing with phosphoric acid increased the thickness of the cell wall, while the use of potash, nitrogen, and lime was prejudicial to this process. The results of analyses indicate that phosphoric acid has a tendency to diminish the ash and some of its components, while potash, nitrogen, and lime had the opposite effect. The thickness of the cell wall was inversely proportional to the content of ash, or certain ash constituents, in the stems, but this was definitely determined only for total ash and potash, and not for phosphoric acid and lime. These experiments are not considered adequate to

prove an actual connection between the thickness of the cell wall and the quantity of ash constituents in the stems. The results are regarded as showing with certainty only that large quantities of phosphoric acid in the fertilizer increased the thickness of the cell wall, and that potash, nitrogen, and lime were in this respect retarding factors.

The author recommends that, in addition to the different precautions taken to prevent lodging, attention should be given to the application of fertilizers in this connection, and that, for instance, when it is necessary to fertilize heavily with lime or nitrogen, sufficient phosphoric acid be also applied to counteract the tendency of weakening the stems.

A list of 17 references bearing on different phases of the question under consideration is given.

The practical application of Mendel's law in cereal breeding, E. TSCHERMAK (*Deut. Landw. Presse, 30* (*1903*), *No. 82, pp. 712, 713*).—After a discussion of Mendel's law, the author presents observations made in breeding wheat, barley, rye, and oats. He found in his work with wheat that the presence and absence of awns, and hairyness and smoothness, appeared strictly to follow the law of Mendel, the absence of awns and hairyness being dominant. The recessive characters, presence of awns, and smoothness, which appeared in one-fourth of the number of individuals in the second generation, remained constant. In color of head, brown was dominant in the first generation over whitish yellow, but in the second generation numerous intermediate forms appeared. The heads relatively darkest and those relatively lightest in color were found most likely to reproduce themselves, but were not constant. The relation between long and short, and open and compact, heads and few and many-flowered spikelets, also proved irregular. The author further observed in his experiments that in the first generation long and open heads with a small number of flowers were dominant over short and compact heads with a larger number of blossoms.

In his work with barleys he observed the following relation of characters:

Dominant characters.	*Recessive characters.*
Dark-colored heads.	Light or yellowish color of heads.
Two-rowed.	Four-rowed.
Two-rowed.	Six-rowed.
Bearded.	Hooded.
Beardless.	Bearded.
Beardless.	Hooded.
Normal form of head.	Branched form of head (*Hordeum compositum*).
Nutans type (no transverse furrow across base of grain).	Erectum type (transverse furrow across base of grain).
Long-haired rachilla.	Short-haired rachilla.
Glumes, nerves denticulated.	Glumes, nerves smooth.

In oats a dark color in the glumes and the seemingly correlative color of the grain were dominant over the light or yellowish color, and the spreading pannicle over the one-sided form. On account of insufficient data, no conclusions with reference to rye are given.

References to recent work in plant breeding, C. FRUWIRTH (*Jour. Landw., 51* (*1903*), *Nos. 2, pp. 223–230; 4, pp. 371–387*).—References are given to 48 recent articles on plant breeding, including work with tobacco, flax, potatoes, rape, beets, clover, and cereals. A brief abstract of the article is given in each case. A number of the articles have reference to Mendel's law.

Barley sickness of soils, A. ATTERBERG (*Jour. Landw., 51 (1903), No. 2, pp. 163–171*).—The results of experiments here reported indicate that for barley culture the moraine soil under observation, of which an analysis is given, requires applications of potash fertilizers in order that the supply of readily soluble potash compounds may be maintained. It was found that most of the northern varieties of barley are not so readily affected by a lack of potash, and that they are able to take their supply from the less soluble compounds occurring in the moraine soil. Many foreign and new varieties, on the contrary, were very sensitive to an inadequate quantity of readily soluble potash. A heavy application of lime on this soil was observed to produce the same effect on barley as an application of potash.

The growth of maize for ensilage, T. J. YOUNG (*Jour. Southeast. Agr. Col., Wye, 1903, No. 12, pp. 40–47, fig. 1*).—The culture of corn for ensilage and the construction of silos are described and the results of a variety test of corn grown for ensilage are reported. An analysis of ensilage is also given. Harvey Seed sown in 12 in. drills gave the best yield, nearly 23 tons per acre, followed in the order given by White Horsetooth, Angel of Midnight, and Longfellow.

Suggestions on cotton culture, W. C. WELBORN (*Philippine Bureau Agr., Farmers' Bul. 9, pp. 12, figs. 8*).—A Spanish edition of a popular bulletin on cotton culture.

Hops, A. D. HALL (*Jour. Southeast. Agr. Col., Wye, 1903, No. 12, pp. 12–30*).—The results obtained with different systems of training hops are reported, the systems described, and their advantages and disadvantages summarized. The yields obtained for a series of years in the college garden at Wye are given in this table:

A comparison of different systems of training hops.

System.	Planting.	Hills per acre.	Relation of yields to average crops.						
			1897.	1898.	1899.	1900.	1901.	1902.	Average.
	Feet.		*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*
Butcher	10 x5	870	76.6	116	93	91.4	90.9	100	94.5
Do	8 x8	680	111	....	107	82.7	100	86	97.4
Do	7 x7	890	111	114	106	104	89.5	76	101.1
Do	7 x6	1,037	106	96.7	105	113	101	127	108.1
Do	$6\frac{1}{2}$x$6\frac{1}{2}$	1,031	....	....	99	109	99.5	....	102.5
Butcher (3 strings to pole)	6 x6	1,210	....	....	83.6	93.3	101	114	98
Umbrella	6 x6	1,210	95.3	90.7	111	124	112	112	107.5
Worcester	$7\frac{1}{2}$x$3\frac{1}{4}$	1,786	93.8	99.2	94	107	106	100	100

In reviewing the advantages of the different systems the author recommends planting a little wider than is usual.

The results of fertilizer experiments in 1902 confirm previous conclusions that the hop shows no special fertilizer requirements and that the subject of fertilization resolves itself into a study of the soil. On clay soil at Marden and Oxted phosphoric acid was needed, while potash was without effect; and at Farnham and Frant phosphates gave no special return, but applications of potash increased the crop. At Farnham lime is especially needed, and at Selling none of the mineral plant foods gave a marked result.

Experiments at Rothamsted on the changes in the composition of mangels during storage, N. H. J. MILLER (*Jour. Roy. Agr. Soc. England, 63 (1902), pp. 135–141*).—A paper reporting a second experiment on this subject (E. S. R., 13, p. 130). The tabulated data show that mangels stored from November to July lost 13 per cent of water, 21.1 per cent of dry matter, 22.7 per cent of organic matter, 21.7 per cent of sugar, 18.6 per cent of pentosans, 8.7 per cent of crude fiber, and 29.5 per cent of nitrogen. The loss in nitrogen was almost exclusively in nonproteids, but there was no indication of increased digestibility.

The author concludes that, apart from the loss in nitrates, there can be no material improvement in mangels when stored. The results indicate the possibility of loss in sugar and digestible proteids, without giving evidence of any actual increase in he latter constituent. Analyses made of a single root kept for 1 year show a loss of 87.5 per cent in sugar, 20 per cent in crude fiber, and 4.5 per cent in furfuroids. There was no loss in total nitrogen, but half of the digestible proteids changed to nonproteids, while the indigestible proteids remained essentially the same.

The continuous growth of mangels for 27 years on the same land, Barn Field, Rothamsted, A. D. HALL (*Jour. Roy. Agr. Soc. England, 63 (1902), pp. 27–59, figs. 9*).—This article has been noted from another source (E. S. R., 15, p. 465).

The lime content of oats on limed and unlimed soil, H. G. SÖDERBAUM (*K. Landt. Akad. Handl. och Tidskr., 42 (1903), pp. 108, 109; abs. in Centbl. Agr. Chem., 32 (1903), No. 12, p. 847*).—In pot experiments previously referred to (E. S. R., 14, p. 434) different phosphates were used with and without addition of varying amounts of lime, and it was found that in 8 out of 10 cases the lime content increased with the increase of the application of lime. As regards phosphoric acid the opposite effect was produced.

Potato variety and manurial trials, K. J. J. MACKENZIE (*Jour. Southeast. Agr. Col., Wye, 1903, No. 12, pp. 34–39*).—The results of cooperative tests with commercial fertilizers and barnyard manure were not very successful, but it is believed that small quantities of active commercial fertilizers applied with barnyard manure tend to increase the yield and improve the quality over the use of barnyard manure alone. Among 5 varieties in a test carried out in this connection Charles Fidler and Up-to-Date gave the best yields. Spraying apparently increased the yield per acre by about 1 ton.

[Sweet potatoes], F. G. SLY (*Dept. Agr., Central Provinces [India] Rpt. 1902–3, pp. 12, 13*).—In this report it is stated that trials were made of 15 varieties of sweet potatoes, 12 indigenous and 3 American. The American varieties proved much the best, producing large crops of excellent tubers. A large number of plants of American sorts have been distributed to cultivators in the provinces.

Culture tests with rye, 1899–1902, W. EDLER (*Arb. Deut. Landw. Gesell., 1903, No. 84, pp. 171, pls. 9*).—Cooperative culture tests were conducted for 3 years with 9 varieties of rye. The weather conditions of the seasons are described, abstracts from the reports of collaborators are given, and the results, including the yields of grain and straw and the weight per 1,000 grains, are reported. Brief descriptions are also given of growing plants of the different varieties in the plant nursery, of developing varieties, and of their resistance to winter weather and rust attacks.

Lochow Petkus rye gave the highest average yield of grain in dry as well as in wet seasons. North German Champagne rye, owing to its low water requirements, is considered suitable for dry soils. On the better soils and in wet years this variety gave smaller yields of grain than most of the sorts tested. Alt-Paleschken rye stood first in yield of straw. The heaviest weight per 1,000 grains was in favor of Lochow Petkus, while Heine Improved Zeeland showed the highest weight per liter. The stooling capacity was greatest in Probstei, North German Champagne, Walkenhaus, and Russian Giant Stem, and the length of straw in Alt-Paleschken, Schlanstedt, Russian Giant Stem, and Walkenhaus.

In thickness of stem, Schlanstedt, Heine Improved Zeeland, and Alt-Paleschken ranked above the others. Schlanstedt and Heine Improved Zeeland appeared to have the stiffest straw and North German Champagne the softest. It was found that North German Champagne ripened earliest, followed a little later by Pirna, Probstei, Walkenhaus, and Russian Giant Stem, and these were again followed by Lochow Petkus, Heine Improved Zeeland, and Alt-Paleschken, while Schlanstedt

ripened last. With reference to their winter resistance the varieties are ranked as follows: Alt-Paleschken, Probstei, North German Champagne, Russian Giant Stem, Walkenhaus, Pirna, Lochow Petkus, Schlanstedt, and Heine Improved Zeeland. The resistance to cold winters was below the average in the last 3 varieties. The experiments presented no data from which conclusions as to the resistance of the different varieties to lodging and rust could have been drawn.

Improvement of sugar cane by chemical selection (*Agr. News* [*Barbados*], *3* (*1904*), *No. 46, p. 19*).—An abstract is given of the main features of an investigation by J. D. Kobus on the subject of raising improved varieties of sugar cane by vegetative reproduction. It was observed that the amount of sugar in the individual stems of the same plant was likely to vary greatly. For the experiment in question plants exhibiting small variations were selected for propagation. The variability in the amount of sugar was greatest in thick-stemmed, older varieties, and least in young varieties recently selected from seed. The quantity of sugar in the cane varied directly with the weight of the same.

Heavy plants produced heavy offspring and the descendants of plants with a high sugar content were richer in sugar and heavier than unselected plants. Simple selections, however, of cuttings of heavy plants produced forms generally richer in sugar but not markedly so, and the progeny of heavy plants poor in sugar seem to contain a smaller quantity of this same substance than the progeny of light plants with a low sugar content. Local variations in soil, which was apparently quite uniform, gave rise to great differences between individual plants. It was discovered that the increased vigor of plants as reflected in the larger yield of sugar was accompanied by greater resistance to the sereh disease.

Wheat experiments, A. D. Hall (*Jour. Southeast. Agr. Col., Wye, 1903, No. 12, pp. 31–33*).—Cooperative tests with Square Head Master and Red Lammas were made on light loam with chalk subsoil, light sandy loam, and deep loam soils. In general the yield of grain was in favor of Square Head Master and the yield of straw in favor of Red Lammas, which gave a longer and finer straw, but lodged more frequently than the other variety. On the light loam with chalk subsoil Red Lammas also gave the greater yield. Red Fife, Preston, and Percy obtained from Canada and sown April 21 yielded 28 bu. 30 lbs., 24 bu. 25 lbs., and 20 bu. 21 lbs., respectively.

HORTICULTURE.

The culture substations, A. V. Stubenrauch (*California Sta. Rpt. 1902–3, pp. 161–194*).—A general account is given of the growth and productiveness of orchard fruits, small fruits, and nuts, including apples, pears, quinces, almonds, apricots, peaches, nectarines, plums, cherries, olives, figs, walnuts, persimmons, and grapes grown at the Foothill, Southern Coast Range, San Joaquin Valley, and Southern California substations. An account of the work with field crops is given elsewhere (p. 764).

Plums and apples at the Foothill Substation have done best on granite soil. On the hill lands at this station it appears to be essential to irrigate walnuts. At the Southern Coast Range Substation practically the whole of the second crop of grapes was destroyed by linnets which visited the station in immense flocks. A large number of apples were grown at the San Joaquin Valley Substation, but under the climatic conditions of the station none of these varieties kept well. The summer temperature appears to be far too high for these fruits. Many of the apples are burnt and shriveled on the trees before they reach maturity. Blight has been especially severe on pears at this station. Grapes yielded at the rate of 7 tons of fruit per acre. At the Southern California Substation pear blight is noted as making rapid inroads on the station pear orchard. Duchesse d'Angoulême has proved one of the best late

summer pears at the substation, and appears to be sufficiently resistant to blight to enable it to produce good crops during most of the season. A variety of fig known as "White Dattato" is considered the best white fig grown at the station. Nearly all varieties of grapes have done well at this substation.

Testing varieties of vegetables, C. H. Brewer (*Amer. Agr., 73 (1904), No. 6, p. 142*).—As a result of a test of a number of varieties of vegetables the author recommends Sparks Earliana tomato, New White Evergreen corn, and Stringless Green Pod, Brittle Wax, and Wardwell Wax beans.

Treating trees that have been injured by mice or rabbits, N. O. Booth (*New York State Sta. Rpt. 1902, pp. 401–404*).—This is a reprint of a circular issued by the station, and gives directions for treatment of trees that have been more or less seriously injured by the gnawing off of the bark by mice and rabbits. Methods of bridge grafting to overcome these injuries are described.

Irrigating oranges, A. J. Hutchinson (*Pacific Fruit World, 17 (1904), No. 18, pp. 4, 5*).—The author notes that under the influence of abundant irrigation the size of oranges is becoming larger, and the fruit coarser and inferior in quality. As a remedy for this he advises the application of water to the trees just at the time a new growth is starting out from the buds. By the application of a sufficient amount of water at this time the new growth can be carried to a good maturity and desirable length. If irrigation is delayed until after the growth has acquired considerable length, then that growth that has already started is merely lengthened without producing any more fruit-bearing wood.

Examination of sugar prunes (Burbank) from several localities, G. E. Colby (*California Sta. Rpt. 1902–3, pp. 90, 91*).—Analyses, chiefly with reference to size, percentage of flesh, pits, and total sugar content are given for a number of sugar prunes and other prunes grown in different localities in California. The sugar content of the sugar prunes in the fresh fruit varied from 13.7 to 20.53 per cent, and the average sugar content of California French prunes is given as 18.5 per cent. In the dried product the sugar content of the sugar prunes was found to be 49.5 to 50 per cent, and the maximum sugar content in dried French prunes 54 per cent.

Review of preliminary work at [Cranberry] experimental station, H. A. Ramsey (*Cranberry Grower, 2 (1904), No. 2, pp. 2, 3*).—Herewith is given a rather detailed account of the experimental plats and methods of treatment in the work on cranberry culture, carried out under the auspices of the University of Wisconsin. An experiment was made to determine the effect of stretching cheese cloth about 2 ft. above the vines for the prevention of blight. The cloth, however, was not put in place soon enough and some of the vines had already begun to blight. The berries continued to blight, however, under the cheese cloth, which seemed to indicate to the author that all blight is not caused by intense heat in the presence of water.

Tests are being made of 187 varieties which have thus far been originated, and continued efforts are being made to secure more valuable varieties by cross fertilizing.

Viticulture, E. H. Twight (*California Sta. Rpt. 1902–3, pp. 111–113*).—This is an outline of the viticultural work that is now being carried on under the auspices of the station. A number of experimental plats have been established in different parts of the State, chiefly for the purpose of determining the adaptation of phylloxera-resistant stocks to the different soils of California. Two plats established in cooperation with this Department will be used to determine questions of adaptation, but mainly for testing the affinity of vinifera scions to resistant stocks. It is reported that the phylloxera is spreading throughout California, and planters are urged to use only resistant stocks in setting out new vineyards.

Attention is called to the serious character of the Anaheim disease, which has been located in at least 3 important vine-growing districts. The use of cuttings from infected districts is condemned.

Home-grown grapes in winter, D. M. DUNNING (*Country Life in America, 5 (1904), No. 4, pp. 302–305, 318–321, figs. 10*).—Detailed directions are given for the construction and management of a small grapery in which to grow high-quality European grapes.

Coffee, vanilla, cacao, and tea, G. CORNAILLAC (*El café, la vainilla, el cacao y el té. Barcelona: Francisco Sabater, 1903, pp. 480, figs. 36*).—A treatise on the cultivation, preparation, exportation, commercial classification, expenses and returns obtained in the cultivation of these crops.

A treatise on cacao (Theobroma cacao), F. E. OLIVIERI (*Trinidad, British West Indies: Mole Bros., 1903, 3. ed., pp. 101, pls. 31, dgm. 1*).—The 20 chapters in this book deal with the various phases of the botany and culture of cacao, including an account of the insects and diseases affecting, fermentation, and the drying of the crop. In discussing the value of various shade trees in cacao culture, special attention is called to the value of the immortelles for this purpose.

Some experiments performed by Professor Carmody are noted, in which it is shown by chemical analyses that the dry flowers of the 50 immortelle trees on an acre furnished about 24 lbs. of nitrogen, while the 250 cacao trees, yielding 500 lbs. of pure cacao, contained but about 12½ lbs. of nitrogen per acre. Previous analyses by the same investigator (E. S. R., 13, p. 354) indicated that the amount of nitrogen in the flowers rapidly diminished. This, however, has been found to be influenced by the method of storing the samples, since when the flowers are spread out thinly instead of in heaps no loss of nitrogen was observed, even when freely exposed for several days to the air.

The objection sometimes made by planters to this tree because of the loss of leaves during the dry seasons is shown to be really an advantage, since with the decrease in number of leaves on the trees at this time there is a corresponding decrease in the amount of water evaporated from the soil.

Indian tea; its culture and manufacture, C. BALD (*Calcutta: Thacker, Spink & Co., 1903, pp. 291, pls. 9, figs. 7, dgm. 1*).—This work is intended as a text-book on the cultivation and manufacture of Indian tea. It gives in extended detail directions for the management of tea estates, including the operations of planting and manufacture, and also hints on buildings, machinery, forestry, accounts, etc. Various insects and diseases affecting tea are also noted, with suggestions as to methods for their control. The book is comprehensive, and appears to cover practically every phase of the subject, except the chemistry of tea and the history, bibliography, and statistics of tea.

The Landolphia of French Congo yielding caoutchouc (*Sci. Amer. Sup., 57 (1904), No. 1467, p. 23,511*).—This is an English translation of a paper by A. Chevalier, given before the French Academy of Science. It contains a botanical account and descriptions of the species of Landolphia in French Congo which yield caoutchouc.

Experiments with ether in the forcing of lilacs, K. RÄDE (*Möller's Deut. Gärt. Ztg., 19 (1904), No. 5, pp. 50–52, figs. 3*).—An account is given of the forcing of Charles X and Marie Legraye lilacs with and without etherization. Under like conditions of temperature the etherized lilacs come into bloom considerably earlier than the unetherized. The advantages of etherizing are briefly stated as follows: The time required to bring the plants into bloom is lessened; they can be forced at a lower temperature with less fuel, and consequently less expense; more leaves develop on the etherized plants, which may be desirable in some cases. In these experiments the temperature of the forcing room varied between 20 and 25° C. A temperature lower than 18 to 20° C. is not considered sufficiently high to give satisfactory results.

Forcing etherized plants, A. MAUMENÉ (*Jardin, 18 (1904), No. 407, pp. 42, 43*).—The details are given of several experiments in forcing lilacs, snowballs, and *Azalea mollis*. In every instance with all these plants those which had been sub-

jected to the fumes of ether started into growth earlier and came into bloom sooner than those which had not been etherized. The author calls attention, however, to the desirability of considering the climate, temperature, and season in forcing plants by means of ether. If the normal period of etherization be 48 hours, then early in the season etherization for 72 hours is advised, while later in the season etherization for 24 to 30 hours may suffice. With an increase of temperature also the length of time of etherization should be decreased.

The book of shrubs, G. GORDON (*London and New York: John Lane, 1903, pp. 83, pls. 14*).—This is the fifteenth of a series of Popular Handbooks of Practical Gardening, edited by Harry Roberts. Directions are given for the culture and use of a large number of deciduous flowering trees and shrubs, including many American shrubs, deciduous shrubs and trees with ornamental foliage, evergreens, conifers, and bamboos.

The book of herbs, ROSALIND NORTHCOTE (*London and New York: John Lane, 1903, pp. 212, pls. 18, fig. 1*).—This book is the twelfth of a series of Popular Handbooks of Practical Gardening, edited by Harry Roberts. Of the 212 pages in this book, but 12 are devoted to the culture of herbs, the remainder containing historical notes on the use of herbs in medicine, magic, decorations, heraldry, ornament, perfumes, etc. The book has very little value from an agricultural standpoint.

Pictorial practical fruit growing, W. P. WRIGHT (*London: Cassell & Co., Ltd., 1903, pp. 152, figs. 108*).—This book aims to teach pictorially the essential facts of fruit growing. Sufficient text is given to complete and make clear the illustrations and the cultural details necessary in growing all the common orchard and small fruits, nuts, melons, etc.

Pictorial practical gardening, W. P. WRIGHT (*London: Cassell & Co., Ltd., 1903, pp. 157, figs. 129*).—The purpose of this little book is to present in a concise manner by aid of apt illustrations, supplemented by a small amount of text, all of the essential features in the culture of flowers and the making of flower gardens; and to a more limited extent fruit and vegetable gardens and the growing of plants in greenhouses.

Pictorial practical bulb growing, W. P. and H. J. WRIGHT (*London: Cassell & Co., Ltd., 1903, pp. 152, figs. 45*).—This book contains in condensed form concise statements, supplemented by numerous illustrations, on the culture of bulbs, interpreting the word in its broadest sense. Preliminary chapters treat of the planting of bulbs in beds, borders, pots, glasses, vases and bowls, window boxes, woodlands, and grass. Following this are 46 chapters dealing with as many different flowers which are grown from bulbs. The pictures are the prominent part of the book and are intended to represent the essential facts in the handling and culture of bulbs.

Bulb growing in the State of Washington, S. W. FLETCHER (*Country Life in America, 5 (1904), No. 4, pp. 311–314, figs. 10*).—An account of the origin and development of the bulb-growing industry in the State of Washington. It is claimed that bulbs superior in quality to Holland bulbs can be grown in the vicinity of Puget Sound.

Bulb culture in the South Atlantic States, W. F. MASSEY (*Country Life in America, 5 (1904), No. 4, pp. 313, 314*).—An account is given of the development and present status of bulb culture in the South Atlantic States, more particularly east North Carolina. The author claims to have eradicated the Bermuda lily disease from his experimental fields. For a further account of the work see E. S. R., 14, p. 445.

Pictorial practical rose growing, W. P. WRIGHT (*London and New York: Cassell & Co., Ltd., 1902, pp. 152, pl. 1, figs. 87*).—This is a brief popular guide to the propagation, pruning, and general culture of roses both out of doors and under glass. Numerous illustrations are designed to take the place of much of the descriptive and detailed matter usually found in books of this sort.

Chrysanthemums and how to grow them, J. B. Wroe (*London: W. H. & L. Collingridge, pp. 86, pl. 1, figs. 12*).—Detailed directions are given for the growing of chrysanthemums for exhibition purposes, with descriptions of numerous varieties. An account is also given of the insects and diseases affecting chrysanthemums, with suggestions for their control, and in addition a table in which the time for starting cuttings of each of 349 varieties, methods of manuring, and other data are given.

The new Shasta daisies (*Pacific Rural Press, 67 (1904), No. 8, p. 113, figs. 2*).—Descriptions are given of two new Shasta daisies, the Alaska and the California, originated by Luther Burbank. The flowers of these varieties average from $4\frac{1}{2}$ to 5 in. across, and are borne on stems 2 to 3 ft. long. Each flower is composed of 38 to 42 wide petals with a very small disk. It is claimed that these flowers are perfectly hardy and will grow anywhere in the United States.

The improvement of home grounds, F. Cranefield (*Wisconsin Sta. Bul. 105, pp. 39, figs. 32*).—This is a popular discussion of the subject of beautifying home grounds, more especially those in the country. It treats of the desirability of massing shrubs and trees, and the necessity of a well thought-out design in planting about the home. A number of diagrams and figures are given showing proper and improper methods of planting.

How to make a flower garden (*New York: Doubleday, Page & Co., 1903, pp. 370, pls. 60, figs. 148*).—This book is made up of a collection of articles on annual and perennial flowers, shrubs, trees, vines, ferns, water gardens, window gardens, cold frames, hot beds, greenhouses, wild gardens, roses, etc., written by as many different authors. It is profusely illustrated; many of the articles and illustrations have previously appeared in *Country Life in America*. The appendix contains lists of flowers for special purposes and brief directions on how to grow 150 of the commonest and most desirable flowers.

The flower beautiful, C. M. Weed (*Boston and New York: Houghton, Mifflin & Co., 1903, pp. 138, pls. 17, figs. 41*).—This contains suggestions on the use of vases and like utensils in which to exhibit flowers for decorative purposes.

FORESTRY.

The university forestry stations (*California Sta. Rpt. 1902–3, pp. 195–201*).—A review is given of the condition of the forestry stations, and a criticism offered of the present method of carrying on these investigations. At present the funds are insufficient for the proper carrying on of the work, and the writer thinks that more money should be put at the disposal of these forestry stations in order that the work may be extended in various lines.

At the Santa Monica Station the principal investigations have been conducted with a view to planting a portion of the upper mesa, most of which was planted to species of eucalyptus, golden wattle, Catalina cherry, and Austrian pine. The results of the seed planting have not been very satisfactory, only a few of the pines and acacias coming up. A special effort was made to plant as large a portion of the plat to eucalypts as possible, in order to test the adaptability of various species to forest planting. The limited amount of available land made it impossible to plant more than a half acre of each variety, and it is hoped that from these plats more accurate and valuable data will be obtained than that hitherto secured, which was often based on a few individual trees. In planting these plats the operations were begun in November and continued throughout the winter, a few plants being set in February and March. The results as shown in the growth of the different lots of trees indicate that fall planting is best for coast regions where the winter temperatures do not fall below the freezing point.

A brief account is given of the distribution of more than 10,000 trees to various tree planters, the distribution being made under definite conditions laid down by the station.

At the Chico Forestry Station the principal investigations have been confined to setting out plantations of tanbark oak (*Quercus densiflora*) and cork oak (*Q. suber*). Four acres each of these varieties were planted with the acorns. In the case of the tanbark oak the acorns were placed in a sprouting bed before planting in the field and the ground was specially prepared for the reception of the young seedlings. A similar method was followed with the cork-oak acorns, but there was not time for the preliminary sprouting of them as they were received too late in the season.

The weather succeeding the planting was unfavorable to growth and germination, and in the case of the tanbark oaks only about 50 per cent germinated and grew for a few inches, after which many of the young seedlings perished. In the case of the cork oaks about 20 per cent of the acorns germinated, most of which remained alive. The results of these plantings show the difficulty of establishing plantations of oaks by seeding the open ground, and unless the season is exceptionally favorable either the surface of the soil should be mulched or the acorns sown under the protection of forest litter.

A comparison was made of the value of 1-year-old eucalyptus seedlings for transplanting as compared with those 4 months old. Practically all of the larger trees died, while 80 per cent of the smaller ones survived. The results obtained confirm the previous experiences in other portions of the State.

Southern forests twenty-five years ago and to-day, C. A. SCHENCK (*Tradesman, 50* (*1904*), *No. 9, pp. 75, 76, figs. 4*).—A review is given of the forest conditions in the Southern States, the status of 25 years ago being contrasted with that of the present time. The lumber output in the South has risen in that time from a value of $40,000,000 to $180,000,000 annually, with a corresponding increase in the capital invested. Attention is called to the necessity of rational methods of management to preserve this industry and at the same time develop the agricultural resources of the region.

Hawaiian forests, W. L. HALL (*Forestry and Irrig., 9* (*1903*), *No. 12, pp. 582–585, figs. 5*).—A description is given of the forests of the Hawaiian Islands, based upon recent observations of the author. Two distinct types of forest are recognized, one which occurs at sea level in the drier portions of the islands, and the other on the mountain slopes at elevations of 1,000 to 8,000 ft. The first type is valuable on account of the timber and other products which it yields; the second for its protective value. Much of the forest, which occurs near sea level, consists of algaroba or mesquite (*Prosopis juliflora*). The distribution and value of this species are commented upon and the character of the mountain forests described. Attention is called to the rapid decrease in the forest area, which is attributed largely to the grazing and tramping of cattle, and an outline is given of the proposed forest service which has been recently put in operation.

The commercial aspect of Australian forestry, E. T. SCAMMELL (*Queensland Agr. Jour., 13* (*1903*), *No. 6, pp. 577, 578*).—An abstract is given of an address by the author on the forest resources of Australia. According to the author, these comprise more than 107,000,000 acres of marketable timber. To this should be added 170,000,000 acres covered by inferior timber, which has a local value for building and general purposes. The commercial timbers of Australia are chiefly species of eucalyptus of which not less than 150 furnish valuable timber. Besides eucalyptus a number of other species are enumerated and their distribution and uses indicated.

The forests of Algeria in 1903, PERRIQUET (*Bul. Agr. Algérie et Tunisie, 9* (*1903*), *No. 23, pp. 521–527*).—A review is given of the forest condition of Algeria, the principal revenues of which are obtained from the timber and bark of the cork oak.

The destructive nature of forest fires, overgrazing, etc., is pointed out and the necessity for a better system of management is shown.

Tree planting in the midlands of Natal, T. R. SIM (*Agr. Jour. and Min. Rec. [Natal], 6 (1903), No. 20, pp. 729–734*).—In a publication noted elsewhere (E. S. R., 15, p. 588) the author has given descriptions of timber trees suitable for planting in this region, and the present paper is designed more for the planting of trees as ornamentals. It is said that trees desirable for timber production may be used for landscape planting, but many ornamental kinds have little or no economic value, and on this account it is seldom worth while attempting to combine timber production with scenic effect. In South Africa mixtures of fast-growing trees have usually proved failures, and the most successful timber plantations are those in which only one species is used.

Notes on the ornamental conifers in the lower Thames Valley, A. WORSLEY (*Jour. Roy. Hort. Soc. [London], 28 (1903), Nos. 1–2, pp. 107–111*).—Descriptions are given of a number of ornamental exotic conifers that have been planted in the lower Thames Valley, and notes are given on their relative hardiness and adaptability to different systems of planting.

Forestry, W. SCHLICH (*Agr. Students' Gaz., n. ser., 11 (1903), No. 5, pp. 131–142*).—In a lecture delivered by the author a review is given of the forestry situation of Great Britain, the sources of its present timber supply, and the steps to be taken to restore British forestry. It is said that 30 per cent of the land in Great Britain and Ireland is either entirely lying waste or used for rough grazing. Much of this is adapted to forestry, and the author believes that with proper attention it could be advantageously restocked.

Experience in Saxony in forest management is cited, and some of the problems to be considered are outlined. The average annual production, cost of planting, value of soils for forestry, etc., are discussed, after which the author states that for economic forestry in Great Britain ash, sycamore, and oak should be planted on lands which are adapted to them, and Scotch and Corsican pine and spruce with some larch on other lands. On very wet lands poplar will probably be found to be the most remunerative.

The exploitation and management of forests, P. MOUILLEFERT (*Exploitation et aménagement des bois. Paris: Félix Alcan, 1904, pp. 476, pls. 10, figs. 97*).—This is the second of a series of books by the author on sylviculture, and treats of the exploitation and management of forests. After discussing the general laws of tree growth the subject of forest exploitation is taken up and the different kinds of pure and mixed forests are described, suggestions being given for their continued propagation and exploitation. Chapters are given on the uses of forest products and a special chapter is devoted to truffles and truffle culture. In the second part of the work forest statistics are given and comparisons drawn between the different systems of forest management.

Forest reserves for public benefit, G. PINCHOT (*Water and Forest, 3 (1904), No. 4, pp. 14, 15*).—In an open letter the author defines the attitude of the Government toward forest reserves, and seeks to remove much of the current misunderstanding regarding the object and effect of forest reserves.

Investigations regarding the root development of trees, A. ENGLER (*Mitt. Schweiz. Centralanst. Forst. Versuchsw., 7 (1903), pp. 274–317; abs. in Forestry Quart., 2 (1903), No. 1, pp. 34, 35*).—Investigations are reported on the periodicity of the annual growth of different species of trees, the root activity beginning some time before bud development. An exception is noted in the case of larch, which makes its early transplanting in the spring or late fall planting necessary. The most vigorous root growth noted was made in June and July, followed by a decline in August, after which there was in October and November a second period of active growth,

which was somewhat less vigorous than the summer growth. The length of the two active periods varied with different species and climate, and the period of summer rest varied from 3 to 8 weeks. The period of maximum root growth coincided with that of maximum shoot growth. In the fall and winter the temperature of the soil was found to influence growth, all growth ceasing at from 5 to 6° C. for beech and 2 to 3° C. for maple.

Attention is called to the practical bearing of these investigations on the time of transplanting. For the most successful efforts in this line, trees should be transplanted shortly after root growth is most active. Deciduous trees can be planted in autumn with more satisfaction than conifers, because their root activity lasts longer and the demand for water at the top ceases sooner.

A nitrogen-gatherer among trees (*Norsk Landmandsblad, 22 (1903), No. 18, pp. 231–233*).—An account is given of the activity of the Danish Heather Improvement Society in planting trees on the barren sandy stretches on the western coast of Jutland. It has been found that spruce will make an excellent growth on these waste areas in the immediate vicinity of mountain pine, even if the soil is practically free from food materials. The root system of the spruce trees has only a poor development to the side where there is no mountain pine, while to the side where such a tree stands, a strong root system is developed that intertwines with the roots of the pine, often coming in immediate contact with these.

There appears to exist a symbiotic relation between these two kinds of trees, which is of mutual benefit to both. If the pine is cut down while the spruce is still young, the latter will die or make a sickly growth; if, on the other hand, it is not cut until after several years, the spruce will not only survive but appears to grow faster than would have been the case if the pine had been left standing. Planting these two trees together has come to be a general practice of the Society. There is no direct experimental evidence presented in explanation of these phenomena, but it is stated as the result of investigations by many scientists that the mountain pine is a nitrogen-gatherer and can utilize the free atmospheric nitrogen, even when growing in places where practically no supply of nitrogen can be obtained from the soil itself.—F. W. WOLL.

The effects of frost upon forest vegetation, R. G. ZON (*Forestry Quart., 2 (1903), No. 1, pp. 14–21*).—A discussion is given of the effects of early and late frosts upon forest vegetation, and the manner in which the young growth is affected is described. The effect of winter frosts is also shown, and various preventive measures like drainage, planting, etc., are described.

Forest protection and extension, M. MANSON (*Water and Forest, 3 (1904), No. 4, p. 7*).—An outline plan is given for forest protection and extension, the first of which consists of fire protection, the second of tree planting. For fire protection the author thinks that a study should be made of forest fires, and that all areas liable to injury should be mapped and patrolled for their protection. In regard to tree planting, the author believes that conifers offer the most promising field for investigation and suggests methods for collecting and planting their seed.

Forest fires in the Adirondacks, A. KNECHTEL (*Forestry Quart., 2 (1903), No. 1, pp. 2–13*).—A discussion is given of the causes of forest fires, means of controlling them, the condition in which the forest is left after a fire, and the vegetation that may spring up over the burned areas. The chief periods of forest fires in this region are April and May, and September and October. The causes of fires are quite numerous, all of which are discussed.

In the Adirondacks the beech and hard maple are the most resistant to fire, while birch, on account of its loose bark, suffers severely. Hemlock and spruce are badly injured, and white pine, although somewhat resistant, is more easily injured than the hard woods. The burned-over areas of State lands are described and attention

called to the fact that under the present law the timber can not be removed, but remains to ultimately fall to the ground and serves to add fuel to future fires.

Winter logging, R. V. R. Reynolds (*Forestry and Irrig., 10 (1904), No. 1, pp. 20–29, figs. 8*).—A popular description is given of the methods pursued in some of the larger logging camps in the Northwest.

American Forestry Association (*Forestry and Irrig., 10 (1904), No. 1, pp. 12–19*).—An account of the twenty-second annual meeting of this association, held in Washington, D. C., December 9, 1903. In the director's report which was submitted to the association, a review is given of the forestry situation in this country, and the work of the Bureau of Forestry and General Land Office of the Federal Government and of various States in forest investigations are briefly described.

DISEASES OF PLANTS.

Some diseases of cultivated plants, F. Corboz (*Bul. Soc. Vaud. Agr. et Vit., Lausanne, 1903, No. 165, pp. 407–412*).—A brief description is given of a number of mildews of cultivated plants, particular attention being paid to those belonging to the genus Peronospora. For the prevention of these the author recommends the thorough use of Bordeaux mixture. Notes are also given on smuts of cereals, for the prevention of which treating the seed with strong solutions of copper sulphate or subjecting to water heated to a temperature of 50 to 55° C. is recommended.

Cultures of the Uredineæ in 1903, J. C. Arthur (*Jour. Mycol., 10 (1904), No. 69, pp. 8–21*).—This report is in continuation of a series upon cultures of plant rusts, and embraces experiments which were inaugurated in 1899. During the season covered by the report 68 collections of materials were employed. Out of these a large number refused to germinate. As in the previous years, success was attained only when reciprocal inoculations were made between plants whose proximity to one another in the field gave definite clues to their possible relationship. A detailed report is given of the different experiments, and in conclusion a list is given of 5 species which have been previously reported and 8 whose different host plants are reported for the first time.

Index to uredineous culture experiments, with list of species and hosts for North America, I, W. A. Kellerman (*Jour. Mycol., 10 (1904), No. 69, pp. 26–45*).—An alphabetical index is given in which the host plants of a number of rusts are shown, together with the name of the author having made the culture experiments.

Potato spraying experiments in 1903, F. C. Stewart, H. J. Eustace, and F. A. Sirrine (*New York State Sta. Bul. 241, pp. 251–292, pls. 12*).—An account is given of the spraying experiments conducted under the 10-year spraying investigations, the plan of which was outlined in a previous bulletin (E. S. R., 14, p. 875). These experiments were conducted at the experiment station at Geneva and at Riverhead, Long Island, the efficiency of a different number of applications being compared. In addition, cooperative experiments were conducted with 6 farmers in different parts of the State, to determine the net profit in spraying potatoes under ordinary farm conditions. The fungicide used was Bordeaux mixture, and to prevent serious injury by leaf hoppers and potato bugs Paris green or a solution of white arsenic was added to the fungicide used in some of the sprayings. Comparisons were made between 3 applications during the growing season and spraying every 2 weeks.

At the experiment station, as well as other points where the experiments were conducted, there was little injury from the early blight, but the late blight, *Phytophthora infestans*, proved quite destructive. The effect of the spraying was markedly shown by the prolonged growing season of the treated plants, and when harvested it was found that the yields were increased in proportion to the number of applications

given the vines. At the station 3 sprayings increased the yield 88 bu. per acre and 5 sprayings 188 bu. per acre. On Long Island the increased yield due to 3 sprayings was 39.5 bu. per acre, and when 5 applications were given the vines the increase was 56 bu. per acre.

As in the previous year's investigations, the chemical analyses of the tubers from sprayed plants showed that they contained a larger percentage of dry matter, mostly starch, than the unsprayed potatoes.

The object of the cooperative experiments was to overcome the objection often made that experiments as conducted by the station do not give results that could be obtained in ordinary farm practice.

In these six cooperative trials 61.166 acres were sprayed. With a single exception, every one of the experiments proved highly successful, and the total increase with the 6 experiments was 3,746 bu., or an average of 61.24 bu. per acre. This increase was worth $1,873, and subtracting from this amount the total expense of spraying, $296.49, there is a remainder left of $1,576 51, or a net profit of $25.77 per acre, to be attributed to spraying under farm conditions. The details of all experiments are given.

Should potato growers spray? II, F. H. Hall et al. (*New York State Sta. Bul. 241, popular ed., pp. 12, figs. 2*).—A popular summary of the above bulletin.

Proof of the identity of Phoma and Phyllosticta on the sugar beet, G. G. Hedgcock (*Jour. Mycol., 10 (1904), No. 69, pp. 2, 3; abs. in Science, n. ser., 19 (1904), No. 474, p. 172*).—It has long been suspected that an intimate relation existed between the leaf blight and root-rot of sugar beets, but so far no cultural proof has been offered to show their identity. The author reports a large number of cultures from sugar beets decaying with a typical black crown rot caused by Phoma, and from the peculiar concentric brown leaf spots produced by Phyllosticta.

In all, about 50 cultures were made and no important differences could be determined between the organisms in the different sets. For the purpose of proving the identity of the fungi, sugar beets were grown in the greenhouse and inoculated with the 2 organisms, control plants being main ined, and from both sets leaf spots bearing mature pycnidia were taken, the fungus isolated, and pure cultures made with the same results as before. Beets whose roots were sound and healthy but whose leaves were diseased were placed in a moist silo, and in a month or so the petioles had become decayed and the crowns affected with all the characters of the typical Phoma rot.

The work reported indicates that in the case of the beet there is only one species of fungus producing these 2 diseases, and according to priority of generic names, the organism should be placed in the genus Phoma. It seems probable that the various species described upon sugar beets, garden beets, and mangels are identical.

A note on Rhizoctonia, G. G. Hedgcock (*Science, n. ser., 19 (1904), No. 476, p. 268*).—According to the author, the bean crop in the vicinity of St. Louis was severely injured during the past year by the fungus Rhizoctonia, which not only attacked the stems and larger leaves of the plants, but produced brown, sunken areas on the surface of the pods, penetrating the latter and discoloring the seeds.

Examination of a number of seeds whose surface was discolored disclosed the fact that the mycelium of the fungus had established itself in the seed coat and in many instances had formed minute sclerotia without rotting the seed or penetrating the cotyledons. Pure cultures of the fungus were easily obtained from such seeds and the presence of the organism did not in any way prevent the germination of the seed. From this it follows that the seed may be a common means of disseminating the disease, and on that account discolored beans should not be planted.

Apple black spot, J. Hamilton (*Queensland Agr. Jour., 13 (1903), No. 6, p. [illegible]*).—A brief account is given of experiments in spraying apple trees for the prevention of black spot. Perfect success is said to have followed the thorough spraying of the

trees with a solution composed of copper sulphate 4 lbs., alum 2 lbs., lime 3 lbs., and water 30 gals. Directions for the preparation and application of this fungicide are given.

Some diseases of coffee, A. L. HERRERA (*Com. Parasit. Agr. [Mexico], Circ. 1, pp. 8, fig. 1*).—Notes are given on the diseases of coffee caused by *Stilbum flavidum* and *Sphærella coffeicola,* the former of which is said to cause great damage to coffee plantations. The thorough use of Bordeaux mixture is recommended as a preventive measure, and extensive experiments are being inaugurated to thoroughly test the efficiency of this treatment.

The use of copper fungicides and the quality of the copper sulphate (*Chron. Agr. Canton Vaud, 16 (1903), No. 21, pp. 597–599*).—Attention is called to the great variation in the quality of the copper sulphate supplied by the markets in 1903 and the consequent variation of the results obtained when applications were made for the control of fungus diseases. In order to secure the best results, it is claimed that some attention should be paid to the quality of the chemicals used and that a Federal control should be established for the guaranty of the purity of such products.

ENTOMOLOGY

Proceedings of the Entomological Society of Washington (*Proc. Ent. Soc. Washington, 6 (1904), No. 1, pp. 60, figs. 4*).—At the meetings of the society the following papers were presented:

The Occurrence of the Earwig-fly, *Merope tuber,* H. S. Barber; Branched Hairs of Hymenoptera, and An Orthopterous Leaf-roller, by A. N. Caudell; The Genera of the Dipterous Family Empididæ, and A Brief History of North American Dipterology, by D. W. Coquillett; An Insect-collecting Trip to British Columbia, by R. P. Currie; Description of the Larva of *Ethmia zelleriella,* Description of the Larva of *Litodonta hydromeli,* Note on the Distribution of the Red Forms of Diacrisia, A Lepidopteron Parasitic upon Fulgoridæ in Japan (*Epipyrops nawai,* n. sp.), *Halesidota maculata* and Its Varieties, The Larvæ of the Mosquitoes *Megarhinus rutilus* and *M. portoricensis,* Notes on the Mosquitoes of British Columbia, A New Variety of the Noctuid *Exyra semicrocea* (*Exyra semicrocea hubbardiana,* n. var.), and A New Genus and Species of Tortricidæ, by H. G. Dyar; Remarks on the Genitalia of *Podisus cynicus* and *P. bracteatus,* by O. Heidemann; The Cotton-boll Weevil in Cuba (*Anthonomus grandis*), by E. A. Schwarz.

In the last-named paper the author reports his experience in studying the cotton-boll weevil in Cuba. First it was suspected that this insect might have some native food plants other than cotton. It was impossible, however, to find the weevil upon any plants except cotton. It was found feeding upon "loose cotton" (*Gossypium brasiliense*), and upon "kidney cotton." The weevil is not especially common upon or injurious to either one of these species, but the evidence obtained by the author indicates that the "kidney cotton" is the original food plant of the cotton-boll weevil, and the author believes that this insect has no other food plant than species of cotton. No parasites of the cotton-boll weevil were found in Cuba.

Report of the entomologist, G. W. HERRICK (*Mississippi Sta. Rpt. 1903, pp. 24, 25*).—Brief notes on insects injurious to pecans, peach-tree borer, Colorado potato beetle, harlequin cabbage bug, San José scale, pine-leaf beetle, fall webworm, and chicken mite.

Entomology, C. W. WOODWORTH (*California Sta. Rpt. 1902–3, pp. 104–110*).—A brief review is given of the entomological work of the station for the period 1901–3. Abstracts are given of the bulletins published during this time. Special attention is called to the work in combating grasshoppers and red spiders, in studying the subjects of peach-tree borers, fumigation, California distillates, etc., and mosquitoes.

The injury due to codling moth has apparently increased during recent years and methods for combating this insect will be investigated.

Injurious insects of 1903, F. L. WASHBURN (*8. Ann. Rpt. State Ent. Minnesota, 1903, pp. XVI + 184, pl. 1, figs. 119*).—A general account is given of the insects which proved to be specially injurious in Minnesota during the year 1903. The author obtained evidence which he considers as proving that there are 2 annual broods of the Hessian fly in Minnesota. In combating this insect the author recommends the usual remedies.

An outbreak of chinch bugs occurred in Stearns County and caused considerable damage. In controlling this pest it is recommended that rubbish be cleaned up and burned and that millet be planted in a narrow strip around cornfields in order to protect the corn. It is also suggested that corn be planted only at some distance from wheat and barley. Notes are given on injuries from grasshoppers, together with a copy of a law passed by the Minnesota legislature regarding the destruction of grasshoppers. A test was made of the Criddle mixture in poisoning grasshoppers, with fairly satisfactory results. Some farmers who have used this mixture report success, while others failed to see any good results from its use.

Notes are also given on the quality of Paris green sold in Minnesota and on a large number of insects injurious to orchards and nurseries. These insects are arranged according to a key for identification, based largely on a scheme proposed by W. Lochhead. The chief features of the inspection laws of various States are mentioned and notes are given on grain plant lice, squash bugs, cutworms, potato beetles, cockroaches, ants, carpet beetles, granary insects, etc. Formulas are also presented for the preparation of the more important insecticides and fungicides.

The monthly bulletin of the Division of Zoology, H. A. SURFACE (*Pennsylvania State Dept. Agr., Mo. Bul. Div. Zool., 1 (1904), No. 10, pp. 32, pls. 2*).—Brief notes are given on remedies for the control of San José scale and other injurious insects and plant diseases, together with an account of lime-sulphur-soda wash, and notes on the economic value of birds.

Some entomological notes, F. F. CREVECŒUR (*Ent. News, 14 (1903), No. 2, pp. 47–50*).—Notes are given on the prevalence and distribution of insects in Kansas. The author states that his collection of insects has suffered greatly from the attacks of museum pests. After trying many remedies for these pests the best success was had in fumigation with hydrocyanic-acid gas. The pest which caused most trouble was *Trogoderma tarsale.*

Agricultural pests in the Government of Tomsk in 1902, V. SOLDATOV (*Selsk. Khoz. i Lyesov., 211 (1903), Dec., pp. 600–644*).—The author discusses the influence of rainfall and other climatic conditions upon the prevalence of injurious insects. The insects to which most attention was given in these studies were locusts and various species of cutworms and related Lepidoptera.

The enemies of agriculture, A. L. HERRERA (*Las plagas de la Agricultura. Mexico: Ministerio de Fomento, 1902, pp. 627–705, figs. 27*).—This number completes the author's handbook on the subject of insect and fungus enemies of agriculture, and includes a discussion of the enemies of tobacco, grapes, and rice.

Insect pests of coffee in South India, H. M. LEFROY (*Dept. Agr. India Bul. 2, pp. 19*).—The chief insect pests of coffee in India belong to the family Coccidæ. Some of these pests injure the shade trees of coffee while others attack the coffee plant directly. Among the insects injurious to shade trees of coffee, mention is made of *Pulvinaria psidii, Lecanium imbricans,* and *L. expansum.* The pests of coffee to which chief attention is given are mealy bug, *Lecanium hemisphæricum, L. viride, Xylotrechus quadripes,* and *Zeuzera coffeæ.* Formulas are given for the preparation of kerosene emulsion, resin wash, tobacco and soap washes, and a mixture of lime and sulphur.

A bibliography relating to insects injurious to bark, A. L. Herrera (*Bol. Com. Par. Agr., 2 (1903), No. 3, pp. 104–114*).—The list of articles relating to the subject is largely compiled from *Insect Life* and the entomological bibliographies published by this Department.

The Coccidæ of Ohio, F. M. Webster (*Ent. News, 14 (1903), No. 9, pp. 288–290*).—Brief notes on the species of bark lice thus far described in Ohio, with special mention of the occurrence and distribution of *Eulecanium quercitronis*, *E. fletcheri*, San José scale, and *Aspidiotus ostreæformis*.

The life history of the scale insects of middle and northern Europe, L. Reh (*Allg. Ztschr. Ent., 8 (1903), Nos. 16–17, pp. 301–308; 18–19, pp. 351–356; 20–21, pp. 407–419; 22–24, pp. 457–469*).—This article is in the nature of a monograph of the various species of Coccidæ found in middle and northern Europe. These belong to various genera, including Dactylopius, Orthezia, Kermes, Lecanium, Pulvinaria, Aspidiotus, etc.

Proceedings of the Boll-Weevil Convention in New Orleans (*New Orleans: Bureau Agr. and Immig., 1903, pp. 91*).—A convention for the consideration of the boll-weevil problem was called by Gov. W. W. Heard, and held sessions in New Orleans, November 30 and December 1, 1903. At these meetings a number of speakers took an active part in the discussion, and various papers were presented on different aspects of the boll-weevil problem. The distribution and general economic aspects of the question were discussed by A. Brittin and C. Schuler. J. H. Connell spoke on the prospects of the cooperation of this Department in combating the boll weevil. An account was also given of the spread of the insect and the difficulties to contend with in exterminating it.

W. D. Hunter referred to the work which has already been done by this Department in fighting the boll weevil in Texas. The speaker stated his opinion as being that extermination of this insect is impossible. Attention should be directed to keeping the pest in check by means of proper rotation of crops and cultural methods. The problem of protecting Louisiana against invasion by the boll weevil was discussed by H. A. Morgan. Attention was called to the importance of the fact that in the United States cotton is the only known food plant of the boll weevil. This fact may be made use of in a system of rotation for preventing invasion by the pest. The habits of the insect were described in detail for the purpose of illustrating feasible methods of eradication.

S. A. Knapp referred to the interest manifested by the Secretary of Agriculture in checking the ravages of the boll weevil, and outlined the methods of procedure which have been adopted on demonstration farms. The speaker stated that the results obtained on such farms have been so satisfactory as to induce many other farmers to put the same methods in practice. The legality and constitutionality of proposed legislation for preventing the spread of the boll weevil from Texas into Louisiana were discussed by J. C. Pugh and W. Guion.

The morning session of December 1 was devoted largely to a discussion of the economic importance of the cotton-boll weevil to various commercial interests. The planters' interest in combating the boll weevil was discussed by F. P. Stubbs; the merchants' interest, by J. M. Parker; the bankers' interest, by S. M. Lawrason, and the oil mills' interest, by S. P. Sullivan. The speakers described the injurious effects of the unrestricted spread of the boll weevil upon the development of the various industries.

F. M. Muller read a paper on Birds in their Relation to the Boll Weevil. In this paper attention was called to the importance of birds in controlling the injurious insects and the necessity of protecting the most beneficial birds. Resolutions were adopted calling upon the farmers to exercise unusual precaution in preventing the importation of the boll weevil, urging cordial cooperation with this Department, and

deprecating sensational or unauthorized reports regarding the occurrence of the boll weevil in any new localities. Committees were appointed to investigate the subjects of boll-weevil legislation and bird legislation.

The Mexican cotton-boll weevil, L. O. HOWARD (*Amer. Mo. Rev. of Reviews, 29 (1904), No. 169, pp. 188-191, figs. 4*).—An outline is given of the economic importance of the pest, its habits, life history, and ravages in Texas, and the work of this Department and the State of Texas in combating it. Considerable advantage has been found in the cultivation of an early crop of cotton from northern seed and grown in rows farther apart than has heretofore been the custom. In the author's opinion it will be impossible to stop the distribution of the pest into various parts of the country where cotton is grown, but the hope is expressed that its ravages may be largely controlled by proper insecticide and cultural methods.

The cotton-boll worm (Heliothis armigera), F. SHERMAN, Jr., (*North Carolina Dept. Agr., Ent. Circ. 2, pp. 6, fig. 1*).—Notes on the habits, life history, injuries, and means of combating this species.

The Hessian fly, F. SHERMAN, Jr. (*North Carolina Dept. Agr., Ent. Circ. 1, pp. 4, fig. 1*).—In North Carolina there are said to be 2 complete annual generations of this insect. The remedies recommended consist in late planting, burning or plowing under the stubble, and the use of a trap crop of early wheat.

Locusts and grasshoppers, W. W. FROGGATT (*Agr. Gaz. New South Wales, 14 (1903), No. 11, pp. 1102–1110, pl. 1*).—Descriptive and economic notes on a number of locusts belonging to the genera Locusta, Acridium, Cyrtacanthacris, etc.

The present condition of the San José scale in Ontario, W. LOCHHEAD (*Ontario Agr. Col. and Expt. Farm Bul. 133, pp. 8, figs. 5*).—This pest first appeared in Ontario about 7 years ago and has been fought assiduously with the result that the problem of controlling it appears simpler at the present time than ever before. Good results have been obtained from the use of various insecticides, and the author recommends these insecticides in the following order of effectiveness: Lime-sulphur-salt mixture, crude petroleum, crude petroleum and whale-oil soap emulsion, whale-oil soap solution, carbolic wash. While these remedies are all effective they are not all equally inexpensive. The whale-oil soap solution proved to be too expensive for large orchards. The lime-sulphur-salt solution apparently killed all the San José scale and was also effective against scurfy bark-louse and oyster-shell bark-louse. Two preparations of carbolic wash were used, one for winter and one for summer applications. This wash appears to be valuable in controlling the plant lice on apple, plum, cherry trees, and also as a fungicide in the control of peach-leaf curl, apple scab, brown rot of plums, etc.

Orchard studies.—XIV. The lime-sulphur wash, W. B. ALWOOD and J. L. PHILLIPS (*Virginia Sta. Bul. 141, pp. 215–246, figs. 17*).—The various formulas recommended by different investigators for the preparation of the lime-sulphur-salt wash are presented in tabular form. From a study of these tables it appears that in 100 gal. of the mixture the quantity of lime varies from 15 to 66 lbs., sulphur from 15 to 33 lbs., and salt from 16 to 25 lbs., while the time of boiling varies from 40 minutes to 3 hours. The authors attempted to determine the chemical composition of the compound for the purpose of reducing the system of its preparation to a definite chemical basis.

The objections raised by horticulturists against the use of this insecticide are that so much apparatus is required in its preparation and that the length of time required for boiling it is so long. In the first experiments made by the authors the formula used was as follows: 50 lbs. lime, 50 lbs. sulphur, and 12½ lbs. salt per 100 gal. of water. Several modifications of this formula were also tested and the period of boiling was varied to considerable extent. Tests were made of the specific gravity of mixtures of various strengths; during these experiments it was found that the

specific gravity varied from 1.001 to 1.071. A formula containing 25 lbs. lime, 20 lbs. sulphur, and 2½ lbs. sulphate of copper per 100 gal. water gave excellent results. As a result of these tests and other experiments with this mixture the author recommends in general the following formula: Lime 30 lbs., sulphur 30 lbs., salt 10 lbs., water 100 gal. As a winter wash the author recommends 2 treatments, one in November or December and the other in February or March.

Experiments were also made in applying this mixture to the trunks and branches of trees in July, August, and September. As a result of these experiments the author recommends lime-sulphur wash as a summer treatment for apple trees, and believes that it may prove safe for peach and other fruit trees.

Lime, sulphur, and salt wash for San José scale, F. SHERMAN, Jr. (*North Carolina Dept. Agr., Ent. Circ. 5, pp. 8*).—Brief notes are given on the formulas used in the preparation of this insecticide, extent of the application of the wash in North Carolina, and directions for preparing and applying it.

Some recent spraying experiments, W. M. SCOTT (*Proc. Georgia State Hort. Soc., 27 (1903), pp. 86–97, figs. 4*).—Notes on the application and effectiveness of lime-sulphur-salt wash as a winter and spring spray, and also of the lime-sulphur-bluestone wash. Notes are also presented on the value of these washes and Bordeaux mixture in the control of peach-leaf curl.

The codling moth, J. LANG (*Jour. Dept. Agr. Victoria, 2 (1903), No. 1, pp. 58–60*).—According to the author's experience there are 2 broods of the codling moth per annum in Australia. The author calls attention to the necessity of clean cultivation and destruction of rubbish in combating this insect, and recommends spraying with Paris green at the rate of 1 lb. to 160 gal. of water to which 6 lbs. of lime have been added.

Pigs for the destruction of codling moth larvæ, J. BRODERICK (*Agr. Gaz. New South Wales, 14 (1903), No. 11, p. 1077*).—The author reports excellent results in the destruction of the larvæ of the codling moth and the prevention of injury from this insect by allowing pigs to remain in the orchard during the whole season.

The round-headed apple-tree borer, F. SHERMAN, Jr. (*North Carolina Dept. Agr., Ent. Circ. 3, pp. 5, fig. 1*).—In combating this species the author recommends digging out the larvæ, mounding the trees, and using certain protective devices, bands, etc.

Notes on the early stages of Corylophodes marginicollis, A. W. MORRILL (*Ent. News, 14 (1903), No. 5, pp. 135–138, pl. 1*).—This insect is reported as occurring on the leaves of horse-chestnut trees. The larvæ and adults were found feeding upon a fungus which grows on the under side of horse-chestnut tree leaves and which was identified as *Uncinula flexuosa*. The insect is described in its various stages and brief notes are given on its distribution.

The resin-gnat Diplosis and three of its parasites, LIDA S. ECKEL (*Ent. News, 14 (1903), No. 9, pp. 279–284, pl. 1*).—Pine trees in the vicinity of Woods Hole are said to be extensively infested with *Diplosis resinicola*. The habits of this insect are mentioned and a description is given of the insect in its various stages. Notes are also given on 3 parasites of this insect, including a form which is described as a new species under the name *Syntasis diplosidis*.

A subterranean root-infesting fulgorid, H. OSBORN (*Ohio Nat., 4 (1903), No. 2, pp. 42–44*).—The author describes as new under the name *Myndus radicis* a species of Fulgoridæ found upon the roots of several kinds of plants, including grasses. Notes are given on the habits of this insect and upon its possible economic importance.

Contributions to the life history of Gelechia nanella from an economic point of view, J. T. HOUGHTON (*Ent. Mo. Mag., 2. ser., 15 (1903), No. 165, pp. 219–221*).—The larvæ of this insect were observed mining in the leaves of apricots and boring into the leaf buds. The burrows thus produced were lined with silk. The species

usually infests pear trees, but was observed on apricots, peaches, cherries, plum, and apple trees. The insect is described in its various stages.

The dorsal glands of the larvæ of Heteroptera, J. Gulde (*Ber. Senckenberg. Naturf. Gesell. 1902, pp. 85–132, pls. 2*).—A large number of species are considered in this study and the anatomical structure and function of the dorsal glands in these different species are studied in a comparative manner. These glands are believed to serve the same function as the dermal glands in cockroaches and the defensive glands of myriapods.

The light organs of native Lampyridæ, J. Bongardt (*Ztschr. Wiss. Zool., 75 (1903), No. 1, pp. 1–45, pls. 3, figs. 4*).—The author made a detailed study of the anatomy and physiology of the phosphorescent organs in insects of the family Lampyridæ, especially *Lampyris noctiluca*. The light organs were removed and subjected to the action of drying, heat, and various gases. It was found that these organs continued to emit light for periods of several days, even when subjected to the influence of inert gases, such as carbon dioxid and hydrogen. The luminosity of the organs, however, soon ceased when these gases were passed over in a constant stream. It is concluded therefore that the cessation of the production of light is not due to the influence of the inert gas of itself, but to the action of the gas in motion.

Urticating larval hairs, E. A. Cockayne (*Entomologist, 36 (1903), No. 483, pp. 201–203*).—A brief reference is made to a considerable number of species of Lepidoptera in which the larvæ bear stinging hairs.

The plum webbing sawfly, H. T. Fernald (*Ent. News, 14 (1903), No. 9, pp. 298–302*).—Notes are given on the habits and life history of *Lyda rufipes* and the insect is described in its various stages. The hibernating larvæ pupate in March below the roots of grasses. The length of the feeding period is from 26 to 30 days. This insect has thus far not occurred in large numbers about Amherst, but it is believed that should it become abundant it would cause considerable damage to plum trees.

Destruction of the winter eggs of phylloxera by means of lysol, G. Cantin (*Jour. Agr. Prat., n. ser., 7 (1904), No. 4, pp. 127, 128*).—The author reports excellent results in the destruction of phylloxera from the use of lysol. This remedy was applied to the trunks of grapes in a 4 or 5 per cent solution. Grapevines thus treated bore good crops of fruit, while control vines situated under the same conditions died within a season or two.

A new oak-tree pest, C. P. Lounsbury (*Agr. Jour. Cape Good Hope, 23 (1903), No. 6, pp. 655–658, pl. 1*).—The author describes *Phylloxera corticalis* as a new pest of oaks in South Africa, where the number of insect pests of the oak is exceedingly limited. This fact is apparently due to the introduction of seed for raising oaks, thus preventing the simultaneous introduction of oak pests. The species described in the article is considered perhaps the most injurious of the oak pests of South Africa. In some instances it almost entirely covers the bark and causes the weakening or destruction of the trees. Among the natural enemies of this pest the author mentions a ladybug (*Exochomus nigromaculatus*).

A knowledge of certain forms of Pieris napi, F. Wagner (*Verhandl. K. K. Zool. Bot. Gesell. Wien, 53 (1903), No. 3–4, pp. 174–178, pl. 1*).—Notes are given on the variations in color pattern observed in the males and females of *Pieris napi*, especially in forms usually referred to as *sulphurea* and *sulphureotincta*.

Sirex, H. Faes (*Chron. Agr. Canton Vaud, 16 (1903), No. 23, pp. 644–647, figs. 3*).—Notes on the habits, life history, and means of combating *Sirex juvencus* and *S. gigas*.

Help notes toward the determination of British Tenthredinidæ, F. D. Morice (*Ent. Mo. Mag., 2. ser., 15 (1903), Nos. 157, pp. 9–14; 159, pp. 53, 54; 161, pp. 114–119; 164, pp. 187–193; 166, pp. 242–245, figs. 9*).—The author presents an account of the more important anatomical characters of this family of insects for the purpose

of furnishing convenient means for separating the various species. A synoptic table is also given to assist in the identification of the genera of this family occurring in Great Britain.

The life history of Vanessa antiopa, F. W. Frohawk (*Entomologist, 36 (1903), No. 476, pp. 2-5*).—Brief notes on the life history and habits of this insect in its various stages.

The destruction of fruit pests, A. H. Benson (*Queensland Agr. Jour., 13 (1903), No. 6, pp. 538–553, pls. 4*).—Directions are given regarding suitable kinds of spraying apparatus and methods of applying spraying materials. Notes are also presented on various insect and fungus pests together with directions for the preparation and use of Paris green, kerosene emulsion, resin wash, lime-sulphur-salt, whale-oil soap, sulphur, Bordeaux mixture, and ammoniacal copper carbonate. The author also describes the apparatus which is necessary for use in fumigating orchards with hydrocyanic-acid gas, and presents a table showing the amount of materials to be used on trees of different sizes.

Insecticides and their use, J. B. Smith (*New Jersey Stas. Bul. 169, pp. 27*).—In this bulletin the author discusses the use and effectiveness of insecticides in general, and presents special notes on the preparation and use of Paris green, green arsenoid, London purple, arsenite of lime, arsenate of lead, Bordeaux mixture, poisoned bait, lime-sulphur-salt, lime-sulphur-soda, sulphid of potash and lime, crude petroleum, soap washes, whale-oil soap, lime, tobacco, sulphur, pyrethrum, carbolic acid, sulphur, and bisulphid of carbon.

Spraying apparatus, F. Sherman, Jr. (*North Carolina Dept. Agr., Ent. Circ. 4, pp. 7, figs. 4*).—General recommendations are given concerning kinds of pumps, nozzles, and other insecticide apparatus which should be used in practice.

Rules and regulations of the Board of Horticulture of British Columbia, J. R. Anderson (*Victoria, B. C.: Bd. Hort., 1903, pp. 7*).—A copy is given of the rules and regulations of the Board of Horticulture made according to the Horticultural Board Act. Notes are given on the treatment of nursery stock, together with recommendations on the methods of preparing and applying various insecticides.

Suggestions to purchasers of nursery stock in North Carolina, F. Sherman, Jr. (*North Carolina Crop Pest Com. Circ. 5, n. ser., pp. 9*).—Notes are given on the duties of the inspector and on the proper form of certificate, and buyers are warned against purchasing trees infested with fungus and insect pests. Notes are also given on the proper care in cultivating and spraying trees in order to prevent injury from such pests.

Examination of "Nature's Wonder" fertilizer-insecticide, G. E. Colby (*California Sta. Rpt., 1902–3, p. 93*).—An examination of this substance, which was claimed to be both a fertilizer and an insecticide, showed that it is harmless to insects and that its fertilizing value is very slight.

Notes on the insecticide use of the gasoline blast lamp, S. A. Forbes (*Illinois Sta. Bul. 89, pp. 145-154*).—The literature relating to the use of the gasoline blast lamp in the destruction of insects is briefly reviewed. It appears that this apparatus has been used in combating harlequin cabbage bug, San José scale, cotton-boll weevil, aster beetles, chinch bugs, scale insects, caterpillars, fungus diseases, etc.

A number of experiments were made, and a report is given upon the same, by E. S. G. Titus. It appears from these experiments that a modified form of gasoline torch, very similar to the ordinary plumber's torch, when under the greatest possible pressure gives a flame with sufficient heat to singe hair at a distance of 10 to 12 in. The effect of this heat was tested on scurfy scale, Forbes scale, woolly aphis, fall webworms, meadow moths, various caterpillars, including cabbage worms, etc., and also on lilac mildew. At the same time tests were made to determine the tolerance of the leaves of various plants for the heat of the torch applied for varying periods.

Mr. Titus concludes from his experiments that "the use of sufficient heat to destroy effectually insect larvæ of the kinds we treated will injure the foliage and often the twigs." The author suggests, however, that this remedy may have a limited field of usefulness in the destruction of San José scale, chinch bugs, and other species of injurious insects.

Carbon bisulphid as an insecticide, J. H. BEATTIE (*Agr. Student, 10 (1904), No. 4, pp. 69–71*).—A brief discussion is presented of the chemical nature and behavior of carbon bisulphid, together with notes on its application in the destruction of injurious insects, especially in buildings.

Instructions for the use of carbon bisulphid as an insecticide, H. H. COUSINS (*Bul. Dept. Agr. Jamaica, 2 (1904), No. 1, pp. 9–12*).—The nature and chemical properties of this insecticide are briefly outlined and instructions are given for using it for destroying insects in the soil, granaries, storehouses, dwellings, etc.

Potash soaps as insecticides, A. L. HERRERA (*Com. Parasit. Agr. [Mexico], Circ. 2, pp. 3*).—Brief notes on the composition of different potash soaps, together with formulas for the preparation of emulsions from these soaps and kerosene and the use of such emulsions as insecticides.

The commercial cultivation of pyrethrum as an insecticide in Southern France and in Algeria, H. BLIN (*Bol. Sec. Agr. Bahia, 2 (1903), No. 4, pp. 279–283*).—Notes are given on the cultivation of various species of pyrethrum and on the harvesting and care of the crop in such a manner as to obtain the greatest insecticide value. The amount of dry powder obtained from each hectare varies from 500 to 900 kg., according to the soil conditions and varieties of pyrethrum cultivated. Brief mention is made of the insecticide power of different varieties of pyrethrum.

A new method of combating insects in houses and granaries, P. LESNE (*Jour. Agr. Prat., n. ser., 6 (1903), No. 53, pp. 857–861, figs. 2*).—A description is given of an apparatus devised in the United States especially for the disinfection of ships, granaries, and storehouses. In this apparatus sulphur is subjected to a temperature of 600 to 700° C.; the gas thus produced is cooled by passing through pipes surrounded with cold water. The gas is found to contain traces of SO_3 along with SO_2. The amount of these gases in an atmosphere treated by means of the apparatus described by the author may reach 14 to 15 per cent. When sulphur is burned in the free air the percentage of these gases in the room does not exceed 4 or 5 per cent. The unusual effectiveness of the gas mixture obtained by this apparatus in the destruction of rats, other injurious mammals, and insects is attributed to the action of SO_3. While the gas mixture is exceedingly destructive to animal life, it appears to be quite harmless in its effects upon fruits, cereals, grains, and ordinary fabrics.

The Mediterranean flour moth, G. H. CARPENTER (*Jour. Dept. Agr. and Tech. Instr. Ireland, 3 (1903), No. 4, pp. 715–720, pl. 1*).—The moth is described in its various stages and notes are given on its distribution and life history. The remedies recommended for the destruction of the insect are steaming, fumigation with sulphur and with carbon bisulphid.

The effect of poisons upon Lasius emarginatus, R. COBELLI (*Verhandl. K. K. Zool. Bot. Gesell. Wien, 53 (1903), No. 1, pp. 18–21*).—Experiments were made in feeding this species of ant upon honey containing solutions of various alkaloids. It was found during these experiments that the ants, without showing any symptoms of poisoning, could eat honey containing solutions of atropin, belladonna, cocaine, morphin, opium, codein, pilocarpin, nux vomica, aconite, digitalis, veratrin, colchicum, strychnin, or Fowler's solution of arsenic.

Ants, green fly, and scale, BONAVIA (*Jour. Roy. Hort. Soc. [London], 28 (1903), pt. 1–2, pp. 84, 85*).—The author discusses the relationship between ants and insects which they attend, such as aphides and scale insects. It is urged that further inves-

tigations should be made in order to determine the exact biological relation between these insects and also to determine effective means for preventing ants from visiting trees infested with plant lice and scale insects.

White ants in orchards, plantations, and fields, A. N. PEARSON (*Agr. Jour. and Min. Rec. [Natal], 6 (1903), No. 21, pp. 777, 778*).—In controlling infestation by white ants the author recommends that the soil should be treated before setting out orchards. For this purpose arsenical poisons and bisulphid of carbon give good results. The same insecticide methods may be used after trees have been planted. It is suggested that in planting sugar cane the seed pieces may be dipped in a material distasteful to the ants—for example, asafetida, mustard-oil cake, petroleum, etc.

The mound-building prairie ant, G. A. DEAN (*Industrialist, 30 (1904), No. 15, pp. 227–238, figs. 6*).—The author describes the various details of the galleries, passages, and other features in the construction of the nests of *Pogonomyrmex occidentalis*.

The hibernation of ants, R. COBELLI (*Verhandl. K. K. Zool. Bot. Gesell. Wien, 53 (1903), No. 7, pp. 369–380*).—A study was made of the hibernation of a number of species of ants, including *Lasius fuliginosus, L. emarginatus, Cremastogaster scutellaris, Camponotus pubescens*, etc. The relationship of these ants to various plant lice was also studied. It was found that the differences in the length and other features of the hibernation period were due largely to specific differences in the ants, especially their resisting power toward cold.

Contribution to a knowledge of Anopheles, W. DÖNITZ (*Ztschr. Hyg. u. Infectionskrank, 43 (1903), No. 1, pp. 215–238, figs. 7*).—Descriptive and biological notes are presented on a number of species of Anopheles, with special reference to such anatomical structures and habits as may be used in differentiating the various species.

The location of the larvæ of Anopheles in Algeria, EDMUND and ÉTIENNE SERGENT (*Ann. Inst. Pasteur, 17 (1903), No. 11, pp. 763–769*).—The larvæ of Anopheles become located in canals, pools of water, ponds, under vegetation, etc., but the adult mosquitoes may be carried to considerable distances away from the breeding grounds. Notes are given on the usual methods recommended for combating the mosquito nuisance.

Note on the use of kerosene as a culicide, ST. G. GRAY (*Jour. Trop. Med. [London], 6 (1903), No. 20, pp. 313, 314, fig. 1*).—In the author's experience kerosene proved a valuable remedy in destroying mosquitoes in pools. It was found, however, that only a small proportion of the adult mosquitoes were killed while depositing their eggs on the surface of water covered with kerosene. The author suggests that a larger percentage of egg-laying females might be destroyed by the use of crude petroleum.

A breeding cage, J. C. DOLLMAN (*Ent. Rec. and Jour. Variation, 15 (1903), No. 1, p. 7, pl. 1*).—The author presents a description of a breeding cage for insects, which is recommended on account of its simplicity, cheapness, and efficacy. The advantages of this form of breeding cage are briefly described.

How shall we arrange our collections? H. T. FERNALD (*Ent. News, 14 (1903), No. 4, pp. 108–110*).—The author presents a discussion of this question with reference to the practical requirements of systematists and economic workers in showing collections. The conclusion is reached that since the true phyletic relationship between different groups of insects has not been established, it is impossible to arrange collections strictly according to a natural system of classification. In some respects such an arrangement is, in the author's opinion, unsuitable for an economic entomologist.

The biology of the honeybee, VON BUTTEL-REEPEN (*Allg. Ztschr. Ent., 8 (1903), No. 22–24, pp. 453–457*).—A controversial article in which it is argued that the evidence upon which N. Kulagin relied in concluding that the drones and workers arise from half-fertilized eggs is unsatisfactory.

The biology of bees, N. KULAGIN (*Allg. Ztschr. Ent., 8 (1903), No. 20-21, pp. 395-397*). During the experiments reported in this paper the author placed colonies of bees in hives which contained bee cells, with drone cells in 1 frame only. Observation of the queen bee disclosed the fact that she laid eggs in the drone cells at 3 different times. Brief notes are also given on the cause of swarming and on the production of honeycomb. The author found that the bees produced comb from the wax with which they were furnished, and that the form of the cell was not determined voluntarily by the bees, but was due to the method of construction of the comb.

The relation of bees to fruit growing, W. NEWELL (*Proc. Georgia State Hort. Soc., 27 (1903), pp. 58-63*).—The author maintains that the pollination of the Florida fruit trees is practically impossible without insects, and that the honeybee accomplishes this more successfully than any other insect. With regard to the relationship of bees to pear blight and brown rot it is admitted that these diseases are carried by bees to some extent, but it is argued that their prevalence would be almost if not quite as great without the agency of bees.

A study of parthenogenesis of drones by the statistical method, P. BACHMETJEW (*Allg. Ztschr. Ent., 8 (1903), No. 2-3, pp. 37-44, fig. 1*).—The author collected statistics relating to the anatomical features of drones, especially the length of the wings. These statistics are tabulated. From a study of the statistics it appeared that the right wing of drones and the left wing of workers are products of parthenogenesis, while the left wing of drones and the right wing of workers are the result of fertilization of the eggs of the queen. It is concluded, therefore, that the worker bees and drones are half-normal individuals which develop from half-fertilized eggs.

The stingless bees of North and South America considered in the light of domestication, R. H. HARRIS (*Ent. Rec. and Jour. Variation, 15 (1903), No. 4, pp. 99, 100*).—A brief reference is made to the characters and relative value of *Aphis dorsata* and *A. mellifica*. The author states that species of the genera Melipona and Trigona are decidedly inferior to the common honeybee. These latter bees build nests in various locations, including the nests of termites. No wax is used in the construction of the nests. The honey of these bees is also greatly inferior to that of the common honeybee. It is argued, therefore, that little return can be expected from the domestication of these species.

How to prevent foundation falling out of frames, H. R. STEPHENS (*Queensland Agr. Jour., 13 (1903), No. 6, p. 568, fig. 1*).—A method is described and illustrated by which the foundation may be prevented from falling down under the weight of a cluster of bees. The method consists in the use of double lines of wire, one on either side of the frame.

Experiments in sericulture in Tunis, F. VERRY (*Bul. Agr. Algérie et Tunisie, 9 (1903); No. 22, pp. 500-507*).—The eggs used by silkworm raisers in Tunis have been largely furnished by the French government and belong to a number of varieties obtained from the Alps and China. Notes are given on the reeling properties, purity, and tenacity of the silk obtained.

Report of the inspector for the silk commission, GUYOT (*Ann. Soc. Agr. Sci. et Ind. Lyon, 7. ser., 10 (1902), pp. 73-75*).—A brief description is given of the agricultural operations in the vicinity of Lyons, and attention is called to the possibility of extending the silk industry with profit.

FOODS—NUTRITION.

The increase of soluble matter in bread by toasting, E. W. HILGARD (*California Sta. Rpt. 1902-3, pp. 100, 101*).—The changes brought about in bread by toasting were studied with samples toasted very thoroughly; prepared by the ordinary house-

hold method, that is, toasted only on the surface; and samples dried for a long time at 100° C. The results of analyses made by G. E. Colby follow:

Changes due to the different methods of toasting bread.

Kind of toast.	Loss in weight on toasting.	Material soluble in water.	Material insoluble in water.	Albumen in soluble portion.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*
Bread heated 1 hour at 100° C	34.70	12.62	87.38	1.70
Light-colored (yellow) toast made at 150° C	35.30	12.45	87.55	
Brown-toast made at 170° C	36.07	26.14	73.86	.91
Dark-brown toast made at 174° C		25.50	74.50	
Brown toast made at about 160° C. by household method		21.77	78.23	[a]1.90

[a] Bread made with milk, therefore the albumen is not directly comparable with other samples.

It is commonly believed that toast is more digestible than bread, and the superior digestibility has been attributed to the sterilization of the toast and the increased solubility of the carbohydrates present. While this might hold good for thoroughly toasted bread, the author does not believe that such is the case with toast as made by the ordinary household method, since this is only browned delicately on both sides. The toasting penetrates only to a very slight depth, ordinarily on the two sides together hardly more than a millimeter, and when it is carried only to the delicate yellow stage the increase in soluble matter will be insignificant and the soft interior of the slice will be no more sterilized than it was in the baking of the bread. In the author's opinion the increased digestibility of toast may be accounted for by the supposition that its agreeable flavor stimulates the digestive secretions.

A study of some ancient breads, L. Lindet (*Compt. Rend. Acad. Sci. Paris, 137* (*1903*), *No. 17, pp. 664–666*).—A summary of some earlier work on this subject, and a brief report of the author's examination of bread from Egypt and Roman bread from Aosta.

Botanical and chemical examinations of prehistoric grains from ancient tombs.—I. Concerning the gluten cells and their distribution in grain, C. Brahm and J. Buchwald (*Ztschr. Untersuch. Nahr. u. Genussmtl., 7* (*1904*), *No. 1, pp. 12–19, figs. 4*).—Microscopical studies of emmer (*Triticum dicoccum*) from an Egyptian tomb of the 18th dynasty (about 1700 B. C.) showed that neither the starch-free cells of the endosperm nor the remaining cells contained aleurone grains or fine plasma grains, but contained gluten in a structureless homogeneous form. The peripheral cells contained minute starch grains and the inner cells contained both large and small grains, the starch being imbedded in the gluten in all cases. When warmed these starch grains exhibited the striated structure and possessed all the properties of fresh starch. It was found that wheat kernels dried for 48 hours at a temperature of 104° C. and 55 mm. atmospheric pressure closely resembled in structure the old Egyptian grains.

Hygienic studies of flour and bread.—XII. Contribution to the bacteriology of spontaneous and leaven fermentations, F. Levy (*Arch. Hyg., 49* (*1904*), *No. 1, pp. 62–112*).—The various forms of bacteria found in sour dough have been classified by Lehmann and Wolffin as forms of *Bacterium levans*, in addition to *B. coli* which was generally recognized as present. The author of this paper has found from his studies that the bacteria all fall under *B. coli*, and he has rearranged the grouping on this basis, recognizing in addition to the typical species 2 conspicuous forms.

From his experiments, reported in full, the conclusion is reached that in the case of spontaneous fermentation and fermentation caused by leaven, *B. coli albidoliquefaciens* and *B. coli luteoliquefaciens* were present, in addition to a typical *B. coli*, all 3

of which produced an abundance of gas and acid. A light yellow organism very similar to *B. coli* was also found which caused liquefaction and formed weak acid, but produced no gas. In the spontaneous fermentation of dough porosity can be and is in practice, brought about by 3 of these gas-forming organisms. When leaven is used as a fermenting agent the bacteria named may be present, but yeast is the principal active agent. Acid is formed only in limited amounts by the organisms named. The most important of the acid-building organisms were pointed out by W. Holliger.[a]

Concerning wheat and wheat flour, I, T. Kosutány (*Jour. Landw., 51 (1903), No. 2, pp. 139-161*).—The estimation and properties of gluten were studied, as well as gluten formation in sprouting grain. The results of baking tests with different sorts of gluten were also briefly noted. The author concludes that glutenin is the anhydrid of gliadin, and conversely that gliadin is a hydrated form of gluten, and believes that the change of one into the other may be induced, and that such a change explains some of the well-known phenomena connected with milling and baking. Concerning these points he makes in effect the following statements:

Flour from new wheat produces a heavy dough; however, when the wheat or flour has stood for a number of weeks normal dough is produced. When the flour or wheat is several years old the dough produced is short and crumbly. It is considered probable that the amount of protein does not change, but that at first gluten predominates, and that it gradually loses water and is converted into glutenin. When dough is allowed to stand, especially in a warm place, it becomes softer, as the author has shown by a number of experiments with various viscometers. This change he explains is due to the formation of gliadin from glutenin by the addition of water.

Dough from sprouted wheat is flat and heavy, the reason being in the author's opinion that by the action of a hydrolizing enzym glutenin has been converted into gliadin. When a clear solution of gliadin in 70 per cent alcohol is allowed to stand for several weeks a precipitate is formed which the author believes is due to the fact that gliadin splits off water and forms glutenin. When gluten is allowed to stand for some days in water it adds water chemically and becomes soluble in alcohol, that is, gliadin is formed. Using the same flour somewhat less gluten is obtained by the aid of warm than of cold water, and the gluten is softer and more sticky. Hard water gives more elastic and more abundant gluten than soft water. When grain is ground care must be taken to prevent the heating of the flour and consequent deterioration. The changes noted in such cases are due, according to the author, to the evaporation of combined water and to oxidation. After a time heated flour improves in quality probably owing to reduction and absorption of water in chemical combination. The changes observed in the quality of flour when stored are regarded as dependent upon the atmospheric moisture and temperature.

The author considers that Hungarian flour yields more bread than many other flours, 100 kg. of such flour producing 145.66 kg. of bread in an average of 150 tests. As an average of more than 300 analyses Hungarian wheat was found to contain 15.346 per cent gluten or somewhat more than the average of a large number of analyses of other sorts. The effects of climate on the character of the wheat crop are briefly spoken of.

Concerning wheat and wheat flour, II, T. Kosutány (*Jour. Landw., 51 (1903), No. 4, pp. 329-353, pl. 1, figs. 3*).—Using a modification of Rejtö's instrument for studying density, studies were made with dough and conclusions drawn, which are based on the form assumed by the dough as shown by a diagrammatic cross section. This method, the author believes, furnishes data for judging of the character of the gluten of the wheat, the relative proportion of gluten and gliadin, the purity of the flour, the best method of manipulation in bread making, etc.

[a] Centbl. Bakt. u. Par., 2. Abt., 9 (1902), pp. 305-312, 361-371, 395-425, 473-483, 521-537.

The deterioration of meat, H. MARTEL (*Principales altérations des viandes. Paris: C. Naud, 1902, pp. 22*).—In this article, which is a reprint from *La Presse Médicale, 1902, No. 52,* animal parasites, bacterial contamination of meat, prophylaxis, and related subjects are discussed.

Methods of judging meat extracts, I, F. KUTSCHER and H. STEUDEL (*Ztschr. Physiol. Chem., 38 (1903), No. 1–2, pp. 101–110*).—Like other investigators, the authors note the occurrence of succinic acid in meat extract. Its relation to the purity of this product is briefly discussed.

Cream as food (*Bul. Iowa State Bd. Health, 17 (1903), No. 4, p. 62*).—Data regarding the dietetic value of cream are summarized. Cream as a fat-supplying food is regarded as especially valuable on account of its mechanical condition and the association of proteid material with the fat. Its value in invalid dietectics is also spoken of.

Analyses of breakfast foods, G. W. SHAW (*California Sta. Rpt. 1902–3, pp. 86–88*).—Analyses of 6 samples of commercial breakfast foods are reported and briefly discussed.

The source of the important foods used in Halle, K. GRABENSTEDT (*Inaug. Diss., Univ. Halle, 1903, pp. 64*).—The author has gathered statistical and other information regarding the food supply of the city of Halle.

Cowpeas, G. W. CARVER (*Alabama Tuskegee Sta. Bul. 5, pp. 10*).—The importance of cowpeas in the diet is briefly discussed, and 25 recipes are given for preparing them in various ways for the table.

Colored legumes, K. LENDRICH (*Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 1, pp. 1–5*).—The results of examinations made with a view to detecting added coloring matter and material used for facing are reported of unshelled peas and whole and split shelled peas.

Lentils, L. IRWELL (*Dietet. and Hyg. Gaz., 20 (1904), No. 1, pp. 6–9*).—A descriptive article.

Famine foods, D. N. PATON and J. C. DUNLOP (*Edinburgh, 1903, pp. 27; rev. in British Med. Jour., 1903, No. 2245, pp. 94, 95*).—A considerable number of seeds and other products from uncultivated plants used by the Bhils in India during the recent famines are described and analyzed. On the basis of the data reported their food value is discussed.

Esculent tubers and vegetables in Liberia, E. LYON (*U. S. Consular Rpts., 74 (1904), No. 281, p. 407*).—Tubers and garden vegetables commonly eaten in Liberia are enumerated and briefly described.

Italian chestnuts and chestnut trees, P. CUNEO (*U. S. Consular Rpts., 74 (1904), No. 281, p. 408*).—Brief statements regarding the use of chestnuts as food in Italy, and concerning budding chestnut trees.

An Arab food, "Halwa" (*Nature [Paris], 31 (1903), No. 1565, p. 398*).—The manufacture of Halwa, of which large quantities are consumed in the East, is briefly described. This food is a paste made of 3 or 4 parts sugar, 0.5 to 1 part butter, and 0.25 part starch, flavored with a small amount of an aromatic substance resembling essence of rose in odor.

The cooking of shellfish (*British Med. Jour., 1904, No. 2248, p. 265*).—Sterilizing small shellfish with steam as a method of preventing the communication of disease to man was studied. The results obtained were fairly satisfactory. The fact is recognized that if overcooked the palatability of the shellfish is lessened. There is less danger of overcooking with steaming than with boiling. "There can be no doubt that if the retailers of cooked shellfish can be induced to substitute steaming for boiling—or rather for scalding—in the cooking of shellfish for sale, there will be a distinct gain in public safety."

The art of home candy making, M. A. PEASE (*Canton, Ohio: Pease & Smith, 1903, pp. 80*).—A large number of receipts for making candy are given, the methods

outlined, it is stated, being those followed by professional candy makers. The recipes are prefaced by a description of the tools required, data regarding the use of the thermometer in candy making, and other general matters. The work also contains a discussion of cake making and a few recipes.

Examination of marmalades, K. WINDISCH (*Ztschr. Ver. Deut. Zuckerind., 53 (1903), pp. 363–371; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 23, p. 1127*).—The composition of several sorts of jam and marmalade is reported.

Composition and manufacture of jams and marmalades, A. HERZFELD (*Ztschr. Ver. Deut. Zuckerind., 53 (1903), pp. 405–426; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 23, pp. 1123–1127*).—Analyses of a large number of jellies, jams, and marmalades of British and German manufacture are reported.

Composition of almond pastes for macaroons, pastries, bonbons, etc., G. E. COLBY (*California Sta. Rpt. 1902–3, pp. 96, 97*).—Analyses are reported of 3 sorts of almond paste and of California and foreign-grown almond kernels. Some data are also recorded regarding bitter almonds, peach-pit kernels, and apricot-pit kernels. The latter, it is stated, yield a fine grade of oil, which is often used in confectionery. The almond pastes, it appeared, were made of ground almonds with water and sugar, and in one case a considerable quantity of cornstarch.

Olives and olive oil in France, R. P. SKINNER (*U. S. Consular Rpts., 72 (1903), No. 274, pp. 403–421, figs. 3*).—The French olive and olive-oil industry is described.

Examination of brine from pickled olives from Spain, G. E. COLBY (*California Sta. Rpt. 1902–3, pp. 92, 93*).—A number of samples of brine from pickled olives were analyzed, with the following results: Total solids, 8 per cent, of which 5.88 per cent was soluble in water after drying, 0.2 per cent insoluble after drying, and 1.92 per cent organic matter. The soluble part consisted of 91.3 per cent common salt, together with small quantities of sodium sulphate and magnesium chlorid. The insoluble part consisted of calcium and magnesium carbonates, with a small amount of calcium sulphate. No boric acid, salicylic acid, benzoic acid, or niter was found.

This examination showed that the brine was substantially a 5.5 per cent solution of common salt. There was no evidence that any aromatic principle had been employed, except, perhaps, laurel leaves.

Comparative solubility of aluminum and tin in lemon juice, G. E. COLBY (*California Sta. Rpt. 1902–3, pp. 91, 92*).—A sample of lemon juice, which had been extracted from the fruit in an aluminum vessel, was found to contain 0.35 part aluminum and 0.28 part tin per 10,000. The value for aluminum was corrected, the author states, by a proper allowance for alumina present in the natural lemon juice. Though the amounts of dissolved metals are very small, yet the use of the metallic vessel, in the author's opinion, should be avoided for the work in question, a porcelain or porcelain-lined vessel being preferable.

[Soluble] coffee (*Spice Mill, 26 (1903), No. 11, pp. 363, 364*).—A recently introduced coffee product is described, which is said to consist of roasted coffee freed from all the bitter chaff and very finely ground with sugar. This material, it is said, is quite soluble, and it is claimed that coffee may be prepared from it for the table with boiling water without additional cooking.

The manufacture of chocolate and other cacao preparations, P. ZIPPERER (*London: E. & F. N. Spon, Ltd.; New York: Spon & Chamberlain, 1902, 2. ed., pp. X+277, pls. 3, figs. 84*).—This is an English edition of a publication previously noted (E. S. R., 13, p. 1101).

What shall we eat? A. ANDREWS (*New York: The Health Culture Co., 1903, pp. 119, fig. 1, charts 3*).—This volume summarizes in a popular way data regarding the composition and digestibility of food and related topics.

The sale of food and drugs acts, W. J. BELL, H. S. SCRIVENER, and C. F. LLOYD (*London: Butterworth & Co., 1903, 4. ed., pp. XLIV+276*).—The decisions of British

courts rendered since the last edition of this work have been included, and the authors state that the whole volume has been carefully revised.

Report of work in food laboratory, H. E. Barnard (*New Hampshire Sanitary Bul., 2 (1904), No. 1, pp. 5–16*).—The work of the New Hampshire food laboratory carried on under the provisions of the State Pure Food Law is briefly described. Of the 549 samples examined 172, or 31.3 per cent, were found to be adulterated. The article is followed by the food standards and definitions decided upon by the State board of health.

Eighteenth Annual Report of the Ohio Dairy and Food Commissioner, H. Ankeney (*Ohio Dairy and Food Comr. Rpt. 1903, pp. 72*).—Under the provisions of the State Pure Food Law a number of samples of food were examined, and prosecutions were made in necessary cases. Of 1,947 samples examined 536 were found to be adulterated. The usual statements are also included regarding the funds received, disbursements, etc.

Disinfection and the preservation of food, S. Rideal (*New York: John Wiley & Sons, 1903, 3. ed., pp. X+494*).—It has been the author's purpose to summarize the information which has accumulated on the subject of disinfection with special reference to the needs of the chemist and bacteriologist, as well as medical officers and others who have a practical interest in the subject. Mechanical disinfection, sterilization by heat, chemical disinfectants, personal and internal disinfection, preservation of food, legal statutes and regulations, and methods of analysis are some of the subjects treated of. The present edition, it is stated, has been revised and new material incorporated which has accumulated in the last few years. The author has designed the section on food preservation especially as a manual for those commercially interested in the subject.

"Notwithstanding a general concensus of opinion against the use of preservatives a few years ago," he states, "it would seem impossible under modern conditions of life to do without some methods of keeping perishable articles of food without incurring a very large loss, and it can not be denied that with proper safeguards in some instances even chemical treatment may be desirable."

The influence of food preservatives on digestion, H. W. Wiley (*Dietet. and Hyg. Gaz., 20 (1904), No. 2, pp. 70–72*).—In an address before the Society of Arts, Massachusetts Institute of Technology, the author briefly described the experiments carried on at the Bureau of Chemistry of this Department to study the effect of food preservatives on man.

The use of antiseptics in food in New South Wales (*Public Health [London], 16 (1904), No. 4, p. 243*).—The regulation of the use of food preservatives is one of the duties of the New South Wales board of health. While their use is not forbidden the amount which may be used is limited to not over 0.001 grain per pound, which is regarded for practical purposes as equivalent to prohibition. The law further requires that when preservatives are added the kind and amount shall be legibly stated on the label.

The list of preservatives given in the schedule and the amount permitted follow: Sulphurous acid not more than 1.75 grains, salicylic acid or benzoic acid not more than 1 grain, and boric acid not more than 10 grains per pint of liquid or per pound of solid food. In the following foods none of these antiseptics may be used, save in the proportion of 0.001 grain per pound or pint: Milk, including condensed milk; cream, canned and bottled foods, jams and fruits, aerated waters and temperance drinks, fresh fish, vinegar, sauces, and pickles. The use of sulphurous acid and boric acid is permitted for preserved fish, bacon, and ham.

Concerning the injurious effects of unripe fruit, R. Otto and W. Kinzel (*Landw. Vers. Stat., 59 (1903), No. 3–4, pp. 217–251*).—Detailed chemical analyses of fruits of varying degrees of ripeness are reported, as well as the results of experiments

with guinea pigs, rabbits, and a smaller number with man. The principal conclusions which were drawn follow:

Although unripe fruit is undoubtedly often harmful, particularly with children, the danger from such food, especially green gooseberries, plums, pears, and apples, when eaten raw is less than commonly thought, and the effects depend in marked degree upon individual peculiarities. Cooked green fruit is practically harmless. The injurious effects when eaten raw do not depend upon chemical constituents, but rather upon the unusual proportions in which the constituents occur and the large percentage of hard-cell tissue.

From their investigations as a whole, the authors feel warranted in drawing the conclusion that the sale of green fruit should not be forbidden. When cooked with the addition of sugar, they believe it is both palatable and wholesome. The possibility of injury by bacterial contamination is spoken of and the statement made that this subject will be investigated further.

Mechanics as exemplified by the animal frame, O. FISCHER (*Sci. Amer. Sup., 56 (1903), No. 1459, pp. 23380, 23381*).—The human body is likened to a machine, and the ways in which it agrees with and differs from machines are discussed. The importance of instantaneous photography in determining the character of certain kinds of motion is spoken of, and methods of carrying out experiments by the aid of photography are briefly described.

The physiology of fatigue (*British Med. Jour., 1904, No. 2246, pp. 145, 146*).—A discussion of papers read by Z. Treves and J. Demoor at the recent meeting of the International Congress of Hygiene and Demography at Brussels.

The physiology of bitters (*British Med. Jour., 1903, No. 2235, p. 1166*).—Reasons for the use of bitters and also for the use of soup at the beginning of a meal are discussed.

Concerning the peptic and tryptic digestion of proteids, LAWROW (*Ztschr. Physiol. Chem., 40 (1903), No. 1–2, pp. 165, 166*).—A controversial article.

Proteolytic action of pancreatic juice, W. M. BAYLISS and E. H. STARLING (*Jour. Physiol., 1903, Aug.; abs. in British Med. Jour., 1904, No. 2249, Epit., p. 21*).—The authors confirm the original statement of Bernard that the real pancreatic juice has no action on proteids. Enterokinase, a substance present in the succus entericus, is necessary to render the pancreatic juice active, or in other words to form trypsin from its inactive precursor, trypsinogen. Other experiments, they state, show that trypsinogen can not be converted into trypsin in any way except by the action of enterokinase.

It is concluded that trypsin is not a mixture of enterokinase and trypsinogen, but is a specific substance and the most powerful proteolytic ferment known. It digests itself rapidly, especially if no dissolved proteid is present for it to act upon. The observers further conclude that enterokinase is a true ferment and is produced only in the small intestine.

The digestibility of casein by pepsin-hydrochloric acid and by pancreas ferments, E. FISCHER and E. ABDERHALDEN (*Ztschr. Physiol. Chem., 40 (1903), No. 3–4, pp. 215–219*).—The examination of the cleavage products obtained when casein was slowly digested for a long time with pepsin and hydrochloric acid and with pancreatin led to the conclusion that a-pyrrolidinecarbonic acid and also the ordinary amino acids are to be regarded as constituents of the proteid molecule and, furthermore, that the combined action of pepsin with hydrochloric acid and of pancreatin induces more complete hydrolysis than pancreatin alone.

Contribution to the subject of the destruction of sugar in the animal body by the action of ferments, J. ARNHEIM and A. ROSENBAUM (*Ztschr. Physiol. Chem., 40 (1903), No. 3–4, pp. 220–233*).—Tests of the glycolytic power of the pancreas, liver, and muscle tissues alone and in combination are reported, which led to the conclusion that all of these materials induce cleavage in sugar molecules, this power

varying in degree in the different materials and being markedly increased by the addition of pancreas tissue, but not by the other combinations tested.

Contribution to the subject of the excretion of gastric juice by man, A. F. Hornborg (*Skand. Arch. Physiol., 15 (1904), No. 3–4, pp. 209–258, dgms. 8*).—A boy who had had gastrotomy performed because of an injury and was fed almost entirely through a fistula, furnished an opportunity for the study of the influence of various factors on the secretion of gastric juice. It was found that the sight of food did not cause its excretion. Generally speaking, chewing foods of good flavor caused a more or or less active secretion, and chewing foods of unpleasant flavor apparently influenced the secretion very little, while chewing foods of indifferent flavor was without influence. When substances having a sharp or biting taste were chewed, apparently the secreting glands of the stomach were not stimulated.

In his experiments the author studied the acidity and activity of the gastric juice. The investigations are discussed in relation to Pawlow's theories, and the report contains a bibliography.

The influence of the diet upon the excretion of uric acid, P. Pfeil (*Ztschr. Physiol. Chem., 40 (1903), No. 1–2, pp. 1–24, pls. 7*).—With healthy men as subjects the effect of different foods and combinations of food on the excretion of uric acid was studied. When no meat was eaten the excretion of uric acid was diminished to a small amount. When meat was eaten it was markedly increased. When a diet containing no protein was consumed the uric acid was still excreted and in about the same way as when no meat was eaten. The author studied the time relations of the excretion of uric acid and related topics.

ANIMAL PRODUCTION.

The available energy of timothy hay, H. P. Armsby and J. A. Fries (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 51, pp. 77, pls. 2, dgms. 4*).—Using a respiration calorimeter of the Atwater-Rosa type, which they have constructed with a number of modifications suiting it to experiments with large animals, the authors, in cooperation with the Bureau of Animal Industry of this Department, conducted a series of experiments with a steer with the special object of determining the available energy of timothy hay. Some of the essential features of the respiration calorimeter are very briefly described. The accuracy of the apparatus was shown by check experiments in which alcohol was burned in the respiration chamber. In one of these in which 975.34 gm. of alcohol was burned 99.1 per cent of the theoretical amount of carbon dioxid and 100.8 per cent of the theoretical amount of heat were measured. Equally close results were obtained in the other check tests.

The 4 periods in which the experiment was divided each covered 2 days in the respiration chamber. The ration consisted of timothy hay with a small proportion of linseed meal, the energy being least in the first experimental period and greatest in the fourth. Data regarding the income and outgo of matter and energy, the amount of time the steer spent standing up and lying down, and other experimental details are reported in full.

In the author's opinion, for herbivora the results are not in accord with the commonly accepted theory that as sources of energy the nutrients may replace one another in proportion to their heats of combustion. As pointed out, isodynamic replacement implies that there is no increase in heat production with an increasing amount of food. . . . The results obtained in the periods below the maintenance ration fully confirm this doubt. Only 63 per cent of the metabolizable energy served to prevent loss of tissue, while 37 per cent simply increased the heat production of the animal. In other words, the digested matter of the hay was not isodynamic with body tissue under the conditions of this experiment. Moreover, the

difference is altogether too large to be ascribed to any experimental error or to be accounted for by the discrepancies in some of the results.

"This difference may be reasonably ascribed to the relatively large expenditure of energy necessary in the digestion and assimilation of the hay. Even upon a comparatively light ration, this amount, in addition to the heat arising from the internal work of the body, appears to have been sufficient to maintain the normal body temperature at the comparatively high stable temperature (18.2° C.). Such being the case, when more hay was added the heat arising from its digestion and assimilation was in excess of the needs of the animal for heat and became an excretum, passing off without being of any direct service to the organism.

"In other words, what one of us has elsewhere designated as the critical amount of food must be relatively small in the case of a material like timothy hay, which requires a large amount of digestive work. In our experiment, even the smallest amount of food seems to have been in excess of the critical amount; consequently, when more food was added the additional heat resulting from its digestion and assimilation could not be used indirectly and served simply to increase the heat production, while only the remaining 63 per cent of the metabolizable energy served as fuel for the body in place of the tissue previously consumed."

On the basis of theoretical considerations, which are discussed, the authors believe that for cattle a maintenance ration is "a question of tissue replacement rather than of heat production, and, therefore, that the value of a given feeding stuff for maintenance depends upon the availability of its energy. We may, for instance, regard it as at least very probable that the work of digestion and assimilation in the case of a material like corn meal would be materially less than in the case of hay; or, in other words, that a larger percentage of its energy would be available for the maintenance of tissue. It would follow from this that in case of a ration consisting largely of grain a less amount of material or of metabolizable energy would be required for maintenance than in the case of a ration consisting exclusively of coarse fodder. In other words, the maintenance ration is a variable rather than a constant, depending upon the kind of food used." In the experiments reported the maintenance requirement of the steer, as computed, was 10,710 calories, the average weight of the animal during the experiment being approximately 410 kg.

"Computing to 500 kg. live weight, on the assumption that the maintenance requirement is proportional to the two-thirds power of the live weight, this equals 12,197 calories. . . .

"If the heat production upon the maintenance ration is in excess of the requirements of the animal, it seems unlikely that small variations in the stable temperature to which the animal is exposed will have the effect upon the maintenance requirement which is ordinarily attributed to them. Still less is this likely to be the case with fattening cattle, where the amount of food and the consequent heat production are largely in excess of the maintenance ration.

"Our results indicate that the proportion of the metabolizable energy of the food which was utilized, above the maintenance requirement, to produce gain was decidedly less than that used below the maintenance requirement to prevent loss of tissue. In other words, they indicate that the conversion of digested and assimilated matter into actual tissue (fat) requires a considerable expenditure of energy, amounting in this case to about 47 per cent of the available energy or 30 per cent of the metabolizable energy. This result is quite in accordance with what we should anticipate. The digested matter of the food of herbivora appears to be resorbed chiefly in the form of carbohydrates and of organic acids. It seems altogether probable that a much less profound change is required to convert these resorbed products into forms suited to maintain the energy metabolism of the organism than is needed to convert them into the form of permanent tissue, especially fat. At the same time it should

be noted that the amount of food given in excess of the maintenance requirement in this experiment was small and, moreover, that the results [in 1 lb.] are somewhat doubtful. We do not feel, therefore, that very much stress should be laid upon the apparent results of this experiment in this particular. . . .

"As the figures show, the proportion of the total energy of the hay which was found to be metabolizable diminished as the amount was increased, the difference arising chiefly from differences in digestibility. Since, nevertheless, the total expenditure of energy in digestion and assimilation appears to be approximately proportional to the metabolizable energy, it seems evident that a large share of this expenditure must be for the work of assimilation. Probably a very large factor in it is the loss of energy in the methane fermentation."

Some of the points mentioned in this bulletin have been briefly noted from earlier publications (E. S. R., 14, p. 993; 15, p. 391).

Examination of grain damaged by water, G. E. COLBY (*California Sta. Rpt. 1902–3, pp. 94, 95*).—Notes are given on the food and fertilizing value of wheat and barley damaged by salt water, and of wheat damaged by fire and smoke. Analyses are reported showing the food and fertilizing value of wheat and barley which had been under salt water for 14 months. Samples of wheat damaged by fire and smoke were also examined, and it is concluded that such wheat may be safely fed to poultry and hogs. The grain damaged by salt water is considered of greater value for feeding than for fertilizing purposes.

Concerning milk molasses, G. LOGES (*Landw. Vers. Stat., 58 (1903), No. 5–6, pp. 400–402*).—"Milk molasses," a commercial feed which is described as a mixture of molasses, peanut hulls, and similar materials with casein of skim milk, is considered too expensive to warrant its use. Ordinary beet molasses is regarded as preferable.

Concerning the chemical composition of beet leaves and tops preserved by the Rosam method, O. FALLADA (*Oesterr.-Ungar. Ztschr. Zuckerind. u. Landw., 32 (1903), No. 1; Mitt. Chem. Tech. Vers. Stat. Centralver. Rübenz.-Ind. Oesterr.-Ungar., 1903, No. 148, pp. 21–27; abs. in Centbl. Agr. Chem., 32 (1903), No. 12, pp. 834–836*).—The Rosam process of preserving beet leaves and tops is discussed and analytical data are reported. In this process the beet leaves and tops are thrown into a pile some 15 by 45 ft. and from 8 to 10 ft. deep, care being taken so that on the surface of the pile the leaves are pointed toward the center. The pile is covered with a layer of earth about 2 ft. thick on the top and 1 ft. on the side. This method of preservation is quite similar to ensiling.

Analyses of foods and fodders, G. W. SHAW (*California Sta. Rpt. 1902–3, pp. 84–86*).—Analyses are reported of Ajonjoli meal (also known as bene-seed meal and sesame-seed meal), linseed meal, cotton-seed meal, blood meal, white oak acorns, and native bird's foot clover (*Lotus californicus*). Sesame meal contained 7.4 per cent of water, 36.67 per cent protein, 26.01 per cent fat, 17.34 per cent nitrogen-free extract, 3.81 per cent crude fiber, and 8.77 per cent ash. The native bird's foot clover had the following percentage composition: Water 8.02, protein 12.25, fat 5.97, nitrogen-free extract 47.41, crude fiber 18.80, and ash 8.35.

Licensed commercial feeding stuffs, 1903, F. W. WOLL and G. A. OLSON (*Wisconsin Sta. Bul. 106, pp. 55*).—In compliance with the provisions of the State law a number of feeding stuffs for which guaranteed composition is required were analyzed, as well as a considerable number of concentrated feeds for which no guaranteed composition is required.

The feeding stuffs analyzed were cotton-seed meal; gluten meals and feeds; hominy feeds; corn or corn and oat feeds; ground corn and oats; wheat bran, middlings, and shorts; miscellaneous dairy feeds; oats; wheat screenings; wheat flour of different grades; buckwheat flour, middlings, shorts, feed, and bran; corn; corn meal; screen-

ing oats; clipped oats; clipped and purified oats; ground oats; mixed grains; barley feed; dried grains (including weed seeds and dried beet pulp); malt sprouts; ground millet and flax screenings; rice bran; poultry feeds (largely of animal origin); and stock foods.

"Fortunately no serious adulterations of concentrated feeding stuffs are practiced in this State, so far as we have been able to ascertain, beyond the admixture of low-grade oat refuse feeds in mixed corn and oat feeds, which . . . is quite common; the admixture of screenings to mill feeds, especially bran, is still practiced by a few mills, but the quality of the mill feed sold in our State is, on the whole, of a high grade."

The care of farm stock (*Bul. Maine Dept. Agr., 2 (1903), No. 4, pp. 105–143*).—Short articles by a number of different authors are included on topics dealing with the feeding and care of farm animals.

Empirical knowledge and experience in the feeding of farm animals, L. Grandeau (*Jour. Agr. Prat., n. ser., 7 (1904), No. 1, pp. 9, 10*).—The fact is pointed out that the feeding of farm animals may be said to rest on a scientific basis. The progress made in recent years is briefly discussed.

Calf-rearing experiments (*Jour. Dept. Agr. and Tech. Instr. Ireland, 3 (1903), No. 4, pp. 627–647, dgms. 4*).—Whole milk; separator skim milk and whole milk 5:1, separator skim milk supplemented by cod liver oil, and separator skim milk supplemented by corn meal were compared with 4 lots of from 7 to 9 calves at Knockbeg, Collooney, Ireland. The test began June 12, 1901. In 20 weeks—that is, when weaned—the gains per head ranged from 176.2 lbs. on skim milk and cod liver oil to 238.6 lbs. on whole milk, the cost of a pound of gain ranging from 3.42 cts. on skim milk and corn meal to 7.98 cts. on whole milk. The feeding was continued until February 16, 1903, when the calves were sold for fattening. Considering the test as a whole, the total gain ranged from 698.5 lbs. with the lot originally fed cod liver oil to 760.6 lbs. with the lot originally fed whole milk.

Beginning June 12, 1901, a second test was made with some of the older calves secured at the same time as those included in the above test. The calves were weaned earlier, the weaning period beginning early in August, and they were sold for fattening February 16, 1903. The rations fed throughout the test were practically the same as in the first test. Considering the entire period, the gains ranged from 678.5 lbs. with the lot originally fed skim milk and corn meal to 759.7 lbs. with the lot originally fed skim milk and cod liver oil. The gains were also most cheaply made by this lot.

It is stated that the experiment furnishes a demonstration of the fact that calves may be successfully reared on skim milk provided a cream substitute is fed with it; that they may be more economically reared on skim milk and a cream substitute than on whole milk; and that the belief generally held locally that creamery milk is the cause of the high death rate among calves is entirely unfounded.

Fattening steers of the various market grades, H. W. Mumford (*Illinois Sta. Bul. 90, pp. 155–217, pls. 13*).—The principal object of this experiment was to determine the relation between the grade of the steers fed and their feeding qualities—that is, whether the quality of an animal determines its capacity for making gains, the ability to use feed economically, and the nature of the gains made. The grades chosen were fancy selected, choice, good, medium, common, and inferior steers, 16 animals constituting a lot in every case.

After a preliminary period all the lots were fed alike for 129 days, beginning November 29, 1902. The grain ration for the early part of the test consisted of chopped corn and cob and later of corn-and-cob meal, with about 8 lbs. of cottonseed meal or linseed meal per bushel of corn in addition. The coarse fodder consisted of clover hay, timothy hay, and later, of alfalfa hay, which through the greater part of the test was chopped and mixed with the grain. A little corn stover was

also fed. During the first month the proportion of coarse fodder to concentrated feed was about 4:3. From this time on the grain ration was gradually increased and the coarse fodder diminished until at last the grain ration was about 5 times as great as the coarse fodder. Considering the test as a whole, the nutritive ratio of the ration was 1:7.64. All the lots were handled alike, being kept in yards with sheds, and throughout the test remained in good health.

At the beginning of the test the steers weighed on an average not far from 1,000 lbs. each. The fancy steers made an average daily gain of 2.57 lbs. per head, at a cost of 6.74 cts. per lb. The average daily gain of the choice steers was 2.543 lbs. and the cost of a pound of gain 8.21 cts. In the case of the good steers these values were 2.341 lbs. and 8.17 cts.; with the medium steers 2.128 lbs. and 8.77 cts.; with the common steers 2.207 lbs. and 8.12 cts.; and with the inferior steers 1.957 lbs. and 8.66 cts. The digestible dry matter required per pound of gain ranged from 9.952 lbs. with lot 1 (fancy steers) to 13.049 lbs. with lot 4 (medium steers). The beef produced per bushel of corn fed ranged from 7.45 lbs. with lot 4 (medium steers) to 9.74 lbs. with lot 1 (fancy steers). The increase in total value of the cattle per 1,000 lbs. of digestible dry matter consumed ranged from $1.91 with lot 4 to $3.11 with lot 1.

The cattle were shipped to Chicago for slaughtering, the shrinkage in shipping ranging from 0.54 per cent with lot 6 (inferior steers) to 2.08 per cent with lot 3 (good steers). When slaughtered the proportion of dressed carcass to live weight ranged from 59.36 per cent with lot 6 (inferior steers) to 61.62 per cent with lot 1 (fancy steers). The greatest range in percentage of caul fat and rough fat was also found with these lots, being for the former 3.39 with lot 1 and 3.83 with lot 6, and for the latter 6.07 with lot 1 and 7.98 with lot 6.

After slaughtering, the steers were judged by experts, and all those in lots 1, 2, and 3 (fancy, choice, and good steers) were rated as No. 1 carcasses, the percentage of prime animals being the largest in lot 1, in which case 15 were designated as prime and 1 as choice. In the case of lot 4 (medium steers), "1 finished as choice, 4 as good, 8 as medium, and 3 as common. Four of the carcasses in this lot graded as No. 1 light, and the remainder as No. 2 tops." With lot 5 (common steers), "5 finished the test as good, 6 as medium, and 5 as common beeves. The grading of the beef was the same as that in lot 4, namely, 4 carcasses graded as No. 1 light, and 12 as No. 2 tops." Considering lot 6 (inferior steers), "4 finished as good, 6 as medium, and 6 as common. Six carcasses graded as No. 1 light, 9 as No. 2 tops, and 1 as No. 3 beef."

This and other data, in the author's opinion, shows the possibility of securing reasonably high percentages of dressed beef of satisfactory grade, even with low-bred steers, provided they are intelligently fed to as high a finish as they are capable of taking. The financial aspect of the test is discussed in detail on the basis of a steady, or what would ordinarily be considered a normal, market and a falling or declining market.

The author's principal conclusions are in effect as follows: More rapid and much larger gains may be secured with the better grades than with the more common grades. When the various grades of beef cattle are put in the best marketable condition there is a very definite relation between the percentages of dressed beef and the grade of cattle involved. The better the grade of cattle the higher the percentage of dressed beef. Low-grade cattle carry larger percentages of internal fat than those which are better bred, while there appears to be a more abundant and more evenly distributed layer of surface fat on the better-bred steers.

Since differences between animals tend to disappear as the feeding process goes on, the differences in quality between various grades are more pronounced than such differences between the various grades of beef or fat cattle. Quality is the more important consideration in feeding cattle; condition, in fat cattle.

The grade of cattle the finishing of which will return to the cattle feeder the greatest profit will depend upon the following considerations: The relative ability of the various grades to use feed for the production of gain and finish, the relative cost of the various grades of feeding cattle, the cost of feed, the method of feeding and time of marketing, and the range in prices between prime and common rough steers or between the highest and lowest grades of beef cattle.

The greater the cost of the feed used the greater is declared to be the advantage in favor of the better grades, both because under normal market condition the gains and finish of these grades are put on with less relative feed consumption than in the lower ones (although this difference is less marked in the inferior than in the intermediate grades), and because the cost of feed is a larger factor in the feeding of the lower than the higher grades.

"The greater the spread in the market between the various grades of feeders, the more is the advantage in favor of the commoner grades. As a rule the price of common rough steers fluctuates less than the price for prime steers, and the price of the inferior and common grades of feeders varies less than those of the choice and fancy grades. . . . The greater the spread in the market between the various grades of fat steers the more is the advantage in favor of the better grades. . . . When prices rule low in the beef-cattle class and the market is dull and has a downward tendency, the range of prices between prime steers and common rough steers is narrow, and, as a result, condition or fat is more important than quality or beef blood. As a rule, prices of common rough steers in the beef-cattle class fluctuate less than the prices for prime steers. Hence it will be seen that in general there is less liability to large losses from market fluctuations in the feeding of the commoner than the better grades of feeding cattle. On the other hand, the chances for making large profits are undoubtedly greatest with the better grades. . . . By reducing the corn fed to meal and mixing same with roughage the importance of pork production as a factor in cattle feeding is minimized. Notwithstanding this, the pig, even under such conditions, should not be eliminated. Properly managed he may return a credit to each steer fed of approximately $2."

The gains of pigs following each lot of steers in the above experiment are given. These ranged from 419 lbs. in the case of the animals following lot 1 (fancy steers) to 520 lbs. in the case of those following lot 4 (medium steers).

Wheat v. maize as food for fattening cattle, T. WINTER (*Bd. Agr. and Fisheries* [*London*], *Rpt. Agr. Education and Research, 1902–3, pp. 66–68*).—One lot of 5 steers was fed 3 lbs. of maize meal per head daily, and another similar lot 3 lbs. of wheat meal, both lots receiving a uniform basal ration of pulped swedes, chaffed oat straw, chaffed hay, and decorticated cotton-seed cake. In 10 weeks the lot fed maize meal gained 791 lbs. and the lot fed wheat meal 749 lbs. The maize meal ration was somewhat the cheaper.

On the basis of the results obtained the author points out the fact that wheat is a valuable feeding stuff and that "it may frequently be more profitable to consume it at home than exchange it on the market for maize, when such a transaction entails considerable expense."

Feeding experiments, E. R. LLOYD (*Mississippi Sta. Rpt. 1903, pp. 12, 13*).—Statistics are given regarding the pigs kept at the station, and the wintering of the station sheep and breeding cattle. In addition, several feeding experiments are very briefly reported.

In a comparison of open yards and shelter, made with 2 lots each containing 5 steers fed the same ration of cotton-seed hulls and meal, the lot fed under shelter gained 623 lbs. in 90 days and the lot fed in the open yard 731 lbs. At the beginning of the trial the difference in weight between the 2 lots was 110 lbs.

Using 2 lots, each containing 4 2-year-old steers, differing in weight by 63 lbs.,

Johnson grass hay was compared with cotton-seed hulls. Lot 1 ate 4,550 lbs. of Johnson grass hay and 1,790 lbs. of cotton-seed meal and gained in the 90 days of the test 342 lbs. On the same quantity of cotton-seed meal and 5,238 lbs. of cotton-seed hulls lot 2 gained 370 lbs.

In a second test a lot of 2-year-old heifers was fed Johnson grass hay without grain and consumed little more than enough to maintain them; while a second lot, fed cotton-seed hulls without grain, would not eat enough for maintenance, losing 83 lbs. in 39 days when 20 lbs. of hulls were consumed per day per 1,000 lbs. live weight.

Four animals pastured on poor Bermuda grass and fed grain twice daily consumed during the summer $24.36 worth of grain and gained 760 lbs; while a second lot of 4 animals, pastured without grain, gained 500 lbs. during the summer. A lot of thin but vigorous 2-year-old steers after being wintered on a ration little more than sufficient for maintenance made an average daily gain of 1.3 lbs. on pasturage for 178 days. A similar lot which had received full feed during the winter made an average daily gain of 0.75 lb. for 158 days on pasture. Heifers of the same age wintered on lignt feed made an average daily gain per head of 1.3 lbs. for 178 days on pasture alone. The pasture contained 20 acres of open land seeded to orchard grass, redtop, alfalfa, melilotus, oats, and hairy vetch. Excluding woodland, the pasture "carried 1 cow to every 1.1 acres for 7 months."

Sheep feeding, W. T. Lawrence (*County Councils Cumberland, Durham, and Northumberland Rpt. 1902, pp. 126, 127*).—At Newton Rigg the advantage of allowing sheep to gather Swedish turnips, as compared with feeding the turnips to pastured animals, was studied with 2 lots, each containing 20 crossbred sheep. In 11 weeks the average gain per head per week with the lot fed the turnips on pasturage was 1.8 lbs. as compared with 2.3 lbs. in the case of the sheep penned on the turnip land. Somewhat smaller profits were obtained with the lot fed turnips on pasture than with the other lot.

According to the author the results fully corroborate those of former years (E. S. R., 13, p. 482), which have shown that in wet or dry weather sheep fatten more rapidly on turnip land than on grass, other conditions being equal.

Sheep-feeding experiment at Newton Rigg, D. A. Gilchrist (*Bd. Agr. and Fisheries [London], Rpt. Agr. Education and Research, 1902–3, pp. 93, 94*).—Noted above from another publication.

Experiments in sheep breeding, T. Winter (*Bd. Agr. and Fisheries [London], Rpt. Agr. Education and Research, 1902–3, pp. 70–76*).—The breeding experiments begun several years ago (E. S. R., 14, p. 996) were continued. As regards the results obtained in crossing Wiltshire, Kerry Hill, Shropshire, and Southdown rams with Welch mountain ewes, the best results were with the Southdown, and in the author's opinion this breed furnishes a particularly suitable cross for Welsh mountain ewes for the production of fat lambs.

In a test of the value of various crosses with large crossbred ewes for the production of fat lambs, while there was not much difference between the Border-Leicester and Suffolk crosses the advantage was rather with the latter. The Border-Leicester crosses were somewhat earlier than the others. The Wiltshire cross was less satisfactory than the preceding year. "The Hampshire cross were later, but they handled well and reached good weight. The Lincoln cross proved disappointing. The lambs were neither so ripe nor so heavy as those in some of the other lots."

The native sheep of the Kerry Hill district of Montgomeryshire were crossed with Border-Leicester, Wiltshire, and Suffolk rams to determine the suitability of these crosses for the production of lambs for market purposes. The Suffolk cross was the most successful. "The lambs fattened earlier, on the whole were heavier, and were equal to any in quality. On this year's trial the Border-Leicester cross was superior to the Wiltshire cross."

Dried grains v. crushed oats as food for fattening sheep, T. Winter (*Bd. Agr. and Fisheries [London], Rpt. Agr. Education and Research, 1902–3, pp. 68–70*).—In a test covering 10 weeks the relative merits of dried brewers' grains and crushed oats were studied with 2 lots, each containing 33 Border-Leicester-Cheviot sheep. The grains tested were fed with decorticated cotton-seed cake and in addition Swedish turnips and hay ad libitum. On the ration containing dried brewers' grains the average gain in weight was 15.12 lbs. per sheep and on the crushed oat ration 16.86 lbs. The author calculates that there was a net profit of $3.26 in favor of the sheep fed the oat ration.

Annual wool review, W. J. Battison (*Boston: Rockwell and Churchill Press, 1903, pp. 47; repr. from Bul. Nat. Assoc. Wool Manufacturers, 1903, Dec.*).—This publication contains estimates of the number of sheep and of the wool products of the United States for 1903, discussions of forest reserves and sheep raising, weight of fleece and shrinkage of wool, and a number of tables furnishing statistical data of interest to those engaged in wool production and the wool trade.

The estimated value of the wool crop of 1903, "based on the value of the scoured pound at the seaboard," is 124,366,205 lbs., having a total value of $58,775,373, the value per pound for fleece being 48.8 cts. and for pulled wool 43.4 cts. The total value of the wool crop is 3.14 per cent less than that of the previous year, the decrease being due to a reduction in the total quantity of wool produced. On the other hand, the value of fleece wool, it is stated, has increased 7.86 per cent and that of pulled wool 9.32 per cent. In 1903 the average weight of fleeces was 6.25 lbs. as compared with 6.50 lbs. in 1902, and the average skrinkage 60.8 per cent as compared with 60 per cent.

Regarding the sheep industry in the United States the conditions indicate "that the future prosperity of the American sheep industry lies in a gradual but radical change in the manner in which it is conducted. The day of extremely large flocks on unlimited ranges is beginning to pass away. The sheep will have to be kept in smaller flocks, and those adapted to closer confinement substituted for breeds which are dependent on a wide range for profitable existence. . . . Surprise has often been expressed that farmers in the Eastern and Middle States do not pay more attention to sheep. The cause appears to be, in a great measure, the same as that which prevents the growing of carpet wools in this country. Other branches of agriculture require less care and exertion, or yield better returns for capital invested and time and labor expended. . . . Notwithstanding the disadvantages, there is still a good profit to be made from sheep, and we note a tendency in New York State toward an increase in the number of small flocks, on farms in heretofore exclusive dairy sections, the sheep being kept partially for the purpose of destroying weeds in the pasture."

Feeding dried potatoes, W. Schneidewind (*Illus. Landw. Ztg., 23 (1903), No. 48, p. 523; abs. in Centbl. Agr. Chem., 32 (1903), No. 12, pp. 830, 831*).—Feeding experiments with pigs convinced the author that dried potatoes, even if finely ground, were less digestible than ground barley; so different methods of preparation were tested with a view to increasing their digestibility, including very fine grinding, soaking in hot and cold water, and treatment with malt. The last method was the only one which gave satisfactory results. Malting was easily accomplished, malt being simply added to potatoes wet with hot water and allowed to stand for several hours. The mass was thick at first but soon became rather thin and was readily eaten in this form. Cattle and horses, it is stated, digest dried potatoes more thoroughly than pigs.

Bacon production, G. E. Day (*Ontario Agr. Col. and Expt. Farm Bul. [illegible], pp. 23, figs. 2, dgms. 5*).—Various problems connected with bacon production are discussed on the basis of results obtained at the station, such topics as the following being con-

sidered: Buildings, Canadian export bacon trade, breeding for bacon, feeding, and management.

Feeding of poultry, C. E. J. Walkey (*Jour. Bd. Agr. [London], 10 (1903), No. 3, pp. 355–369, figs. 2*).—The feeding and care of chickens, ducks, geese, and turkeys are discussed; rations are suggested; directions for making poultry houses are given, and other related topics are spoken of.

Poultry fattening by trough and machine (*Mark Lane Express, 88 (1903), No. 3748, p. 70*).—Four tests, each with 44 chickens and covering about 3 weeks, were made at the Agricultural and Horticultural Training Farm at Uckfield. The chickens were fed from troughs and later with a cramming machine, receiving a mixture of skim milk, ground oats, and fat in different proportions. The best results were obtained when 8 lbs. of ground oats and 1 lb. of fat were fed per gallon of skim milk.

Fattening fowls in Ireland (*Mark Lane Express, 88 (1903), No. 3724, p. 171*).—In a test made by the Windgap Cooperative Poultry Society, County Kilkenny, 28 fowls, divided into lots of 7, and fed in coops for 10 days on maize meal and pollard 4:3, wet with separator skim milk, gained nearly 1 lb. each. The total profit was calculated to be $3.54.

Breeding geese for "foie gras" (*Mark Lane Express, 88 (1903), No. 3762, p. 482*).—The fattening of geese for the production of large livers for use in making "foie gras" is briefly described. During the fattening period, which lasts from 4 to 5 or possibly 6 weeks, the birds are kept in close cages and are fed 2 or 3 times a day, by cramming, a daily ration consisting of 1.5 lbs. maize meal and beans cooked in water, the amount being increased as the appetite grows. The geese are supplied with fresh water to which a little wood charcoal is sometimes added.

The effect on hens' eggs of the rays emitted by radium, G. Schwarz (*Arch. Physiol. [Pflüger], 100 (1903), No. 9–10, pp. 532–546, figs. 5*).—Two-hundredths gram of radium bromid inclosed in a brass box was placed on the shell of an egg. In the bottom of the box there was an opening covered by a plate of mica which permitted the passage of the Becquerel rays. In one of the tests the operation was carried out in an atmosphere of hydrogen.

From the results of all the tests it appeared that the rays induced a number of marked changes. Where they acted upon the shell a light-gray color was noticeable. The membrane lining the egg was unaffected, but the white was thickened and a sort of skin formed in it. A luminous light-gray patch about 5 mm. in diameter was observed in the yolk. This patch was somewhat harder than the surrounding portion. The flavor was changed.

The author concludes that the Becquerel rays induce changes in albumenoid bodies similar to those produced by dry distillation, but do not cause extensive changes in native proteids. They remove the color from the organic pigment lutein. Furthermore, these rays exercise a marked effect upon lecithin in cell substances. This fact, it is believed, explains their biological effect, and especially their effect upon rapidly growing normal and pathological tissue.

Pheasants, C. L. Darlington (*Boston: Hub Poultry and Supply Co., 1902, pp. 48, pls. 4, fig. 1*).—On the basis of personal experience, the author gives directions for housing, breeding, feeding, care, and management of Asiatic pheasants, quail, prairie chickens, and partridges or ruffed grouse. In the author's opinion all these birds may be successfully and profitably raised in captivity.

DAIRY FARMING—DAIRYING.

Report of dairy department, J. S. MOORE (*Mississippi Sta. Rpt. 1903, pp. 14–19*).—A record is given of 9 cows for one year. The average yield was 5,329 lbs. of milk and 295.2 lbs. of butter fat. The cost of feed was $30.34, and the value of butter, at 25 cts. per lb., $86.11. A comparison was made of Johnson grass hay and cotton-seed hulls. The experiment included 2 lots of 3 cows each and lasted about 12 weeks. The results indicated that 15 lbs. of well cleaned cotton-seed hulls is equal in feeding value to 10 lbs. of prime Johnson grass hay. Data are given for an experiment in feeding 3 calves on skim milk.

Creaming by the centrifugal separator and by the shallow pan system were compared as regards the loss of fat in the skim milk. The average results of a number of tests showed 0.078 per cent of fat in the skim milk from the centrifugal separator, and 0.33 per cent from the shallow-pan system, the temperature in the latter case ranging from 61 to 69° F. It is stated that the results indicated a much smaller percentage of fat in the skim milk from the shallow-pan system than is usually claimed.

The dairy industry in Denmark, H. DE ROTHSCHILD (*L'industrie laitière au Danemark. Paris: Octave Doin, 1904, pp. 106, pls. 33, figs. 5, map 1*).—This report is addressed to the Minister of Agriculture of France, under whose direction a study was made of the feeding of cows, the production and sale of milk, and the manufacture of butter in Denmark, and is a clear, well illustrated exposition of the subject.

In part 1 of the report, dealing with the production of milk, the author describes the breeds of dairy cows and considers stable hygiene, feeding, milking, instruction in dairying, cooperative societies for the improvement of dairy herds by feeding and breeding, and feeding experiments. In part 2, on commerce in milk, descriptions are given of the 2 principal dairies supplying the city of Copenhagen with milk. In part 3, dealing with the manufacture and exportation of butter, descriptions are given of a cooperative dairy and a cooperative butter factory; and dairy societies, control of margarine and butter, butter exhibits, and exportation of butter are discussed.

Butter-fat tests of thoroughbred cows, L. ANDERSON (*California Sta. Rpt. 1902–3, p. 119*).—Data are given for official 7-day tests of 3 Holstein cows.

The Hegelund or Danish method of milking compared with the ordinary method, HENKEL (*Milch Ztg., 33 (1904), Nos. 1, pp. 4–6; 2, pp. 19, 20*).—The Hegelund method of milking is described and several tests of the method are reported.

One test lasting about 1 week was made in Bavaria with 37 cows. The cows were first milked in the ordinary manner, except that unusual care was taken to secure all the milk possible. They were then milked by the Hegelund method. The average daily yield by the ordinary method was 7.16 kg. of milk, containing 3.85 per cent or 275.8 gm. of fat. The residual, or after-milk obtained by the manipulation method averaged 217.4 gm. per day and contained 7.8 per cent or 17 gm. of fat. The increase yield obtained by the Hegelund method was therefore 3.4 per cent of milk and 6.2 per cent of fat. In no case was it impossible to obtain additional milk by the Hegelund method.

Similar tests with 6 cows were made in two localities in Algau. The average additional yield by the Hegelund method was 272.1 gm. of milk and 20.9 gm. of fat, or 2.5 and 5.3 per cent, respectively.

In each of 3 other experiments 3 cows were milked in the ordinary manner for several days, then by the Hegelund method for a similar period, and finally by the ordinary method during a third period. Weather conditions interfered somewhat with one of the tests, nevertheless the results as a whole were considered as favorable to the Hegelund method.

The additional time required by the Hegelund method following ordinary milking averaged from 2 to 2½ minutes. The increased yield is thought to pay well for the

extra time, although other advantages such as increasing the productive capacity of cows, lessening the occurrence of diseases of the udder, and necessitating increased cleanliness are claimed for the method. On the basis of the results obtained it is estimated that the general adoption of the method would increase the annual value of the milk production of Germany to the extent of $30,000,000.

Results of demonstration experiments on the feeding of dairy cows, conducted under the supervision of the Government during the winters of 1901-2 and 1902-3, J. VANDERVAEREN (*Bul. Cercle Études Agron.* [*Brussels*], *1904, No. 9, pp. 505–519*).—During the winters of 1901–2 and 1902–3, 92 feeding experiments were conducted in the different provinces of Belgium under the supervision of representatives of the ministry of agriculture. The details of these experiments have appeared in two reports (E. S. R., 14, p. 488; 15, p. 809). This article summarizes some of the results. It was found that the rations in ordinary use were frequently more expensive than necessary, and were often deficient in proteids. Under the direction of an expert the ration in ordinary use was compared with a new ration made up of the same materials with the addition, in most instances, of feeding stuffs rich in proteids furnished gratuitously by the Government. Each experiment comprised two periods during which the ordinary ration was fed and an intervening period during which the improved ration was fed, the three periods being separated by transitional periods. The results of the experiments are presented in two tables. In 37 out of the 39 experiments conducted with 129 cows during the first winter the results showed a net profit varying from about 1.7 to 2.1 cts. per day per cow, not including the increased value of the manure. In 52 out of the 53 experiments conducted with 156 cows during the second winter the increase in net profits varied from about 0.9 to 28 cts. per cow per day. Averaging all results the net profit the first winter was increased about 6.4 cts. per cow per day, and the second winter about 6.3 cts. From these results it is estimated that the average increase in net profit per year from rational feeding would amount to about $9.65 per cow.

Demonstration experiments on the feeding of dairy cows, conducted at the expense and under the supervision of the Government during the winter of 1902-3 (*Bul. Agr.* [*Brussels*], *19* (*1903*), *No. 6, pp. 991–1193*).—This is a detailed report upon 53 feeding experiments carried out in the different provinces of Belgium with a view to improving the rations in ordinary use. The number of cows in the different experiments was usually 2 to 4. The experiments lasted generally about one month, and in each instance consisted in a comparison of the ordinary ration and a modification of this ration believed to be better adapted to the conditions. The results are discussed and summarized for the individual experiments, but no general conclusions are drawn.

Concentrated commercial feeding stuffs and the feeding of dairy cows, A. GRÉGOIRE (*Bul. Cercle Études Agron.* [*Brussels*], *1904, No. 9, pp. 495–504*).—The author discusses the composition of feeding stuffs, the rôle of the different nutrients in animal nutrition, and the calculation of rations, and describes some of the more frequently used concentrated feeds such as linseed cake, cotton-seed meal, malt sprouts, etc. Some of the results of the demonstration experiments conducted in Belgium are given in the discussion. In 39 out of 51 instances the amount of digestible proteids actually fed was below the amount estimated as required.

Relations between food fat, body fat, and milk fat, A. EINECKE (*Mitt. Landw. Inst. Univ. Breslau, 2* (*1903*), *No. 3, pp. 559–645, dgm. 1*).—This article consists of a critical review of the literature of this subject and the details and summarized results of 4 feeding experiments.

Goats were used as the experimental animals, the number varying in the different experiments from 2 to 4. Each experiment consisted of 3 periods of 14 days each, not including a preliminary period. During the second period an emulsion of either rape-seed oil, cocoanut oil, or linseed oil was fed, the results being compared with

those obtained during the first and third periods, when only the control ration, consisting for the most part of hay and wheat feed, was fed The nutritive ratio of the rations was approximately 1:5.4. The fat content of the milk was determined gravimetrically and by the Gerber method, and determinations were made of the Köttstorfer, Reichert-Meissl, and Hübl numbers, the index of refraction, and the melting point of the butter fat. Slaughter tests were also made in some of the experiments.

No constant relation was observed between the feeding of 30 or 50 gm. of rape-seed oil per head per day and the yield of milk. Neither was there apparently any specific influence exerted by the fat in the food upon the percentage of fat in the milk. The yield of fat on the whole was slightly increased by the feeding of rape-seed oil and linseed oil. Cocoanut oil fed at the rate of 30 gm. per head per day increased the yield of fat, and fed at the rate of 50 gm. decreased the yield. In no case, however, was the increase in yield sufficient to justify, from a practical standpoint, the intensive feeding of fat.

In 3 of the experiments the results showed a specific influence of the fat in the food upon the chemical composition of the butter fat, while in the fourth experiment no such influence was apparent. Rape-seed oil and linseed oil decreased the Köttstorfer and Reichert-Meissl numbers and increased the Hübl and refractometer numbers. Cocoanut oil in one experiment increased the Köttstorfer number and decreased the Reichert-Meissl, Hübl, and refractometer numbers, while in another experiment it was apparently without influence in this respect. The melting point of the butter fat was lowered to a slight extent by rape-seed oil and cocoanut oil, and to a greater extent by linseed oil. The influence of feeding fat upon the chemical composition of butter is considered as clearly established by the experiments of the author and by the experiments cited in the article.

Determinations were made of the Köttstorfer, Reichert-Meissl, and Hübl numbers of the body fat of goats killed at the end of the different periods. While the Hübl number of butter fat was increased by the feeding of fat, that of the body fat was decreased. The results are discussed in relation to the hypothesis of Soxhlet, that in the intensive feeding of fat the organism utilizes primarily the body fat rather than the food fat in the production of butter fat, which hypothesis, as well as that relating to the profitableness of such feeding, were not considered as confirmed by the work reported.

The source of milk fat, its changes, and experiments in the determination of individuality in milk secretion, I. Dolgikh (*Arch. Vet. Nauk, St. Petersburg, 33* (*1903*), *Nos. 11, pp. 1118–1159; 12, pp. 1243–1325*).—The literature of this subject is critically reviewed in connection with bibliographical references, and an attempt is made to draw from this mass of literature conclusions regarding the source of milk fat and the individuality of milk secretion in different cows.

It was found in a study of the literature that the time of the maximum production of milk varied in different cows according to individual peculiarities, which could not be definitely formulated. In general the quantity of milk produced was greater when the cows were fed on a heavy ration than when fed on medium or light rations. A considerable difference, however, was observed in the ability of different cows to make profitable use of large quantities of fat. The ability of yielding large quantities of milk and producing correspondingly large quantities of milk fat appears to be capable of increase, but depends also to a considerable extent upon the potential nervous energy of individual cows and upon the physical development of the various organs of the body.

Influence of feeding and milking on the composition of milk, P. Dechambre (*Jour. Agricole* [*Paris*], *14* (*1903*), *Nos. 164, pp. 191–194; 165, pp. 216–219*).—The author discusses briefly the rôle of proteids, fats, and carbohydrates in the nutrition of cows, the influence of various feeding stuffs upon the composition of milk, and

the effect of different methods of milking. Sanitary precautions to be observed in milking are mentioned.

On the variation in the composition of cow's milk, W. A. D. RUDGE (*Dept. Agr. Cambridge Univ. Rpt. 1902–3, pp. 92–98, dgms. 3; Bd. Agr. and Fisheries* [*London*], *Rpt. Agr. Education and Research, 1902–3, pp. 120–125*).—Three cows were milked at equal intervals, twice daily for 14 days, and at intervals of 16 and 8 hours for another period of 14 days. Determinations were made of the total solids and fat in the milk of each cow morning and evening. The data showed considerable variations in the yield and fat content of the milk, especially when the intervals between milkings were unequal; a larger yield of milk with a lower fat content following the longer interval. The cow giving the richest milk showed also the greatest variations in the yield and fat content of the milk.

Daily variations in the acidity and fat content of milk, M. SIEGFELD (*Molk. Ztg.*, *17* (*1903*), *No. 49, pp. 1075, 1076*).—The morning's milk of 5 dairies was tested daily for about 6 weeks. The acidity in terms of cubic centimeters of decinormal sodium hydroxid required to neutralize 100 cc. of milk varied from 13.2 to 19.5. Differences of 1 or 2 cc. from morning to morning were common. The greatest difference was 4.9. The daily variations in amount of fat in the milk of the 5 herds exceeded 0.5 per cent from 1 to 9 times during the 36 days on which tests were made. The greatest daily variation was 1.05 per cent. Causes of such variations are noted and earlier work by the author is cited (E. S. R., 12, p. 786; 13, p. 885).

The influence and the disposition of some mineral substances fed to milch cows, C. SCHULTE-BÄUMINGHAUS (*Mitt. Landw. Inst. Univ. Breslau*, *2* (*1902*), *No. 1, pp. 25–69; abs. in Centbl. Agr. Chem.*, *32* (*1903*), *No. 7, pp. 477–483*).—A study was made of the effect of feeding calcium hydroxid, sodium chlorid, iron acetate, and calcium phosphate. None of these substances affected apparently the yield of milk or its fat content; neither was the total ash appreciably affected. Calcium hydroxid and calcium phosphate increased slightly the percentage of calcium in the ash. There was no increase in the phosphoric acid or iron due to the feeding of these substances.

A contribution to the study of slowly creaming milks, L. MARCAS (*Bul. Agr.* [*Brussels*], *19* (*1903*), *No. 6, pp. 1228–1234*).—In continuation of the work of Henseval (E. S. R., 14, p. 388), the author made a comparative study of ordinary milk and milk showing a slow rising of the cream. In creamometer tests with ordinary milk at 10 to 14° C. the layer of cream was clearly differentiated in 6 to 8 hours, while with samples of slowly creaming milk the separation was not complete in 12 hours and occasionally no differentiation was apparent at the end of 24 hours. A similar difference between the 2 types of milk was shown in experiments with the centrifuge. The fat content of the slowly creaming milk was generally higher than that of ordinary milk. The averages of a number of analyses of the 2 types showed respectively 3.95 and 3.08 per cent of fat. The other constituents in the slowly creaming milk were also normal. The results of a number of experiments with different centrifugal separators showed that the skim milk from the 2 types of milk varied in fat content from 0.1 to 0.15 per cent. A still greater difference was observed in the skim milk obtained in the creamometer tests. Determinations were made of the phosphoric acid and lime in the ash of the slowly creaming milk, and instead of finding a deficiency, as reported by other investigators and advanced as a cause of the peculiarity, the author found a slight excess of these constituents.

Premature coagulation of milk, R. BURRI (*Milch. Ztg.*, *32* (*1903*), *No. 45, pp. 705–707*).—The milk of a number of cows was found to coagulate in 5 hours when kept at 37° C., while ordinarily coagulation under such conditions would not occur until a much later period. A bacteriological examination of this milk when fresh showed the almost exclusive presence of 2 forms of bacteria, one a liquefying micrococcus and the other lactic-acid bacteria, which latter comprised 5 per cent or more of the total number of bacteria present.

The micrococcus developed to the exclusion of the lactic-acid bacteria, and was practically the only form found at the time of coagulation. This organism is believed to be an inhabitant of the udder, especially of the milk ducts, and its growth there is thought to be facilitated by incomplete milking. Its action in coagulating milk, which was also demonstrated experimentally, is attributed to the production of a rennet ferment. The coagulated milk was sweet to the taste and showed no higher percentage of acid than normal milk.

Chemical composition of the milk supply of Milan, C. BERTOCCHI (*Ann. Soc. Chim., 1903, No. 4–5; abs. in Rev. Gén. Lait, 3 (1904), No. 7, p. 163*).—Analyses were made of 4,700 samples of milk from 2,100 cows in one locality, and of 18,610 samples from 2,300 cows in another locality, the average composition in the first case being specific gravity 1.0317, fat content 3.61 per cent, solids-not-fat 8.91 per cent; and in the second case specific gravity 1.0316, fat content 3.70 per cent, and solids-not-fat 8.91 per cent. The author concludes that the local regulation requiring 9 per cent of solids-not-fat should be modified.

The bacterial content of fresh milk, A. LUX (*Centbl. Bakt. u. Par., 2. Abt., 11 (1903), Nos. 6–7, 195–201; 8–9, pp. 267–277*).—The 6 species of bacteria most frequently found in the 260 samples of cows' milk and 95 samples of goats' milk examined were *Staphylococcus mastitis albus*, *S. mastitis aureus*, *Galactococcus versicolor*, *Bacterium prodigiosum*, *B. luteum*, and a non-liquefying, gas-producing bacterium (*B. lactis ærogenes*, *B. acidi lactici*, or *B. coli commune*). The different organisms are described. Of these the *Staphylococcus mastitis albus* was by far the most frequently found.

The results of the experiments are given in a series of tables which show among other data the number and kind of bacteria in the first, second, and third streams of milk, a sample obtained at the middle of the milking, and a sample obtained at the end of the milking; and also the number of bacteria in the milk from the different teats. Considerable variations were observed in the number of bacteria in the different samples. In general, however, the first milk was no richer in bacterial content than the second or third streams, and often contained less than the samples obtained at the middle and end of the milking.

The daily variations in number of bacteria per cubic centimeter in milk drawn from the same teat were marked. The figures for 6 consecutive days were as follows: 2,044, 1,844, 600, 1,467, 11, and 44. The influence of the length of time between milkings upon the bacterial content of the milk was also studied. Samples of milk obtained after intervals varying from 2 to 24 hours showed a bacterial content in one instance ranging from 22 to 1,217, and in another instance from 65 to 2,933 per cubic centimeter, the numbers increasing with the length of time. Some influence on the bacterial content of the milk was attributed to the feeding stuffs, which were not uniform for the different groups of animals.

Powdered milk, A. DUBOIS (*Jour. Agr. Prat., n. ser., 7 (1904), No. 1, pp. 15, 16, fig. 1*).—The Just-Hatmaker method of making milk powder is described.

Dried milk, J. VANDERVAEREN (*Rev. Gén. Agron. [Louvain], 12 (1903), No. 11, pp. 471–477*).—A summary of information regarding preparations made from skim milk dried and ground.

A new aroma-producing species of bacteria in butter, S. A. SEWERIN (*Centbl. Bakt. u. Par., 2. Abt., 11, 1903, Nos. 6–7, pp. 202–206; 8–9, pp. 260–266*).—The cultural characteristics of a bacterium isolated from sour cream, having a pleasant, fruity odor, are described. The organism, to which the name *Bacterium aromaticus butyri* is given, was capable of producing the characteristic aroma in different culture media at room temperatures. In milk the aroma was produced to a marked extent only when the organism was grown in symbiosis with lactic-acid bacteria. The development of the organism in butter rather than in the cream from which it was made

resulted in the appearance of the aroma in the course of 2 to 4 weeks. When grown on ordinary gelatin the development of aroma ceased in 3 months; but when grown on other media, including lactose-gelatin, the development of the aroma was constant during the 8 months in which observations were made.

Weedy flavors in butter, L. ANDERSON (*California Sta. Rpt. 1902–3, pp. 121–126*).—Several experiments were made at a creamery for the purpose of finding a method of getting rid of flavors in butter which seemed traceable to weeds eaten by cows. Full data, including analyses of the butter, are given for the 7 experiments made. Butter made according to the regular practice of the creamery and with no starter, or with a buttermilk or Hansen's pure culture starter, had in all cases the objectionable flavor attributed to the weeds. Butter made from cream which had been mixed with an equal volume of warm water and again run through the separator was commented upon as having no flavor whatever. Butter made from pasteurized cream was also free from the weedy flavor.

Ripening of cheese in cold storage compared with ripening in the ordinary curing room, H. H. DEAN and R. HARCOURT (*Ontario Agr. Col. and Expt. Farm Bul. 131, pp. 16, dgms. 2*).—This gives the results of 8 series of experiments conducted during 1902 in continuation of earlier work (E. S. R., 14, p. 909).

In the first series 4 cheeses were made from the same vat of milk. One cheese was ripened in cold storage at about 38° F., one was placed in an ordinary curing room for 1 week and then in cold storage, one was placed in an ordinary curing room for 2 weeks and then in cold storage, and one was ripened in the ordinary manner. The experiment was repeated 6 times during the period from April to September. The loss in weight of the 4 cheeses during 1 month averaged, respectively, 2.26, 2.90, 3.20, and 4.21 per cent. Very little difference was observed in the quality of the cheese ripened in cold storage, while that ripened in the ordinary curing room was much inferior in quality.

In the second series 4 cheeses were ripened in cold storage and one was ripened in the ordinary curing room. One cheese was removed from cold storage at the end of 1 month, one at the end of 2 months, and one at the end of 3 months. Six experiments of this kind were made during the season. The cheese ripened entirely in cold storage stood first as regards quality. The cheese ripened in the ordinary curing room was the poorest. While the quality was improved by the length of time in cold storage, no marked deterioration was observed in the cheese removed from cold storage to a higher temperature.

In the third series the effect of an extra quantity of rennet was studied. In each of 8 experiments 4 cheeses were made, rennet in all cases being used at the rate of 6 oz. per 1,000 lbs. of milk. One cheese was placed in cold storage directly from the press, one at the end of 1 week, one at the end of 2 weeks, and one was ripened in the ordinary curing room. The average total scores were respectively as follows: 94.45, 93.89, 92.75, and 89.10. As compared with the results obtained in other series of experiments, the extra quantity of rennet was believed to improve the quality of the cheese. The results were also believed to indicate that where a large quantity of rennet is used the cheese should be placed in cold storage soon after being made.

In the fourth series cheese was made by using a large quantity of rennet (6 oz. per 1,000 lbs. of milk), cooking to 94° instead of to 98°, and using a small quantity of salt (2 lbs. per 100 lbs. of curd), and compared with cheese made in the ordinary manner. An increase of 1.1 per cent in the yield of cheese resulted from using an extra amount of rennet, cooking to a lower temperature, and using less salt when the cheese was ripened in the ordinary curing room; and an increase of 2.1 per cent when ripened in cold storage. Cheese made in this way, however, did not score as high as cheese made in the ordinary manner.

In the fifth series less salt was used than ordinarily and the cheese was ripened in cold storage. Salting at the rate of $2\frac{3}{4}$ lbs. per 100 lbs. of curd decreased the yield slightly, but improved the quality as compared with salting at the rate of $2\frac{1}{4}$ lbs.

In the sixth series boxing cheese directly from the press, or after remaining one week in an ordinary curing room, and ripening in cold storage was compared with ordinary methods of handling. The cheese put in boxes directly from the press and ripened in cold storage scored highest. "The results indicate very forcibly that cheese may be put into a dry, clean cheese box directly from the press, or after being one week in an ordinary ripening room, and then be put in cold storage at an average temperature of 38 to 40° and 90 per cent humidity with very satisfactory results."

The results of the seventh series indicated that the use of formalin is effective in preventing the growth of mold. The method, however, is not considered very satisfactory on account of the expense.

Further experiments were made during 1902 in coating cheese with paraffin. The cheeses were dipped directly from the press and at the end of 1, 2, and 3 weeks, and ripened in an ordinary curing room and in cold storage. As regards the appearance of the cheese, the best results were obtained by dipping after about one week and placing in cold storage. There was no great difference as regards the quality of the cheese. Paraffining reduced the loss from shrinkage, the cheese dipped directly from the press and cured in cold storage losing practically nothing in weight during 1 month, while cheese dipped at the end of 1 week lost 0.78 per cent; dipped at the end of 2 weeks, 1.57 per cent; dipped at the end of 3 weeks, 2.36 per cent; and cheese not coated, 3.16 per cent. The authors state that so far as their work has gone they are not prepared to recommend the general paraffining of cheese to the ordinary factoryman.

No white specks were observed in cold-cured cheese, which is attributed to the fact that the temperature was not allowed to fall below the freezing point.

Determinations were made each month during the season of the total nitrogen, nitrogen in soluble form, and ammonia in cheese ripened in cold storage and in the curing room. During the first month 9.9 per cent of the total casein in the cheese in cold storage was changed to soluble compounds, while 17.6 per cent of the casein in the cheese in the curing room was rendered soluble. For the first 2 months the percentages were, respectively, 12.6 and 23.1, after which the average monthly gain for the cheese in cold storage was 2.06 per cent, and for the cheese in the curing room 1.95 per cent. Judging from the rate of formation of soluble compounds, the cheese in the curing room ripened about as much in 1 month as the cheese in cold storage did in 4 months. The rate of formation of ammonia compounds corresponded closely to the rate of decomposition of casein. Cheese made during June, July, and August contained more soluble compounds when taken from the press than cheese made in the spring and fall. The rate of ripening in both cold storage and in the curing room was also more rapid than that of cheese made during the other seasons. The use of $2\frac{3}{4}$ lbs. of salt per 100 lbs. of curd as compared with the use of $2\frac{1}{4}$ lbs., decreased the amount of moisture in the cheese by nearly 1 per cent and retarded the rate of ripening.

The appearance of strictly anaerobic butyric-acid bacilli and other anaerobic forms in hard cheese, E. von Freudenreich (*Centbl. Bakt. u. Par., 2. Abt., 11 (1903), No. 10–11, pp. 327–330; Rev. Gen. Lait, 3 (1904), No. 12, pp. 265–268*).—The author does not believe that anaerobic bacteria reported by Rodella (E. S. R., 15, p. 401) as occurring regularly in hard cheese have anything to do with the ripening process. Similar experiments were made by him in 1895 and 1896,[a] the results of which indicated that strictly anaerobic bacteria were

[a] Centbl. Bakt. u. Par., 2. Abt., 1 (1895), No. 24, p. 854; 2 (1896), No. 10–11, p. 316.

not numerous in cheese, although they might be found in all cases by the use of large quantities in the preparation of cultures.

In 0.5 gm. of cheese the anaerobic forms were not regularly present, while the lactic-acid bacteria numbered millions. In only one instance has the author found anaerobic bacteria belonging to the class producing butyric-acid fermentation present in large numbers, and the eating of this cheese caused the sickness of a number of persons. The strictly anaerobic bacteria as well as the Tyrothrix forms are believed to be found in cheese only as accidental infections and of no importance in cheese ripening.

Studies on the micro-organisms of Swedish cheese, Gerda Troili-Petersson (*Centbl. Bakt. u. Par., 2. Abt., 11 (1903), Nos. 4–5, pp. 120–143; 6–7 pp. 207–215, pls. 3*).—Bacteriological studies were made of the common farm cheese of Sweden (Herrgårdsost) which is very similar to the Emmenthaler. Descriptions are given of the 38 species of bacteria, yeasts, and fungi found. Strictly anaerobic bacteria were only exceptionally found. Tyrothrix forms were present only in very small numbers. *Oidium lactis* was found only once. Lactic acid and peptonizing bacteria were present, the former predominating toward the end of the ripening process. Rennet-producing staphylococci were found, as were also several species of yeasts. Gas-producing bacteria were present in small numbers. The yeasts, peptonizing micrococci, and certain bacteria were common only in the early stages of the ripening process. The total number of bacteria was greatest in fresh cheese and tended to diminish with the age of the cheese. Bacteria were not found to be evenly distributed throughout the cheese, but formed colonies varying greatly in form and size. It is the author's intention to study further the relation of the different micro-organisms to the process of cheese ripening.

A comparison of the bacterial content of cheese cured at different temperatures, F. C. Harrison and W. T. Connell (*Ontario Agr. Col. and Expt. Farm Bul. 130, pp. 24*).—This has been noted from another source (E. S. R., 15, p. 717).

Cheese making, L. Anderson (*California Sta. Rpt. 1902–3, pp. 119–121*).—Brief notes are given on instruction at creameries and cheese factories by representatives of the station, and on the results of the first trial in making cheese by students in in the dairy school. The cheese was scored by a well-known expert and by a commercial firm, and the results were considered very encouraging to the enterprise.

Proceedings of the ninth annual meeting of the Georgia Dairymen's Association, 1903 (*Proc. Georgia Dairymen's Assoc., 1903, pp. 43*).—This contains the addresses delivered at the meeting held at Athens, Ga., August 4 and 5, 1903. G. W. Holmes discussed the subject of practical dairying, making suggestions concerning the selection, care, and feeding of cows and the handling of milk. B. W. Hunt discussed the addition of phosphates to cattle rations, stating that his practice was to give one-half ounce of phosphate of lime to each cow several times per month. W. A. Henry discussed the subject of agricultural education, paying particular attention to the work being done by the University of Wisconsin; and also the subject of feeding stuffs, with special reference to Georgia conditions. I. C. Wade expressed his views concerning the model dairy cow, and discussed in a general way dairying in the South. C. L. Willoughby pointed out ways of lessening the cost of dairy production, emphasizing particularly the importance of growing more feeding stuffs rather than purchasing commercial feeds. B. W. Hunt urged the putting forth of greater efforts in the extermination of the cattle tick (*Boophilus bovis*).

VETERINARY SCIENCE AND PRACTICE.

Veterinary science and bacteriology, A. R. WARD (*California Sta. Rpt. 1902-3, pp. 114-118*).—In 1901 a study was made of an outbreak of hog cholera at Red Bluff. Texas fever caused considerable loss to dairymen in Orange County. An investigation was made of the causes of ropy milk and scours in calves. Verminous bronchitis in calves was treated by the administration of the usual remedies by intratracheal method as well as by inhalation and by way of the mouth. No noticeable results were produced. By an act of the California legislature a poultry experiment station has been established at Petaluma and work is being carried on at this place in the study of poultry diseases. This investigation is prosecuted in cooperation with V. A. Moore.

Annual report of the civil veterinary department, Bengal, 1902-3 (*Calcutta: Bengal Secretariat Press, pp. 18, pl. 1*).—Notes are presented on veterinary dispensaries in various parts of Bengal and on the prevalence and treatment of glanders, rinderpest, and other diseases. Brief notes are also given on the condition of the Bengal Veterinary College.

Report of the chief inspector of stock and brands, C. J. VALENTINE (*Rpt. Min. Agr. South Australia, 1903, pp. 38-42*).—Brief notes on ticks, lice, worms, and foot rot in sheep; pleuro-pneumonia, tuberculosis, and actinomycosis in cattle; and various diseases of horses, camels, and hogs.

Generalized tuberculosis in cattle, SCHROEDER (*Berlin. Tierärztl. Wchnschr., 1903, No. 30, pp. 471, 472*).—An examination of cases of generalized tuberculosis showed that the meat was in good condition, while the lungs, liver, portions of the ribs, and other structures were extensively affected by the disease. The lymphatic glands and other structures around the joints were so greatly altered that lameness was produced as a result.

The infectiousness of milk of tuberculous cows in the light of recent investigations, LYDIA RABINOWITSCH (*Centbl. Bakt. u. Par., 1. Abt., Ref., 34 (1903), No. 8-9, pp. 225-236*).—A critical review is presented of recent literature relating to this subject. While there is not an entire agreement in the results obtained by different investigators with the milk of tuberculous cows, it is concluded that the investigations thus far made indicate that the milk of such cows may be pathogenic for both children and young animals.

Tuberculosis caused by dead tubercle bacilli, N. PANOV (*Dissertation, Yuriev, 1902, pp. 134, pl. 1*).—The literature of this subject is critically reviewed in connection with a bibliography. The author's experiments were made on rabbits, and the tubercle bacilli were obtained from consumptive human patients. Rabbits were inoculated with cultures of dead tubercle bacilli and were later examined for the purpose of studying the histology of "necrotuberculosis." It was found that dead tubercle bacilli contained positively chemotactic toxins which developed other active properties in direct contact with the living cells. These toxins cause the formation of tubercles, which at first become necrotic in the center, but later exhibit degeneration and proliferation of connective tissue. When introduced into experimental animals in large quantities dead tubercle bacilli may cause death, and when inoculated by the subcutaneous method they produce suppuration.

Intestinal tuberculosis in sheep, T. MICUCCI (*Gior. R. Soc. Accad. Vet. Ital., 52 (1903), No. 35, pp. 817, 818*).—On account of the comparative rarity of this disease in sheep, detailed notes are given on a case of intestinal origin in which the liver was enlarged and cirrhotic and infested with flukeworms. The organ was also permeated with tubercles. The lymphatic glands of the liver were hypertrophic and somewhat degenerated. The lungs and other abdominal organs, except the

liver, were in a normal condition. A bacteriological examination of the tubercles in the liver showed the presence of numerous tubercle bacilli.

Culture of the tubercle bacillus on yolk of egg and gelose, F. Bezançon (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 16, pp. 603–605*).—Notes are given on the behavior of the tubercle bacillus on this medium when maintained at a temperature of about 38° C., with special reference to the variability of the tubercle bacillus.

The valuation and slaughter of tuberculous animals, Loze (*Jour. Agr. Prat.* [*Toulouse*], *99 (1903), No. 4, pp. 211–215*).—Brief statistics are given on the prevalence of tuberculosis in France and on the legal procedure in the payment of indemnities for cattle slaughtered on account of infection with tuberculosis.

Diagnosis of anthrax, Krüger (*Berlin. Tierärztl. Wchnschr., 1903, No. 22, pp. 353–355*).—This article is of a controversial nature and in it the author seeks to show that bacteriological examination of tissues of animals affected with anthrax is not a reliable means of diagnosing this disease. In many instances a most careful examination of tissues has failed to show the presence of the anthrax bacillus. It is urged that all other means of diagnosis should be used in conjunction with the bacteriological test.

The transmission of anthrax on tanned leather, S. V. Obukhov (*Arch. Vet. Nauk. St. Petersburg, 33 (1903), No. 10, pp. 1030, 1031*).—A harness which had been on a horse that had recently died with anthrax was placed on a healthy horse, with the result that the latter animal subsequently contracted anthrax. The author had success, however, in treating the case by antisepsis of the anthrax swellings and internal use of sodium salicylate.

Cutaneous infection with anthrax bacilli, A. Treutlein (*Centbl. Allg. Path. u. Path. Anat., 14 (1903), No. 7–8, pp. 257–264*).—In the author's experiments 2 rabbits were used in testing the possibility of cutaneous infection. Small areas of skin were carefully shaved, so as not to cause any lesion or reddening. Anthrax cultures were then rubbed upon the skin by a sterilized cork. The rubbing was done gently and with very slight pressure. Infection took place, and the animals died after 3 and 4 days, respectively. The anthrax bacilli penetrated through the hair follicles, from which they penetrated into the lymphatic spaces and later into the blood system. Attention is called to the significance of the results of this experiment in explaining the etiology of anthrax in men engaged in tanning and similar commercial occupations.

Vaccination against blackleg, D. G. Guccione (*Gior. R. Soc. Accad. Vet. Ital., 52 (1903), No. 23, pp. 591–595*).—In the author's experience in the use of Arloing's method of vaccinating for blackleg, 301 cattle were vaccinated, and of this number only 1 died with the disease. Of 28 control animals, however, maintained under the same conditions, 5 died. The method is believed to be perfectly harmless, and it is recommended that cattle be vaccinated at the age of 6 months, preferably in the free end of the tail.

Vaccination against blackleg, E. Bastianini (*Gior. R. Soc. Accad. Vet. Ital., 52 (1903), No. 30, pp. 697–699*).—Statistics are given on 3,621 cattle vaccinated for the prevention of blackleg. Of this number only 8 died. The method of vaccination used was that proposed by Arloing, and in the author's opinion this method is very effective and harmless.

The rational treatment of hemoglobinuria of cattle, Evers (*Berlin. Tierärztl. Wchnschr., 1903, No. 52, pp. 793–797*).—During the author's practice post-mortem examinations were made on 96 cattle which had died of this disease, and the conclusion was reached that the death of affected animals and all pathological alterations of various organs were to be ascribed to the destruction of the hemoglobin. The pathological symptoms disappeared as soon as the normal quantity of hemoglobin was restored. The author therefore undertook experiments for the purpose of testing

the effect of the artificial introduction of hemoglobin into cattle affected with this disease. Pure hemoglobin was purchased for this purpose and was prepared in tablets weighing 2 gm. each. During the year 1903, 43 cattle were treated in this manner, and of this number 41 recovered completely. The 2 animals which died were some distance from town and could not be treated so carefully as the other cattle. The hemoglobin was dissolved in physiological salt solution in the proportion of 1 to 50 during the first experiments, but later the percentage of hemoglobin was considerably increased. Detailed notes are given on a number of cases in which this treatment was applied. The hemoglobin was injected hypodermically and no test was made of intravenous injections. Animals submitted to this treatment recovered very rapidly, usually within from 5 to 8 days. The author believes that while hypodermic injections of hemoglobin may not cure all cases of Texas fever, it may be depended upon to give very satisfactory results in the majority of cases when administered carefully.

A disease of cattle in German East Africa resembling Texas fever, A. BRAUER (*Berlin. Tierärztl. Wchnschr., 1903, No. 27, p. 424, figs. 3*).—In various parts of German East Africa the author had occasion to observe a disease which closely resembles Texas fever in clinical symptoms. The elevation of temperature is at first rather slight, but finally reaches 42.8° C., or more. The pulse and respiration are rapid and the rate of mortality is about 50 per cent. The blood parasites appear in the early stages in the form of cocci, which are present in the blood corpuscles in considerable numbers.

Texas fever and tsetse-fly disease in West Africa, ZIEMANN (*Deut. Med. Wchnschr., 29 (1903), No. 16, pp. 289, 290*).—Redwater and blackwater are said to be local names of Texas fever, and are due to symptoms which are noted in a certain percentage of cases. In the control of Texas fever the author recommends the destruction of the ticks on infected animals and the vaccination of calves during the first two or three days of life. Vaccinated calves show small parasites in a typical form in the blood within five or six days after vaccination, but do not show hemoglobinuria or other symptoms of the disease. As a result of vaccination, a high grade of immunity is shown toward natural infection. Notes are also presented on the prevalence of tsetse-fly disease and bovine malaria in West Africa.

Tsetse-fly disease in Kamerun, ZIEMANN (*Deut. Med. Wchnschr., 29 (1903), No. 15, pp. 268, 269*).—During a study of this region with reference to the occurrence of tsetse-fly disease, the author found that the disease prevailed greatly in the interior, while the coast region was uninfected. Attention is therefore called to the desirability of regulating traffic in domesticated animals between these two regions. It is stated that the tsetse-fly disease is one of the chief causes of the present unthrifty condition of animal industry in Kamerun.

The susceptibility of mammals to tsetse-fly disease, E. MARTINI (*Deut. Med. Wchnschr., 29 (1903), No. 32, pp. 573–575, fig. 1*).—Tsetse-fly disease has already been shown to be infectious for most of the larger domesticated mammals, and also for the small experimental animals. The author tried a number of experiments in the inoculation of goats and zebras, and found that these animals were subject to a fatal form of the disease.

The rôle of ticks in the propagation of piroplasmoses, MÉGNIN (*Compt. Rend. Soc. Biol. Paris, 55 (1903), Nos. 1, pp. 4–6; 4, pp. 147–149; 5, pp. 175, 176*).—The author's investigations related to carceag of sheep and other protozoan diseases, and led him to the conclusion that ticks were as a rule not responsible for carrying these diseases. It is argued that the adult female is the only form which can transmit the disease, and that after it once detaches itself from an animal it does not seek for another host. It appears doubtful to the author, therefore, whether ticks can be considered as agents in the transmission of these diseases. It is urged that attention should be directed to the possible agency of certain biting Diptera.

The article is of a highly controversial nature, and an attempt is made to throw doubt upon the arguments advanced by A. Laveran in favor of the agency of ticks in transmitting these diseases. The species of ticks considered in the controversy are *Rhipicephalus annulatus*, *R. bursa*, and *R. sanguineus.*

The agency of ticks in the propagation of piroplasmoses, A. Laveran (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 2, pp. 61–63*).—The author agrees with Mégnin to the extent of admitting that a large proportion of the adult female ticks after they have fallen to the ground do not seek for another victim. It is argued, however, that the agency of ticks in the transmission of certain protozoan diseases, such as Texas fever, must be admitted, since it has been demonstrated by numerous observations, and the probability of ticks being instrumental in transmitting other protozoan diseases is greatly strengthened by recent investigations.

Piroplasmosis and hemoglobinemia in dogs, G. Szoyka (*Deut. Tierärztl. Wchnschr., 11 (1903), No. 25, pp. 234–236*).—The author had occasion to examine 2 cases of hemoglobinemia in dogs. The clinical symptoms of these cases are described in detail. Blood was taken from both dogs and used in inoculation experiments. The results of these experiments showed that the blood was not virulent and that no blood parasites were present. The disease was therefore not due to piroplasma, and the author considers it necessary to assume that dogs are subject to a hemoglobinemia which is clinically not distinguishable from the form caused by piroplasma.

The rôle of ticks in the development of carceag, Motas (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 14, pp. 501–504*).—According to the author's experiments, the larvæ and nymphs of *Rhipicephalus bursa*, even when born of mother ticks gorged with the blood of diseased sheep, are incapable of transmitting carceag. It is only the sexually mature tick which is capable of transmitting the disease. Eggs obtained from ticks gorged with the blood of diseased sheep contain the specific protozoan, but this organism must undergo further development before it is capable of producing the disease.

Serum therapy for foot-and-mouth disease, D. Bernardini (*Clin. Vet., 26 (1903), No. 18, pp. 105–107*).—An outline is given of the method used by Nocard in controlling this disease by vaccination. In the author's opinion the immunizing effect of a vaccine persists only for a short time.

The treatment of aphthous and healthy cattle and horses with corrosive sublimate, F. Boschetti and A. Titta (*Gior. R. Soc. Accad. Vet. Ital., 52 (1903), Nos. 8, pp. 182–184; 9, pp. 198–203; 10, pp. 230–232; 11, pp. 241–245*).—Healthy cattle, also cattle affected with foot-and-mouth disease were treated with hypodermic and intratracheal injections of corrosive sublimate. The same drug was administered to horses by the intratracheal, hypodermic, and intravenous methods. Detailed notes are given on the reactions produced in the various experimental animals and the pathological lesions produced by the corrosive sublimate are carefully described.

As a result of the authors' experiments it is concluded that corrosive sublimate in the treatment of foot-and-mouth disease in cattle, whether administered by the intravenous, hypodermic, or intratracheal methods, and whether given in small, medium, or large doses, produces an elevation of temperature within from 15 to 30 minutes, instead of a lowering of temperature as maintained by Baccelli. General trembling and nervous disturbances together with pathological lesions are also observed. The toxic effects of corrosive sublimate are very marked in some cases, and include the general symptoms of mercurialism, such as inappetence, prostration, and fluctuations in temperature. The results are the same by whatever method the corrosive sublimate is administered.

The spread of the infectious processes is not checked by the administration of the corrosive sublimate. It was also found that different animals reacted differently to the drug, so that the doses could not safely be measured out according to the weight of the animal. Corrosive sublimate was endured rather better by horses than by

cattle, but did not give satisfactory results in controlling the disease. On account of the danger connected with the use of corrosive sublimate in the treatment of foot-and-mouth disease the authors recommend that it be entirely disregarded in favor of other remedies.

Parturient apoplexy (*Bd. Agr. and Fisheries [London], Leaflet 96, pp. 2*).—Notes are given on the symptoms, methods of prevention, and treatment of this disease. In cows which are predisposed to the disease it is recommended that iodid of potash infusion be given immediately after calving, whether the symptoms of the disease have appeared or not.

Parturient paresis in cows, HOHMANN (*Berlin. Tierärztl. Wchnschr., 1903, No. 23, pp. 361–364*).—The author briefly reviews the various theories which have been proposed in explanation of this disease. An examination of a number of cases showed that the uterus was never contracted, as has been claimed by several writers, and that an obstruction to the flow of blood in the jugular vein did not cause hyperemia of the brain. Experiments were tried in which the normal circulation of the blood was interfered with in various ways, for the purpose of testing the influence of such artificial interference upon the blood pressure and the cerebral activity of the animals.

It was found to be impossible to produce any pronounced effect upon the brain action by ordinary means used in altering the blood circulation. The author believes that the essential lesions of the disease do not occur in the musculature, since meat of animals suffering from parturient paresis has been shown to be a harmless food material. The author believes that the symptoms of this disease closely resemble those of eclampsia and may be due to extensive disturbances in the nervous control of the blood circulation. In the experience of the author all cases of this disease must be considered as of a serious nature and likely to prove fatal if evidence of paralysis of the medulla oblongata appears before any remedies are applied.

In treating the disease the author recommends that the animal be maintained in a position so that it rests upon all 4 legs, that the head be kept in an upright position, and that cold applications be made to the head and neck. If there is evidence of paralysis of the brain it may be well to give subcutaneous injections of spirits of camphor or caffein. These operations should always be associated with the application of the Schmidt method and treatment by means of compressed air.

Treatment of parturient paresis by means of oxygen, A. ZEHL (*Berlin. Tierärztl. Wchnschr., 1903, No. 30, pp. 469–471*).—The author treated 9 cases of this disease with oxygen, and gives detailed notes on the history of all these cases. A complete recovery took place in all cases and the author believes that this method is perhaps most satisfactory in the treatment of parturient paresis. In the author's experience this disease develops in cows which have been dry for a few weeks previous to calving, and never occurs in cows which are milked up to the time of parturition. The author believes, therefore, that a long dry period before calving must be considered a predisposing cause of the disease. The beneficial effects of oxygen are regarded as due to the purely mechanical action of such treatment.

Infectious pneumo-pleuritis in calves, EVERS (*Berlin. Tierärztl. Wchnschr., 1903, No. 17, pp. 277, 278*).—The author tested the effect of Collargol in the treatment of diarrhea of calves, but found during these experiments that while the diarrhea yielded promptly to this treatment a large proportion of the calves died later of pneumo-pleuritis. This disease appeared in a number of localities in an epizootic form and attacked calves varying in age from 8 days to 4 months. In young calves death occurred within 4 days after the outbreak of the disease, while in older animals the course of the disease was somewhat prolonged.

The pathogenic findings in cases of this disease varied according as the disease assumed a chronic or acute form, but resembled in a general way those of swine plague. In young calves affected with the acute form of the disease the pathological

lesions were confined almost entirely to the lungs. Experiments were made in controlling this disease by vaccination with Septicidin. During his experiments 5 calves were treated and exposed to infection, but exhibited a perfect resisting power to the disease. Calves which have already exhibited the first symptoms of the disease may be successfully treated in some cases by the administration of from 5 to 30 cc. of Septicidin, while 10 cc. is sufficient for immunizing purposes.

Hydrotherapy in pneumonia, G. Giugiaro (*Gior. R. Soc. Accad. Vet. Ital., 52 (1903), No. 36, pp. 841–847*).—The author recommends, as a result of experiments in treating pneumonia, that the use of vesicants be discontinued as more or less harmful and ineffective. It is also recommended that less dependence be placed upon chemical febrifuges, such as quinin, since these remedies exercise an irritating action upon the stomach, nervous system, and kidneys. In the place of vesicants and febrifuges the author recommends the use of cold and hot water compresses upon the thoracic region, according to the nature and stage of the disease.

Pulmonary actinomycosis, M. Schlegel (*Berlin. Tierärztl. Wchnschr., 1903, No. 26, pp. 409–411*).—A detailed description is given of the alterations in cases of actinomycosis in the laryngeal glands, and in the lungs and pleura. In the foci of this disease upon the bronchi and bronchioles inflammatory processes are most pronounced, the walls of the bronchi are greatly thickened, and actinomycotic masses are distributed through them. The author believes that infection in the lungs is spread through the bronchioles and lymphatic vessels. Pulmonary actinomycosis in Germany appears to be more prevalent than has heretofore been supposed.

Aspergillosis in cattle, A. Bartolucci (*Gior. R. Soc. Accad. Vet. Ital., 52 (1903), No. 21, pp. 490–492*).—A number of cattle were affected with what the author suspected of being aspergillosis. The symptoms of the disease are described in some detail. The chief lesions were found in the lungs, in which there were characteristic areas of hepatization and inflammatory infiltration of the interlobular connective tissue. The spores of *Aspergillosis fumigatus* were found in these foci.

The working of the Scab Act, A. G. Davidson (*Agr. Jour. Cape Good Hope, 23 (1903), No. 5, pp. 558–570*).—The Scab Act of Cape Colony was passed in 1894 and amended in 1899, but has never given satisfaction. The causes of failure to eradicate scab are outlined by the author.

It is stated that sheep raisers have failed to show a hearty cooperation in the enforcement of the law and many scabby sheep thus escape treatment. A number of badly infested localities exist, and sheep after dipping are allowed to travel over such localities and become reinfested. Another cause of the prevalence of sheep scab is the careless manner in which the dipping operations are performed. In localities where the best trained and most competent men have been sent as inspectors the best results have been obtained. The author recommends the appointment of sheep inspectors by the government, the dipping of all stock under supervision, the enforcement of strict regulations regarding the removal of stock, systematic treatment of infested corrals and premises, and a system of brands to be used in identifying treated sheep.

Sorghum poisoning, W. Maxwell (*Queensland Agr. Jour., 13 (1903), No. 5, pp. 473, 474*).—The presence of hydrocyanic acid in sorghum has been demonstrated, and the quantity of the poison appears, according to the investigations of the author, to be dependent upon the nature of the soil upon which the sorghum is grown. On soil rich in nitrogenous elements the quantity of hydrocyanic acid is largest.

Some stock-poisoning plants of North Dakota, L. Van Es and L. R. Waldron (*North Dakota Sta. Bul. 58, pp. 319–354, figs. 7*).—The authors discuss the conditions under which stock most frequently become poisoned with native plants. Notes are also given on methods of preventing plant poisoning, as well as on chemical, mechanical, and physiological antidotes. The more important known or suspected of being poisonous plants in North Dakota are chosen for special discussion. These include

Cicuta maculata, *Sium cicutæfolium*, wild parsnip, *Delphinium carolinianum*, loco weeds, death camas, swamp camas, lupines, and ergot. The remedies usually recommended for the treatment of animals poisoned with these plants are discussed and notes are given on the distribution of each species and the possibility of eradicating them.

The action of bile, corrosive sublimate, and formalin on hydatids, F. Devé, (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 2, pp. 75–79*).—In general, bile was supposed to possess considerable power in the destruction of hydatids, and experiments were made to test this action. It was found that hydatids were capable of living for a considerable time in the abdominal cavity in spite of the prolonged presence of bile. In some cases the scolex resisted the action of bile completely and proceeded to undergo its usual developmental stages.

In experiments on echinococci the author found that corrosive sublimate (1: 1,000) or formalin (1: 200) would destroy the motility of these organisms within a period of 2 or 3 minutes. Further experiments were made with the scoleces of hydatids, during which corrosive sublimate and formalin were employed at the same strength. It is concluded from these experiments that echinococci are destroyed by 5 minutes' exposure to corrosive sublimate (1: 1,000) or formalin (1: 100).

Malignant catarrhal fever of cattle and the use of meat from animals affected with this disease, S. de Benedictis (*Clin. Vet., 26 (1903), Nos. 8, pp. 45–48; 10, pp. 57–60*).—A description is given of the condition of the meat observed in various cases of this disease, with special reference to lesions in the musculature. The author states that it is to be deplored that such contradictory legal decisions have been given regarding the enforcement of the law in such cases. The meat is believed to be highly unsanitary.

Intestinal coccidiosis in cattle, N. Pieroni (*Gior. R. Soc. Accad. Vet. Ital., 52 (1903), No. 7, pp. 152–156*).—A number of cases of this disease were observed, and detailed notes are given on the post-mortem findings in 1 case. No other lesions were found except in the walls of the intestines, in which there were numerous foci of an infection, especially in the mucous coat of the lower portion of the alimentary tract. The author believes that the pathogenic organism in this case is *Coccidium oviforme*.

Meat products in Naples in 1902, L. Granucci (*Gior. R. Soc. Accad. Vet. Ital., 52 (1903), No. 38, pp. 889–899*).—Brief notes are given on various causes of condemnation of meat as observed during the course of inspection of meat and meat products in Naples. Tuberculosis was observed in buffalo meat; echinococci in the spleen of cattle, hogs, and sheep; fibro-sarcomata in the diaphragm of cattle; and notes are also given on various tumors found in meat and vital organs. The various pathological findings in the meat sold in the markets of Naples are presented in a tabular form.

The distribution of Cysticercus bovis in Italian meat products, A. Boccalari (*Gior. R. Soc. Accad. Vet. Ital., 52 (1903), No. 18, pp. 409–415*).—Statistics are given showing the percentage of infestation by this parasite in beef coming from various provinces of Italy. It is suggested that infested meat be subjected to a low temperature for the purpose of destroying the parasites.

Contagious coryza, Weber (*Deut. Tierärztl. Wchnschr., 11 (1903), No. 42, pp. 391, 392*).—The author describes the symptoms and course of this disease in 2 horses which came under his observations. There was great difficulty in respiration in both cases, and in one case it was found necessary to water the animal from a tube which was inserted into the esophagus. The parotid glands and also the glands at the entrance of the thorax were greatly swollen.

Ichthargan, Goldbeck (*Deut. Tierärztl. Wchnschr., 11 (1903), No. 33, pp. 307, 308*).—Ichthargan was used in the treatment of malignant edema in the horse. It was injected intravenously in a solution in water at the rate of 1: 40, and in quantities of 4 gm. daily. Better results were obtained from the use of this remedy than from Collargol.

Ichthargan and its use in veterinary medicine, Müller (*Berlin. Tierärztl. Wchnschr., 1903, No. 24, pp. 385–388*).—The author employed this remedy first in the treatment of pneumonia in horses. The remedy was applied in a 3 per cent aqueous solution intratracheally, and caused a rapid improvement in all the animals treated within a very short time. Good results were also obtained in the use of Ichthargan in the treatment of angina in horses, malignant cartarrhal fever in cattle, and swine plague. The use of this drug in the treatment of periodical ophthalmia was without good results.

The therapeutic use of Ichthargan, R. Eberhardt (*Berlin. Tierärztl. Wchnschr., 1903, No. 21, pp. 337–343*).—This drug was used by the author in the treatment of a number of skin diseases as well as in 7 cases of influenza. In the treatment of eczematous skin diseases of the horse and herpes tonsurans of cattle excellent results were obtained by the use of Ichthargan. In all the cases of influenza the drug caused the lowering of the temperature almost to the normal, and when the temperature rose again on the succeeding days it was readily controlled by the intratracheal application of Ichthargan.

The value of Crede's silver preparation in the treatment of morbus maculosus in the horse, O. Fettick (*Deut. Tierärztl. Wchnschr., 11 (1903), Nos. 34, pp. 317–320; 35, pp. 325–328*).—The author reviews in a critical manner the literature of this subject and gives a detailed account of the use of colloidal silver in the treatment of 16 cases of morbus maculosus. It was found that even while this remedy was applied during the early stages of the disease, the symptoms became worse and the disease ended fatally in a large percentage of cases. In some cases the swellings were somewhat reduced and the petechiæ became paler, but the same results were observed not only in cases where colloidal silver was not used, but even when no treatment whatever was administered. The author concludes therefore that colloidal silver is not a specific for morbus maculosus.

Composition of some prominent veterinary proprietary remedies, S. Avery (*Agriculture [Nebraska], 2 (1903), No. 9, pp. 16–19*).—A number of proprietary remedies used as dips and for preventing the attack of flies, curing hog cholera, etc., were analyzed. All of these remedies are sold at prices much higher than the actual cost of materials requires. A number of them were found to be quite ineffective.

The nuisance of patent medicines, J. Schmidt (*Deut. Tierärztl. Wchnschr., 11 (1903), Nos. 43, pp. 401–403; 44, pp. 409–411*).—A list is presented of a large number of proprietary medicines, together with brief notes on the unfounded claims which are made by the manufacturers regarding the efficacy of these medicines. In the control of this nuisance the author believes that the first necessary step is the proper information of the public regarding the worthlessness of such remedies, and the passage of laws forbidding their sale. Such a law has already been adopted in Bavaria.

Hog cholera, N. S. Mayo (*Industrialist, 30 (1903), No. 8, pp. 120–122*).—Attention is called to the great economic importance of hog cholera throughout the corn-raising section of the country. At least 3 contagious diseases are commonly referred to as hog cholera. In Kansas a law has been passed requiring owners to bury or burn within 24 hours all hogs that have died of hog cholera.

Observations on swine erysipelas, swine plague, and hog cholera, Träger (*Berlin. Tierärztl. Wchnschr., 1903, No. 25, pp. 394–403*).—Swine erysipelas is said to be on the increase in various parts of Germany and some evidence of increase has been obtained for swine plague and hog cholera. The number of animals vaccinated for the prevention of these diseases has greatly increased during the past few years and the results of such vaccinations are highly satisfactory. In the control of contagious diseases of hogs the author believes that compulsory notification occupies an important place, and attention is also called to the necessity of more strict measures of

disinfection after outbreaks of contagious diseases. The author described some of the difficulties met with in persuading the more ignorant farmers of the necessity and harmlessness of known methods of vaccination. The prejudice of such farmers against vaccination sometimes leads to the unnecessary distribution of the disease through not complying with legal regulations regarding such matters.

A contribution to the identity of swine erysipelas and urticaria, H. Schmidt (*Berlin. Tierärztl. Wchnschr., 1903, No. 22, pp. 351, 352*).—Notes are given on a number of cases of these diseases which were diagnosed by the author. A history is given of a case of swine erysipelas in a sow, which was treated with swine erysipelas serum. Within 1 day after the last injection of serum 8 pigs were born of this sow, all of which exhibited the bluish-violet rectangular spots characteristic of the disease. It is believed that these cases are evidence of the possible congenital origin of swine erysipelas.

The period at which the organism of swine erysipelas and fowl cholera may be recognized in the internal organs of mice after hypodermic inoculation, T. Tiede (*Ztschr. Tiermed., 7 (1903), No. 1, pp. 41–67*).—There are 4 common methods by which this problem is studied, viz: By treating the point of inoculation with chemical disinfectants, with hot iron, by removing the tissue around the point of inoculation, and by killing and examining infected animals after periods of determined length. The author reviews in a critical manner the work which has been done by previous investigators on this subject in a study of anthrax, malignant edema, glanders, sheep pox, etc. From a study of this literature it appears that no general rules can be laid down regarding the time required for the penetration of bacteria from the point of infection into the internal organs. This period varies according to the virulence of the micro-organisms, the susceptibility of the experimental animals, and especially the method of inoculation. The author's experiments were confined to a study of the bacilli of swine erysipelas and fowl cholera, and the method followed consisted in inoculating the mice in the ear with virulent cultures and killing the experimental animals after definite periods have elapsed. The various internal organs were then carefully examined for the presence of bacteria. It was found during these experiments that the bacillus of swine erysipelas could be demonstrated in mice inoculated hypodermically as follows: In the spleen and liver after 15 hours; in the liver and lungs, and to some extent in the spleen, after 24 hours; and in large quantities in all organs after 48 hours. The organism of fowl cholera was found sparingly in the spleen, liver, lungs, and heart after 15 minutes; in considerable numbers in all organs after 45 minutes, and generally distributed in all organs after 4 hours. The quantity of bacilli increased constantly from this period until death took place.

Vaccination for swine erysipelas in 1902, Teetz (*Berlin. Tierärztl. Wchnschr., 1903, No. 19, pp. 304–306*).—In the author's experiments hogs were vaccinated with serum and immediately afterwards with an attenuated culture of the bacillus of swine erysipelas. In a number of cases in which the serum and culture were given simultaneously unsatisfactory results were obtained. A striking curative property was observed when dogs were inoculated with serum and cultures in rapid succession. In the locality where these experiments were made it was stated that Septicidin had given unsatisfactory results.

From the author's experience with swine erysipelas it is concluded that the disease appears in 3 forms: Simple erysipelas of the skin, urticaria, and a mixture of these 2 forms. The author believes that vaccination is unnecessary in the case of urticaria, since animals usually recover from this disease without treatment. In internal erysipelas no hope can be entertained of successful treatment, provided the skin already exhibits a pronounced red color. Vaccination with doses 4 or 5 times the ordinary size proved ineffective in such cases.

Report on vaccination for swine erysipelas in Saxony by the use of Lorenz vaccine, H. RAEBIGER (*Berlin. Tierärztl. Wchnschr., 1903, No. 22, p. 351*).—The Government has undertaken to pay indemnity for all losses caused by vaccination with the Lorenz vaccine prepared in the vaccine institute at Prenzlau. Indemnity was paid for all animals which died within 12 months after vaccination. Of the 165,000 vaccinated animals only 42 died of swine erysipelas. In the future it is recommended that all hogs which die with apparent symptoms of swine erysipelas be examined and that portions of the lungs, heart, spleen, or kidneys be sent to the vaccine institute for examination.

The most suitable position of hogs for vaccinating purposes, BURY and GOLDBERG (*Berlin. Tierärztl. Wchnschr., 1903, No. 22, pp. 350, 351*).—In the experience of the authors the best success and the least trouble was had in restraining hogs by means of a cord drawn through the mouth and fastened to the head.

The position of the hog during vaccination, PLATSCHEK and JOSEPH (*Berlin. Tierärztl. Wchnschr., 1903, No. 30, pp. 472, 473*).—Young pigs may be readily held in the hands by one assistant, while larger hogs may often be successfully vaccinated in comparatively dark and close quarters by rapid manipulations without the use of any throwing apparatus.

The etiology of rabies, A. RABIEAUX (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 2, pp. 91–93*).—The author conducted a number of experiments in an attempt to explain the cause of the virulence of the saliva of rabid animals. The saliva was obtained in a pure condition through the canal of Wharton. Numerous experiments were made in attempting to cultivate some organism from the virus thus obtained. These experiments were without results. It was found that when a virulent emulsion was injected into the aqueous humor of the eye of rabbits and dogs the virulence of the aqueous humor rapidly disappeared.

Treatment of tetanus with sodium iodid, E. GRAMS (*Berlin. Tierärztl. Wchnschr., 1903, No. 15, pp. 249–255*).—During the past 7 years the author treated 35 cases of tetanus by means of sodium iodid. As a rule this remedy was administered intratracheally in doses of 5 gm. in solution. Detailed notes are given on the effects of the drug in different cases.

The author believes as a result of his studies on tetanus that this disease is always of traumatic origin. The symptoms appear in most cases within 14 days after infection and it is believed that it is only in subacute cases that any hope of success may be had from treatment. The average course of the disease in subacute cases is about 30 days. In the treatment of the disease the author recommends careful attention to diet, the use of a slinging apparatus if necessary, and the administration of sodium iodid intratracheally, intravenously, *per os*, or *per rectum*. The quantity of the drug to be used is not of primary importance, but good results were obtained by the author from the use of 2 to 3 gm. dissolved in 10 gm. of water and administered immediately after infection and daily for 2 or 3 days thereafter.

Tetanus in dogs, GRUNAU (*Berlin. Tierärztl. Wchnschr., 1903, No. 29, p. 458*).—On account of the rarity of typical cases of this disease in dogs the author gives brief notes on cases which he has observed. In a case which resulted from wound infection the head was held stretched out in a straight line and considerable difficulty in swallowing was manifested. The case exhibited pronounced opisthotonus.

A pathogenic Streptothrix found in dogs, TROLLDENIER (*Ztschr. Tiermed., 7 (1903), No. 2, pp. 81–109, figs. 9*).—A detailed post-mortem examination was made on a dog which it was thought had been poisoned with strychnin or some other toxic substance. As a result of this examination it was found that some of the lymphatic glands were enlarged and caseous, while a pronounced inflammation was discovered in the membranes of the brain and in the kidneys. An organism was isolated from the diseased tissue and was cultivated on various nutrient media.

Inoculation experiments were also carried out on various experimental animals. It was found during these experiments that the organism was pathogenic for mice, guinea pigs, rabbits, and dogs, and slightly so for fowls, horses, calves, and cats. The morphology of this organism is described and notes are given on the pathology of the affected tissue. The organism, while referred to as a Streptothrix, is believed to be more properly referred to the genus Actinomyces, and the author therefore proposes the name *A. bicolor*.

Roup, an experimental study, F. C. Harrison and H. Streit (*Ontario Agr. Col. and Expt. Farm Bul. 132, pp. 48, figs. 25*).—For many years this disease has appeared in the poultry yards of the Ontario Agricultural College, usually during damp autumn weather. It causes a direct loss of from 10 to 15 per cent of fowls and attacks principally young birds. Detailed notes are given on the clinical symptoms and pathological lesions of this disease in various parts and organs of the body. In pathological material obtained from diseased birds the authors demonstrated the presence of *Bacillus cacosmus*, which is called the roup bacillus. Notes are given on the behavior of this organism on various nutrient media. The virulence of the roup bacillus, as first obtained was quite weak, but was increased by repeated passages through pigeons. Numerous infection experiments by different methods were carried out. It was found that in order to infect fowls experimentally it was necessary to use roup bacilli from a culture which had been freshly isolated. Pigeons when inoculated with a roup bacillus became infected and exhibited symptoms similar to roup in fowls. Extensive necrosis of muscle tissue was produced by inoculation with the roup bacillus. Feeding experiments with roup bacillus yielded negative results. Several attempts were made to immunize fowls and rabbits, but without any success. Inoculation experiments with *Bacillus pyocyaneus* showed that this organism is capable of producing chicken diphtheria, but that its virulence is soon lost by growing on ordinary culture media.

Treatment of fowl cholera by Septicidin, Schmidt (*Berlin. Tierärztl. Wchnschr., 1903, No. 27, pp. 421–423*).—An outbreak of this disease took place during the past season in a village near Dresden and spread rapidly, showing a high virulence. The author vaccinated 60 birds with Septicidin, including chickens and ducks. For each bird 1 cc. of the serum was used. On another estate 36 chickens, turkeys, and ducks were vaccinated with doses of 2 cc. of Septicidin. As a result of vaccination of these fowls the rate of mortality from fowl cholera was reduced to 5 per cent, while among birds which were not vaccinated the mortality was frequently 100 per cent. According to the author's experience Septicidin may be used also in the diagnosis of fowl cholera.

AGRICULTURAL ENGINEERING.

The testing of road materials, L. W. Page and A. S. Cushman (*U. S. Dept. Agr., Bureau of Chemistry Bul. 79, pp. 77, pls. 5, figs. 10*).—The main object of this bulletin is to describe in some detail the methods and work of the road-material laboratory of the Bureau of Chemistry of this Department established in December, 1900, and to give the results obtained up to the present time. "Incidentally, the physical, mechanical, and chemical agencies which act upon road materials are discussed and a brief history of the testing of such materials is given."

The principal activities of the laboratory are classified as follows: "(1) Tests for determining the quality of materials to aid road builders in selecting those most suitable for their work; (2) the investigation of various processes to develop simple, appropriate, and reliable tests; (3) the collection of data for use in drawing up specifications for standards of quality; (4) scientific research to develop new materials or mixtures, and the study of problems which may arise in road building.

"The most important work comes under the first head, for the main object of the

aboratory is to obtain results, by means of appropriate tests on small samples, which will agree sufficiently well with the results of practice to aid the road builder in selecting the most suitable materials from those available for his work."

The methods and tests used in the laboratory, which are described and for which data are in some cases given, include the abrasion, cementation, absorption, specific gravity, and weight per cubic foot, hardness, and compression and tensile strength tests of rock and gravel; and "rattler," absorption, cross-breaking, and compression tests for paving brick. In tests of cement the methods of the American Society of Civil Engineers are followed. The petrographic and chemical methods used in the examination of rocks for the purpose of classification are also described. The results of examinations of a large number of materials from different parts of the United States are given.

As regards the general question of the practical application of laboratory results the authors say:

"The proper interpretation and application of the results obtained in the laboratory are quite as important as the general accuracy and appropriateness of the tests themselves. It is probable that many engineers and others interested in the subject of road building who have found time to examine the question only superficially have misunderstood the bearing and value of road-material testing. In all cases the results obtained in testing materials of construction are of relative rather than absolute value. Even quite a large variation in the results yielded by different test pieces of the same sample should not condemn the practical value of the figures if they are properly applied and interpreted. . . .

"Given a number of materials for laboratory examination, it is not pretended that an actual practical grade of excellence can be established. On the other hand, if more than one material is available, it is quite possible for the laboratory to point out which one would yield the best results, both as to immediate excellence and length of life under known conditions of climate and traffic."

The farm railroad (tramway) and the results obtained with it on the Buhlendorf estate, REICHERT (*Fühling's Landw. Ztg., 52 (1903), Nos. 22, pp. 797–817, figs. 17; 23, pp. 852–864, figs. 7*).—The advantages of farm tramways in general are explained; the installation on the Buhlendorf estate, which is largely devoted to sugar-beet growing, is described; and the uses made of the tramways on this estate and the profits resulting from their use are discussed.

An example of thin macadam road construction along the Charles River, Massachusetts, J. A. HOLMES (*Engineer. News, 51 (1904), No. 2, pp. 32, 33, figs. 3*).

The construction of roads, paths, and sea defenses, F. LATHAM (*London: Sanitary Pub. Co., Ltd., 1903, pp. IV+221, figs. 57*).

The construction of terraces, E. LEPLAE (*Rev. Gén. Agron.* [*Louvain*], *12 (1903), No. 10, pp. 435–442*).—This is an extract from a course of instruction given at the agricultural institute of Louvain.

The possibilities of irrigation in South Africa, C. D. H. BRAINE (*Agr. Jour. Cape Good Hope, 24 (1904), No. 1, pp. 48–58*).—A general discussion of this subject.

Preliminary plans and estimates for drainage of Fresno district, California, C. G. ELLIOTT (*California Sta. Rpt. 1902–3, pp. 57–64, dgms. 2*).—A reprint of Circular 50 of this office (E. S. R., 15, p. 94).

The Cache River drainage survey, A. H. BELL (*Engineer. News, 51 (1904), No. 5, pp. 115, 116*).—This is a brief account of the preliminary operations of a commission appointed by the Governor of Illinois under the provisions of a recent bill passed by the legislature of the State for a survey of the Cache River to ascertain the practicability of straightening and deepening the channel of the river for the purpose of preventing overflow of the bottom lands and for the drainage of these lands.

The mitigation of floods in the Hunter River, J. H. MAIDEN (*Jour. and Proc. Roy. Soc. New South Wales, 36 (1902), pp. 107–131*). This article discusses the causes

of floods in Hunter River and suggests the following remedial and preventive measures: "(1) Intelligent control of ringbarking or felling; . . . (2) repair of little incipient rivulets by gradual replanting or placement of obstructions (logs, etc.); (3) planting of willows and other trees, shrubs, grasses, etc.; (4) chamfering of the banks; (5) fencing of banks; and (6) burning as much as possible of the dead timber and branches to prevent their finding their way into the water-courses and scouring the banks."

The composition of sewage in relation to problems of disposal, G. W. FULLER (*Tech. Quart., 16 (1903), No. 2, pp. 132–160*).—From a review of investigations relating to this subject the author reaches the conclusion that it is "questionable whether the amount of added knowledge which may be obtained from a continuance of present methods year after year is going to be commensurate with the cost. In fact, it seems that the time is approaching when it is worth while to consider a recasting of the program for sewage analyses. . . .

"In studying exhaustively the chemical and biological changes which take place in polluted waters, and the conditions under which putrefaction may be avoided, it is believed that the relative significance should be studied of the 'absolute oxygen-consuming powers' of the organic matter in sewage or effluent expressed in terms which can be readily appreciated; of the oxygen dissolved in the sewage or effluent, together with that which may be yielded by nitrates, sulphates, and other constituents of the liquid; of the oxygen similarly contained in the water into which the sewage or effluent is discharged; of the oxygen which may be received in the water by means of aeration and from higher forms of vegetable life; and of the absolute oxygen-consuming powers of the organic matter in the water of the stream and in the sediment on the bottom and sides of the stream itself. To these factors should be added the effect of the very important items of temperature and the period of time during which biological changes may take place."

Farm buildings, J. DANGUY (*Constructions rurales. Paris: J. B. Baillière & Sons, 1904, pp. 442, figs. 273*).

Barn plans and outbuildings (*New York: Orange Judd Co., 1903, pp. XVI + 388, pl. 1, figs. 374*).—A revised and enlarged edition of this book, first issued about 20 years ago, in which has been incorporated plans and descriptions of modern improvements in construction, ventilation, sanitation, etc., of farm buildings. The original edition was prepared largely by B. D. Halsted, the revised edition by E. C. Powell.

A new type of steam shovel (*Engineer. and Min. Jour., 77 (1904), No. 5, p. 205, fig. 1*).—The construction and operation of the Kilgore direct-acting steam shovel are discussed.

Fowler's steam disk plow (*Deut. Landw. Presse, 30 (1903), Nos. 98, p. 844; 102, p. 881, fig. 1*).—Brief notes on the construction and operation of this plow.

An automobile cultivator, G. CAYE (*Nature [Paris], 31 (1903), No. 1555, pp. 237, 238, figs. 2*).—A revolving "digger" drawn by an automotor is described.

Combined cultivators and seeders, M. RINGELMANN (*Jour. Agr. Prat., n. ser., 7 (1904), No. 2, pp. 46–51, figs. 6*).—Various forms are described, with brief accounts of tests.

Cotton gins: The saw gin, F. MAIN (*Jour. Agr. Prat., n. ser., 6 (1903), No. 50, pp. 774–776, figs. 2*).—The construction and operation of this type of gin are discussed. A previous article (E. S. R., 15, p. 522) discussed roller gins.

Recent progress in the field of agricultural machinery, W. HEERBERGER, A. NACHTWEH, L. WROBEL, E. WROBEL, and W. STEEGER (*Fühling's Landw. Ztg., 52 (1903), Nos. 1, pp. 36–39, figs. 4; 2, pp. 76–78, figs. 2; 3, pp. 112–114, fig. 1; 4, pp. 190, 191, fig. 1; 6, pp. 223–228, figs. 6; 7, pp. 266–268, figs. 2; 8, pp. 300–303, figs. 3; 9, pp. 332–337, figs. 3; 10, pp. 367–372, figs. 6; 11, pp. 402–408, figs. 6; 12, pp. 433–447, figs. 9; 13, pp. 482, 483; 14, pp. 520–523, fig. 1; 15, pp. 554, 555, fig. 1; 16, pp. 594–596, figs. 2; 17, pp. 636–638, figs. 2; 18, pp. 684–686, figs. 3; 19, pp. 721, 722, figs. 2; 22, pp. 837–840, figs.

3; 23, pp. 889–892, figs. 5).—Notes are given on a self-feeding thresher, butter workers, portable engines, hand distributor for fertilizers, dust-proof plow hub, beet seed cleaning apparatus, thresher with simple cleaning device, sod plow, fan, coupling, clutch, seed cleaner and grader, steam plow (cable), safety device for threshers, plows, feed cutters, combined harvesting machines (mower and tedder, and wagon truck and rake), mowing machines, two-row beet digger, continuous milk cooler, horse rakes, beet harvesters, straw carrier for threshing machines, and steam boilers.

MISCELLANEOUS.

Fifteenth Annual Report of Arkansas Station, 1902 (*Arkansas Sta. Rpt. 1902, pp. 148*).—This includes the organization list of the station; a brief statement by the director concerning the publications of the station during the year; a financial statement for the fiscal year ended June 30, 1902; and reprints of Bulletins 71–76 of the station on the following subjects: Why apple trees fail (E. S. R., 14, p. 43); sweet-potato experiments (E. S. R., 14, p. 435); pork-production experiments and hog ranching (E. S. R., 14, p. 486); the phosphate rocks of Arkansas (E. S. R., 14, p. 430); alfalfa (E. S. R., 14, p. 433); and pig-feeding experiments with cotton-seed meal (E. S. R., 15, p. 68).

Report of California Station, 1902–3 (*California Sta. Rpt. 1902–3, pp. 222*).—This includes a financial statement for the fiscal year ended June 30, 1902; the organization list of the station; a general review of station work by the director; a report on farmers' institutes, by E. J. Wickson; numerous articles abstracted elsewhere; brief summaries of several of the bulletins issued by the station; reports of the California Substations; and a list of donations and exchanges.

Sixteenth Annual Report of Michigan Station, 1903 (*Michigan Sta. Rpt. 1903, pp. 73–293*).—This contains a financial statement for the fiscal year ended June 30, 1903; a report of the director on the work of the station during the year; departmental reports; meteorological observations noted elsewhere; and reprints of Bulletins 203–210 and Special Bulletins 17–19 of the station on the following subjects: Analyses of some of the commercial feeding stuffs of Michigan (E. S. R., 15, p. 67); mosquitoes and other insects of the year 1902 (E. S. R., 15, p. 61); report of South Haven Substation (E. S. R., 15, p. 38); notes on small fruits (E. S. R., 15, p. 42); sugar-beet experiments, 1902 (E. S. R., 15, p. 35); Michigan mushrooms (E. S. R., 15, p. 123); vegetable and bush fruits (E. S. R., 15, p. 252); fertilizer analyses (E. S. R., 15, p. 348); sugar beets in the Upper Peninsula (E. S. R., 15, p. 36); and spraying calendar (E. S. R., 15, p. 61).

Sixteenth Annual Report of Mississippi Station, 1903 (*Mississippi Sta. Rpt. 1903, pp. 31*).—This includes the organization list of the station; a financial statement for the fiscal year ended June 30, 1903; and reports of the director and heads of departments containing outlines and some of the results of station work during the year. Parts of these reports are noted elsewhere. A brief summary of the work at the McNeill Branch Station, by E. B. Ferris, concludes the report.

Twenty-First Annual Report of New York State Station, 1902 (*New York State Sta. Rpt. 1902, pp. 473*).—This contains the organization list of the station; a financial statement for the year ended September 30, 1902; and reprints of Bulletins 212–229 of the station on the following subjects: Director's report for 1902 (E. S. R., 14, p. 1131); control of rusty spot in cheese factories (E. S. R., 14, p. 908); two unusual troubles of apple foliage (E. S. R., 14, p. 774); potato-spraying experiments in 1902 (E. S. R., 14, p. 875); raspberry cane blight and raspberry yellows (E. S. R., 14, p. 981); a destructive apple rot following scab (E. S. R., 14, p. 1088); a study of some of the salts formed by casein and paracasein with acids: Their relations to American Cheddar cheese (E. S. R., 14, p. 607); methods for the estimation of the

proteolytic compounds contained in cheese and milk (E. S. R., 14, p. 545); some of the compounds present in American Cheddar cheese (E. S. R., 14, p. 805); miscellaneous notes on injurious insects, II (E. S. R., 14, p. 62); treatment for San José scale in orchards: II, Spraying with kerosene and crude petroleum (E. S. R., 14, p. 470); San José scale investigations, IV (E. S. R., 14, p. 1094); variety test of strawberries (E. S. R., 14, p. 761); investigations concerning the self-fertility of the grape, 1900–1902 (E. S. R., 14, p. 869); a study of grape pollen (E. S. R., 14, p. 870); report of analyses of commercial fertilizers for the spring and fall of 1902 (E. S. R., 14, p. 558); inspection of feeding stuffs (E. S. R., 14, p. 790); and report of analyses of Paris green and other insecticides in 1902 (E. S. R., 14, p. 889). A reprint of a circular is noted elsewhere. An appendix contains a list of the periodicals received by the station, and meteorological observations noted elsewhere.

Fourteenth Annual Report of West Virginia Station, 1901 (*West Virginia Sta. Rpt. 1901, pp. 27*).—This includes the organization list of the station; a financial statement for the fiscal year ended June 30, 1901; and a rather full review of the work of the station during the year, by the director.

Report on farmers' institutes—summer season, 1903 (*Bul. North Carolina State Bd. Agr., 24 (1903), No. 10, pp. 64, figs. 2*).—This bulletin contains the following papers read at farmers' institutes during the summer of 1903: Stock Raising, Common Diseases of Farm Animals, The Cattle Tick and the Quarantine Restrictions, and Condimental Stock Foods and Condition Powders, by T. Butler; Improvement of the Soil, and The Home Garden and Orchard, by W. F. Massey; Varieties of Corn and Cotton and Their Improvement by Seed Selection, by C. B. Williams; Soil Improvement, and Fertilizer Materials and Fertilizers—Mixtures for Different Crops, by B. W. Kilgore; and Forage Crops for the Southern Farm, by C. C. Moore.

North Dakota Farmers' Institute Annual, 1903, edited by E. E. KAUFMAN (*North Dakota Farmers' Inst. Ann. 1903, pp. 192, figs. 32*).—This is made up of a large number of short articles, some of which are taken from other publications. Among the original articles mention may be made of the following: Testing Cows, by E. E. Kaufman; What the Department of Agriculture is doing for the Farmer of the Northwest, by C. B. Smith; Problems in Breeding, by W. M. Hays; Farming in North Dakota, by T. A. Overstad; The Market for Macaroni Wheat, by M. A. Carleton; Farmers' Institutes, by J. H. Worst; Varieties of Corn, and Corn Culture, by E. G. Schollander; The Care of the Corn Crop, and The Construction of Silos, by C. J. Zintheo; Eradicating the Mustard, by E. G. Schollander; Small Fruits in North Dakota, by R. S. Northrop; Some North Dakota Weeds, by L. R. Waldron; and The Underground Water Supply, by D. E. Willard.

Conditions for intensive and extensive agriculture in Germany, J. FROST (*Inaug. Diss., Univ. Berlin, 1903, pp. 91*).—This thesis treats of the relationship of climate, soil, dismemberment of estates, transportation, markets, labor, and capital to intensive and extensive agriculture in Germany.

Management of the Estate Lobositz, W. MEDINGER (*Inaug. Diss., Univ. Halle, 1902, pp. 203*).—The history of the estate is given and the climate, location, soil, and management are described. The history of the management dates back over a century.

Development of French agriculture under the present tariff system, B. FRANKE (*Inaug. Diss., Univ. Berlin, 1903, pp. 19*).—In connection with a discussion of the subject the author presents statistics with reference to production, consumption, and value of different agricultural products for a series of years. Comparative data for other countries are also given.

Agriculture in New Zealand, M. MURPHY (*New Zealand Offic. Yearbook [illegible], pp. 588–605*).—The agricultural conditions of New Zealand are spoken of with reference to the principal crops grown, and the cattle, sheep, horse, swine, and poultry industries. Many statistics are given.

Twenty-fourth annual report of the Director of the United States Geological Survey to the Secretary of the Interior, 1902-3, C. D. WALCOTT (*Ann. Rpt. U. S. Geol. Survey, 24* (*1902-3*), *pp. 302, pls. 26*).—This report explains the organization of the bureau and outlines the work of the year in its various branches.

"The Survey as now organized is divided into five branches, the geologic, topographic, hydrographic, publication, and administrative. The geologic branch includes the divisions of geology, and paleontology, of mining and mineral resources, and of physics and chemistry." The topographic branch includes divisions of topography and geography and forestry. The hydrographic branch includes "the work of the division of hydrography and also that of the reclamation service, organized to carry on the surveys and examinations authorized by the reclamation law. The proceeds of the sale of public lands in the Western States and Territories, which were set aside to create a fund for this purpose, amount to between $3,000,000 and $4,000,000 a year. . . . A division of hydrology has also been added to the hydrographic branch, the purpose of which is to study geologic conditions governing the occurrence of underground waters. Another feature of this branch is the division of hydro-economics, of which the chief raison d'être is the investigation of the quality of water and its effect on various industries."

Foreign trade in farm and forest products, 1903, G. K. HOLMES (*U. S. Dept. Agr., Bureau of Statistics Circ. 15, pp. 20*).—The total value of the imports of farm products during 1903 was $456,199,325 and of the exports, $878,479,451. The imports of the forest products amounted to $71,478,022 and the exports to $58,281,124.

Wine statistics of Switzerland, 1902 (*Landw. Jahrb. Schweiz, 17* (*1903*), *No. 9, pp. 443-541*).—This is the third report of this character, and consists of statistical data relating to the wine industry in the different cantons of Switzerland, and analyses of over 700 samples.

Accessions to the Department Library, 1903 (*U. S. Dept. Agr., Library Buls. 46, pp. 67; 47, pp. 56; 48, pp. 45; 49, pp. 64*).

NOTES.

Connecticut Storrs Station.—As previously noted (E. S. R., 15, p. 525), the station has arranged for conducting experiments in cooperation with the Bureau of Animal Industry of this Department in the making of soft cheeses. In connection with this work, Dr. Charles Thom, of Ithaca, N. Y., has been appointed mycologist; Alfred W. Bosworth, formerly of the Rhode Island Station, chemist; and E. B. von Heyne, of Waterville, N. Y., practical cheese maker.

Florida University and Station.—The recent legislature enacted a law giving the university power to investigate, segregate, or destroy domestic animals afflicted with communicable diseases. The station veterinarian was appointed for this work. Two considerable outbreaks of glanders in the State have been suppressed. Twenty-six thoroughbred Shorthorn cattle have been inoculated this winter for protection against Texas fever, with no deaths so far. The practicability of shipment of cattle direct to the owner and subsequent inoculation for fever is also being tested. Its success so far seems certain. This will relieve the owner of considerable expense attendant upon having the work done at the station itself. The old greenhouses having become unsuitable have been repaired and put in excellent condition. Cooperative experiments in the control of potato diseases have been instituted in connection with C. G. White, at Hastings, which is the largest potato-producing section of the State.

Hawaii Station.—Plans have been made for an office building and a chemical laboratory building, to be erected with funds appropriated by the Territorial legislature. The new buildings will be located on the naval hospital site adjacent to the land already occupied by the station.

Idaho University and Station.—Short courses in horticulture and dairying have been conducted at the university this season.

Kentucky College and Station.—The legislature has appropriated $15,000 annually toward the maintenance fund of the college. A bill providing $25,000 for a building for the normal department of the college passed both branches, but was vetoed by the governor on the ground of economy. The fund for the enforcement of the pure-food law has been increased from $7,500 to $10,500 annually.

Nebraska Station.—Operations have been begun on the substation at North Platte, established by the State legislature, and W. P. Snyder, assistant in animal husbandry in the station at Lincoln, has been appointed superintendent of the new substation. As previously noted, this station is located on a tract of 1,920 acres of land 3 miles south of North Platte. The tract includes 280 acres of bench land, only about 20 feet to permanent water, and already under an irrigation ditch. The balance is table-land 2,900 to 3,000 feet above sea level. About 160 acres of this is level and will be used for farming purposes, while a large portion is broken and only valuable for pasture. This pasture land is covered with buffalo grass and other excellent grasses. Most of the experiments in dry farming will be duplicated, one set being made on the bench land and one on the table-land. Experiments will also be made on the effect of dehorning steers under range conditions, a lot of 150 2-year-old cattle being equally divided, one half being dehorned and the other half allowed to run without dehorning. Experiments will also be made to determine the amount of grain which

can profitably be fed to hogs to produce the cheapest pork on alfalfa pasture; and at an early date experiments in the growing of timber for posts and for wind-breaks will be started. After wind-breaks have been established, experiments in orcharding will be undertaken.

Rhode Island Station.—A. G. Lander, B. S. A., a graduate of Cornell University, has been appointed second assistant chemist, vice A. W. Bosworth, resigned.

South Carolina College.—J. V. Lewis, professor of geology and mineralogy and of soil physics, has resigned to take effect June 8.

Tennessee University and Station.—The station is preparing an exhibit of 50 cases for the Tennessee World's Fair Commission, to be shown at St. Louis. These cases represent the various lines of work in progress at the station, and show in a graphic manner the crop-producing capacity of Tennessee soils and the relative merits of the several fertilizers for these crops, the character and variety of crops that can be produced, and the results of various feeding experiments conducted by the station. The exhibit will constitute a central feature of the general agricultural display of the State. The short courses in agriculture and dairying recently closed showed a gratifying interest in these courses. Farmers' institutes have been held in practically every county in the State during the year. These institutes have been uniformly successful and the attendance satisfactory. Preparations are now being made for the twenty-ninth annual meeting of the East Tennessee Farmers' Convention, to be held in Knoxville June 1, 2, and 3, and steps are being taken to organize a State live-stock breeders' association.

Vermont University and Station.—L. R. Jones has been given leave of absence until September and will spend the time in Europe studying potato diseases and in search for disease-resistant varieties.

Wisconsin University.—F. J. Wells, assistant professor of agricultural physics in the college of agriculture, died March 1 after a brief illness. Professor Wells was a graduate of Lawrence University, and for several years a teacher in the public schools of the State. Believing that the agricultural field offered a good opportunity for his energies he entered the college of agriculture as a graduate student, devoting his time mainly to agricultural physics and chemistry. In March, 1902, he was appointed instructor in agricultural physics and was later advanced to the position of assistant professor. His sudden death was a great shock to all of his associates. Frederic Cranefield, assistant horticulturist, has resigned to accept the secretaryship of the State Horticultural Society, with headquarters at Madison.

Wyoming University and Station.—The short course given at the university from March 1 to 12, the first attempt at a short course in the State, was most gratifying in the attendance and the interest evidenced. There were over 150 in attendance; 131 registered as students, and 73 of these were ranchmen representing 8 of the 13 counties in the State. During the first week, which was devoted to irrigation, addresses were made by Elwood Mead of this Office, L. G. Carpenter of Colorado, John E. Field of the Reclamation Service, C. T. Johnston, State engineer of Wyoming, and Judge C. N. Potter of the Wyoming supreme court, besides members of the faculty. The second week was devoted to live-stock judging and management, and the interest increased up to the last day of the course. The course has attracted wide attention throughout the State and will probably be made an annual feature. W. E. Field has been appointed head farmer, and H. C. McLallen, of the New Mexico College and Station, has been appointed general assistant in the station to have charge of the notes and records.

United States Department of Agriculture.—Fourteen horses and mules used at the Arlington Farm have died of cerebro-spinal meningitis, supposedly from eating immature, moldy corn. Within 8 days after the first appearance of the affection all the animals were dead, including all those kept at the farm.

Frederick L. Lewton, of Pennsylvania, has been appointed scientific assistant in botany, in the Bureau of Plant Industry, and entered upon his duties early in April.

Overton W. Price, assistant chief of the Bureau of Forestry, has been appointed lecturer in the Forest School of Yale University.

Association of American Agricultural Colleges and Experiment Stations.—A circular recently issued by the executive committee announces that the next annual meeting of the association will be held during the week beginning October 30, 1904. The place of meeting has not been definitely determined upon, but if satisfactory arrangements for railroad and hotel rates can be secured Des Moines, Iowa, will probably be selected.

National Farm School.—L. J. Shepard resigned his position as agriculturist of the National Farm School at Doylestown, Pa., at the close of February to accept a position in charge of a 700-acre farm in Morristown, N. J. He has been succeeded by W. H. Bishop, formerly of the Delaware College and Station. C. P. Halligan, a graduate of the Massachusetts Agricultural College and recently connected with the Arnold Arboretum, has succeeded W. B. Madison as horticulturist, who, as previously noted, has gone to the Mount Hermon School, near Northfield, Mass.

Live-stock Exhibit of the Colleges and Stations at St. Louis.—The committee on the exhibit of the colleges of agriculture and mechanic arts and experiment stations at the Louisiana Purchase Exposition has provided for the exhibition of the work with live stock and in agronomy at these institutions. This will include demonstrations of the methods of teaching and investigation and exhibits of the results of investigation, together with a daily programme of lectures and class demonstrations in stock and grain judging. The exposition authorities are expected to provide suitable quarters, consisting of a judging and demonstration pavilion, with amphitheater of ample seating capacity, and facilities for conducting slaughter and block tests and cooking trials. Exhibits of different classes of live stock have been assigned to different institutions and will show the results of different methods of feeding, the improvement of grade animals by good sires, the influence of age on cost of production, and other points of interest in this connection. A number of slaughter and block tests are planned for. This live-stock exhibit will supplement the exhibits made in the educational building, and should prove a most instructive feature as illustrating the methods which have been worked out at the colleges and stations.

County Experiment Stations.—Under this caption *Wallaces' Farmer* describes the experimental work done last year on the Sioux County, Iowa, poor farm in cooperation with the experiment station at Ames, and notes the movement of other counties to follow the example. The trials at the Sioux County farm were with varieties of corn, and were laid out and supervised by representatives of the State station. The results reported are of so much interest that the future financial support of the undertaking is assured. At least four other counties in the State will conduct experimental work on their poor farms this season. The value of these experiments to the farmers in such lines as growing seed corn acclimatized and suited to the immediate locality is pointed out, and other useful lines suggested which will make the county poor farms "practical experiment stations of the greatest value." The writer predicts that in a few years every county dominated by progressive farmers "will insist that the county poor farm be an experiment station for that county."

A Pure Seed Bill.—A bill introduced in the National House of Representatives to prevent the adulteration of blue grass, orchard grass, and clover seed, has been favorably reported, with amendments, by the Committee on Agriculture. The bill prohibits the interstate and international traffic in seed of orchard grass, Kentucky blue grass, red clover, mammoth clover, or alfalfa, which is mixed, adulterated, or misbranded; and provides a penalty of not less than $200 or more than $500 for the first offense, and from $300 to $1,000, or imprisonment not exceeding one year, for each subsequent offense. An inspection of the varieties of seed mentioned, to extend throughout the whole country, is to be made by the Bureau of Plant Industry of this

Department. Seed condemned as being mixed, adulterated, or misbranded is to be confiscated and disposed of by direction of the court. The legal conception of mixing, adulterating, and misbranding is defined in detail.

Our Future "Public Analysts."—In an article under this caption in the issue of *Science* for March 18, R. O. Brooks, of the New Jersey Laboratory of Hygiene, directs attention to the growth of public supervision of food products and standard drugs, and to the need of supplying men for this work. He points to the State experiment stations as the logical and most appropriate institutions for carrying out the technical part of the inspection, the food commissioner being mainly a prosecuting officer, and commends these institutions for that service on account of their equipment and personnel, which make research work on composition, nutritive value, etc., feasible, and the present relations of the station chemists to the Association of Official Agricultural Chemists. The need of considerable special training for this branch of service and the dearth of properly trained men to fill prospective positions are pointed out, and the colleges maintained under the land-grant and Morrill acts are thought to be especially qualified for training at least the locally needed public analysts of the future. The association of the experiment stations with these colleges is mentioned as an especial advantage. These colleges "have facilities (departments, professors, and laboratories) wherewith to give instruction in the subject of foods, their composition, nutritive and economic value, methods of adulteration and detection of the same, etc.; and in the senior year or as postgraduate assistants, give the students an opportunity to gain an insight into and a little actual experience in food investigation work, and also, if possible, in methods of rapid legal inspection work at the local experiment station, or at least from the official chemists of these stations. The preparatory subjects, which we may consider as junior year electives, would include organic chemistry and outlines of organic analytical methods (fat extractions, melting point determinations, etc.), histological botany and microscopy and physiology, especially the subjects of nutrition, digestion, and assimilation. In the senior year the really special studies would be undertaken, viz, the study of foods as previously outlined; the natural composition, nutritive and economic value, utility, methods of adulteration, etc., of foods being taught by lectures, while the methods of scientific investigation and rapid legal inspection, especially the use of the microscope and the utilization of histological botany, would be taught simultaneously in the laboratory. . . . Such a comparatively simple, wholly possible and practicable course of training, especially if supplemented with actual experience in the local experiment station, would supply a national and soon to be a pressing need for competent trained 'public analysts,' similar to those regarded necessary by the smallest and least pretentious English towns and cities."

National Diploma in Agriculture.—As many of our readers know, the National Agricultural Examination Board, representing the Royal Agricultural Society of England and the Highland and Agricultural Society of Scotland, has for several years past been issuing a national diploma in the science and practice of agriculture to candidates who successfully pass the examinations. The fifth annual examination will be held early in May at Yorkshire College, Leeds. It is interesting to note that the examination consists of two parts, which must be taken in different years, the second part being taken within two years after passing the first part. The examination in part 1 comprises agricultural botany, mensuration and land surveying, general chemistry, geology, and agricultural entomology; and in part 2 practical agriculture, agricultural bookkeeping, agricultural chemistry, agricultural engineering, and veterinary science. Candidates who obtain an average of 75 per cent in the two parts receive the diploma with honors, and a gold medal is awarded to the candidate making the highest grade.

Proposed Aberdeen Agricultural College.—The establishment of an agricultural college in Aberdeen, Scotland, has been under consideration for some time, and from

the latest reports given in *Mark Lane Express* is looked upon with favor. Last year over $5,000 was spent on agricultural education in the county, about $2,000 being given to the agricultural department of Aberdeen University and the remainder spent by the education committee on local classes. The new college would undertake the whole of the work in agricultural education, bringing about a thorough coordination of efforts in this direction, and the amount of money heretofore available would be doubled by the promised grant from the education department, which, it appears, has signified its dissatisfaction with the present arrangement. The Aberdeen County secondary education committee has appointed a subcommittee to confer with the county finance committee with reference to recommending a sum which the county might appropriate for the new college.

Forestry Exhibition at Perth.—An exhibition of objects relating to forestry in all of its branches is to be held in the show yard of the Highland and Agricultural Society at Perth, Scotland, in July, under the auspices of the Royal Scottish Arboricultural Society. Prizes are offered for collective exhibits of timber grown in Scotland, for a report on the damage done to forest trees by insect pests and the measures which have been successfully adopted for their extermination, specimens showing the comparative quality of larch timber grown on different soils and situations and the respective ages at which it reaches marketable size and maturity, examples showing the best methods of utilizing small wood in the manufacture of fancy wood articles, for a scientific instrument for expeditiously measuring the diameter of trees at a given height, and for the best exhibit of timber preserved by a practical and economical process.

Prize Competition.—The Association of Berlin Butter Dealers has offered the following prizes: (1) 3,000 marks for a method of determining palm fat in butter, (2) 1,000 marks for a method of determining palm fat in lard, and (3) 2,000 marks for a method of determining lard in butter. The methods must be capable of being carried out in a properly equipped laboratory in a day, must not cost more than 6 marks for a determination, and must be accurate in mixtures containing 15 per cent of the foreign substance. The competition is open until February 1, 1905. The address of the association is Verein Berliner Butterkaufleute, Alexander strasse 64, Berlin.

Personal Mention.—George A. Putnam has been appointed to succeed G. C. Creelman as superintendent of farmers' institutes in the Province of Ontario, Canada.

It is reported in *Science* that L. H. Bailey, of Cornell University, will superintend the nature-study courses in the summer session at the University of Tennessee.

President Andrew S. Draper, of the University of Illinois, has resigned to become commissioner of education in New York State, under the new unification bill which has recently received the governor's signature.

The death is announced of Henry Michaelson, supervisor of the Pikes Peak Forestry Reserve and a writer on matters relating to irrigation and forestry.

It is reported in *Science* that Prof. E. von Behring will succeed Prof. Robert Koch as head of the Berlin Institute for Infectious Diseases, and that the Prussian Government will take over the serum institute founded by Professor von Behring in the neighborhood of Marburg.

Prof. Ludwig Bühring, successor to Prof. M. Maercker as director of the Halle Agricultural Chemical Control Station, died suddenly February 15 at the age of 58.

Dr. F. W. Dafert, director of the Agricultural Chemical Experiment Station of Vienna, has been called by the Austrian ministry of agriculture to the position of director of the department of agricultural experiment stations. Prof. Johann Wolfbauer has been appointed acting director of the Vienna Station.

Miscellaneous.—The bill before the New York legislature to appropriate $250,000 for buildings and equipment for the College of Agriculture at Cornell University continues to meet with considerable opposition, in which the presidents of six or seven

other universities and colleges in the State are very active. A bill introduced some weeks ago appropriating $200,000 to establish a State college of agriculture at Cobleskill has been advocated by the opposition, and also naturally by the people in the region of Cobleskill, prominent among whom was the president of Union College. The chancellor of Syracuse University is reported as having taken a leading part in this opposition, advocating first a division of the Federal funds among the colleges of the State, and more recently the appointment of a commission. In an address before the finance committee of the senate, the chancellor made grave charges against Cornell University, and this address was published in a pamphlet entitled "A Protest and Some Other Proposals Concerning Agricultural Education," which has been widely circulated, followed by a second set of charges. This agitation has called forth a twenty-four page circular on Agricultural Education in New York State, by Prof. L. H. Bailey, in which he answers the charges against the university, and maintains that agricultural education in the State can best be provided for at the institution where large provision in teaching force and equipment already exists. The Cornell bill has passed the assembly and early action in the senate is expected.

The Cornell Countryman notes that out of 43 students in the general winter course in agriculture at Cornell, 30 chose poultry husbandry for their elective course. This is gratifying evidence of the interest taken by students in this new department.

From the same source we note that at the meeting of the New York State Grange, early in February, it was voted to establish four grange scholarships in the college of agriculture at Cornell University, which contributes a distinctly new feature to the educational movement in the State.

The Forest School of Yale University has received, by gift of G. H. Myers, the library of the late Robert Henry, of Munich, containing about 1,500 books and pamphlets on forestry.

Announcement is made that at the fifth summer session of Columbia University provision will be made for instruction in foods and human nutrition. A course of five lectures a week on the chemistry of food and nutrition, with collateral reading and with or without laboratory work, is offered by Dr. H. C. Sherman; and Prof. H. T. Vulté, of the department of domestic science, will give courses on food principles and on food production and manufacture. The course on food principles will include sugars, starches, proteids, fats, etc., with special attention to the changes taking place during domestic manipulation and digestion. The course in food production and manufacture will cover such matters as the milling of cereals, composition and use of leavening agents, jellies and preserves, oils and fatty bodies, and water for drinking and detergent use. Courses in the theory and practice of teaching nature study in elementary schools, consisting of lectures, readings, discussions, and practical work, and in biological nature study, including lectures, readings, and work in the laboratory and the field, will be conducted by Prof. M. A. Bigelow and Miss Ada Watterson, of the department of nature study. The school opens July 6 and will continue until August 17.

The Cyprus Journal is the title of a new agricultural periodical published at Nicosia, Island of Cyprus, under government auspices. It is printed in three languages—English, Greek, and Turkish, the first two being in parallel columns and the Turkish in a separate part. From the first number of this journal we learn that the government has lately purchased a farm at Athalassa, near Nicosia, for the purpose of establishing a "model and experimental farm." In addition to culture and fertilizer experiments, and demonstrations of the use of modern agricultural implements, attention will also be paid to improving the quality of the native breeds of cattle. Other lines of effort for the promotion of agriculture, which are carried on by the government, are the maintenance of a nursery and experimental grounds, the distribution gratis or by sale at low prices of various kinds of plants, and the introduction of agricultural implements and machinery and their sale at greatly reduced

price on easy terms of payment. Expensive irrigation works have been constructed in recent years from which much permanent good is anticipated; money has been advanced by the loan commissioners for waterworks and other objects of public utility, and effective measures have been taken to improve the breed of the larger island cattle.

A recent number of *Gardening* states that a school for the training and instruction of women in practical horticulture has been established at Godesberg, on the Rhine.

According to statistics for the present academic year, of the 37,813 students matriculated at the 21 universities of the German Empire, 35,082 are German and 2,731, or 7.2 per cent of the total number, are foreigners, of whom 276 are Americans. Of the foreigners 199 are students of forestry and 146 of agriculture.

The Sixth International Zoological Congress will be held at Berne, Switzerland, August 14 to 19, 1904.

A departmental committee has been appointed to inquire into the workings of the British fertilizers and feeding-stuffs act of 1893. The committee is now engaged in taking testimony on this subject.

The directors of the Highland and Agricultural Society have under advisement the inauguration of a series of agricultural motor implement trials, with substantial prizes to encourage the perfection of this class of machinery.

It is reported in *Oesterreichische Chemiker-Zeitung* that the younger potash establishments of Germany are planning an independent combination, with headquarters either at Hamburg or Berlin, repeated efforts of the minister of commerce having failed to secure them concessions from the older organization.

O

EXPERIMENT STATION RECORD.

VOL. XV. MAY, 1904. No. 9.

The bill making appropriation for the National Department of Agriculture was passed by Congress April 23. It carries a total appropriation of $5,902,040, an increase of $423,940, which, while it is somewhat less than the annual increase for several years past, will provide for a continued steady growth of the Department. The above comparison does not take account of the emergency appropriation made last year for eradicating foot-and-mouth disease, a portion of which, amounting to a quarter of a million dollars, was made available earlier in the session for combating the cotton-boll weevil. The increase for the coming year is not as generally distributed throughout the Department as it has been in some years, about nine-tenths of the increase being for the Weather Bureau and the Bureaus of Animal Industry, Forestry, Plant Industry, and Chemistry, in the order named.

The Weather Bureau receives $1,337,740, an increase of about $89,000, which applies mainly to salaries and general operating expenses. The Bureau of Animal Industry is given $50,000 additional for its inspection and investigation work, and $25,000 for experiments in animal breeding and feeding in cooperation with the State experiment stations. Its total for next year is $1,362,880. The Bureau of Plant Industry, which has grown rapidly since its organization, receives a relatively large increase—$69,500—distributed quite generally among its different lines of work, and making a total of $744,430. The first appropriation for this Bureau after its organization four years ago was $231,680, exclusive of the $250,000 for seeds, which is now assigned to it. Its appropriation for investigation—i. e., exclusive of the seed fund—has therefore considerably more than doubled in the past four years. In addition to its regular appropriation, the Bureau will this year receive quite a share of the emergency appropriation for combating the cotton-boll weevil. For investigations in vegetable pathology and physiology there is an increase of $20,000 and provision for erecting a greenhouse; and for work in pomology, out of a total of $43,500, a new provision allows the expenditure of $10,000 in cooperation with the California Station, for determining the adaptability of various grape stocks to the different soil and climatic conditions of the Pacific Coast, and their resistance to disease. The

allowance permitted for seed and plant introduction from the general seed fund is increased to $40,000 (formerly $30,000); and provision is made for an inspection of grass, clover, and alfalfa seed, the results to be published with the names of the parties offering the seed for sale. The clause relating to investigation on domestic sugar production provides for developing the growing of sugar-beet seed in this country and demonstration of the superiority of high-grade seed and of methods of increasing the tonnage of sugar beets. Twenty-five thousand dollars is provided for moving the greenhouses adjacent to the Department building in order to accommodate the new building.

The appropriation for the Bureau of Forestry is $425,140, an increase of $75,140; for the Bureau of Soils, $214,680, the only increase being for the salaries of two draftsmen; and for the Bureau of Chemistry, $149,800. The latter is an increase of $64,500 and carries as a new item $15,000 for the chemical and physical examination of road materials, formerly conducted with the cooperation of the Office of Public Road Inquiries. The appropriation for studies on table sirup is continued, with provision for a report at the next session of Congress; and starch-producing plants are added to the list of industrial plants and products to be studied. The increase for the Bureau of Chemistry is much the largest it has received since it became a bureau.

The former Division of Foreign Markets is incorporated in the Bureau of Statistics, which receives an additional appropriation of $24,600, aside from that for the above Division, making its total $197,260. The Division of Entomology is raised to the grade of a bureau, and the scope of its work broadened to include "investigations of insects in relation to diseases of men and domestic animals, and as animal parasites." In other respects its lines are more specifically enumerated than formerly, covering all phases of economic entomology and related investigation. Its total appropriation of $82,450 is a slight increase over the present year.

The new appropriation gives this Office, as before, $40,000 for the general expenses of the Office proper, $15,000 each for the experiment stations in Alaska, Hawaii, and Porto Rico, $5,000 for farmers' institutes, $20,000 for nutrition investigations, and $67,500 for irrigation investigations, which are extended to include drainage, an increase of $2,500 in the latter case. This makes a total of $177,500 for the Office and the various lines of work assigned to it. In its internal organization and the scope of its work the Office is in effect a bureau, and has long since outgrown the title of "office" as at present used in the Department organization.

For the Biological Survey $51,850 is appropriated, the same as last year; for Road Inquiries, $35,000, also the same; for the Library, $20,200; and for the Division of Publications, $240,640, an increase of

$11,320. The latter appropriation carries the allowance for Farmers' Bulletins, but as usual does not include the fund available for printing the other miscellaneous bulletins of the Department. The allowance for this purpose out of the general printing fund is $185,000, including $25,000 set aside for the Weather Bureau. Aside from this, $300,000 is provided for the Department Yearbook; and the annual reports of the Bureau of Animal Industry, the Weather Bureau, the Soil Survey, and this Office, together with other special reports ordered by Congress, are provided for specifically. All told, the expenditures for Department printing make the imposing aggregate of nearly or quite $850,000 a year.

The great need of adequate buildings to provide office and laboratory accommodations suited to the needs of this large and growing Department is emphasized by the rent item which the new act carries. This amounts to about $37,000, a considerable increase over last year. While the total amount may not be required, the annual rental on most of the buildings is a fixed charge, and the temporary quarters required fitting up and special equipment, much of which is of no permanent value. Plans for the new building are well in hand, and now that the location has been definitely decided upon the details will be prepared as promptly as possible. The location selected is immediately in rear of the present building and back of the line of the boulevard extending from the Capitol to the Washington Monument.

The new appropriation act illustrates in a striking manner how intimately the work of the Department and the experiment stations is associated in the mind of Congress.

The clause relating to the work of the latter, which was inserted by the House committee, was subsequently stricken out, and the wording of the appropriation for the stations as finally passed remains unchanged.

The stations are mentioned in the bill no less than fifteen times, outside of the clause making specific appropriation for them. These references provide for the cooperation of the Department with the stations in extending its work, and place the aid of the Department at the disposal of the stations in other ways. For example, the appropriations for inaugurating experiments in animal breeding and feeding, for continuing the work of plant breeding and selection, for testing plant introductions, for studying the influence of environment upon the composition of cereals, sugar and starch-producing plants, for determining the adaptability for grape stocks, for studying market conditions affecting the fruit and vegetable trade, for grass and forage plant investigations, for drainage and irrigation investigations, and for studies on human food and nutrition, all make specific mention of the experiment stations as cooperating

agencies; and, on the other hand, directions are given for furnishing duplicates of models of fruits and vegetables to the stations as far as practicable, for standardizing the naming of varieties of cereals as a basis for the work of the stations, for making the results of work in tropical agriculture available to the work of the stations, for aiding in disseminating the results of the stations' work by farmers' institutes, and for assisting the agricultural colleges and experiment stations in disseminating information on road building.

The increasing need of larger funds for the stations is emphasized by the rapidly increasing funds of the Department for its work in various lines, and the frequent inability of the stations with their present funds to cooperate with the Department in extending its work in their States.

The interests of the Department and the experiment stations are bound together by a common cause and a unity of purpose, which places them in a position of reciprocal helpfulness. That this is appreciated by Congress is evidenced by the wording of the appropriation act, which suggests a closer bond of union than is indicated by the Hatch Act.

The establishment of a central experiment station in Cuba marks the beginning of agricultural investigation in that island. Thus far practically nothing has been done in the line of experimentation in any branch of agriculture, and the conditions are in many respects exceedingly primitive. The modern methods of agriculture as related to animal production, crop production, and soil fertility are practically unknown, and very little has been published regarding the plant diseases of Cuba, which are numerous and troublesome. The movement to establish systematic experiments and investigation has come as the result of a real need and of faith in the methods which have been productive of such far-reaching results in this and other countries.

The new station is located at Santiago de las Vegas, in Havana Province, about twelve miles from the city of Havana. It is under the general supervision of the secretary of public works, who is now also acting secretary of agriculture, the secretary of agriculture appointed when the department was established a few years ago having resigned. The director of the station is Prof. F. S. Earle, late of the New York Botanic Gardens, who has been associated with the work of the Bureau of Plant Industry of this Department, and the experiment stations in Mississippi and Alabama. Professor Earle brings to his work exceptional fitness for the direction of agricultural investigation in the tropics, and a thorough knowledge of the methods of the experiment stations of this country.

The station is located on a tract of 180 acres of land which is old and worn, but in many respects is typical in character. The place was originally a Spanish barracks, and has a large stone building with

about 40,000 sq. ft. of floor space, and several stables and other buildings. These can be readily adapted to the needs of the station and will save the expense and time of building. General Wood established an industrial school for orphan boys upon this farm, with the plan to make practical instruction in agriculture a prominent feature. About 300 boys were in the school when it was moved into Havana, and some experimental work with sugar cane had been commenced.

The station starts out with a liberal appropriation of $75,000 a year, and a good prospect for continuance, as there is much interest in the new undertaking. Six departments are planned for: (1) Agriculture, (2) animal industry, including veterinary science, (3) horticulture, (4) chemistry and soil physics, (5) botany, and (6) plant pathology, including entomology. The agricultural department is the only one organized at present. It is in charge of Francisco Cruz, a native Cuban, who is an expert in tobacco culture and well informed in other lines of agriculture. Mr. Cruz had been at the head of one of the provincial departments of agriculture, where he had started some promising lines of investigation.

The new station is spoken of as a central station, in the expectation that it will be the beginning of an experiment station system, the exact nature of which has not yet been determined upon. This may take the form of branch stations affiliated with the central station, or cooperative work carried out on private farms.

The field is a virgin one for investigation, and opportunities for useful lines of work present themselves on every hand. Cuba is thought to be one of the best cattle countries in the world, having magnificent pastures and abundant forage crops. There are only a few blooded animals in the island, however, and there is great opportunity for improvement in breeding and management. Dairying as an industry is practically unknown, and there is thought to be a fine opportunity for its development.

In tobacco culture, for which the island is famous, there is said to have been no systematic work in seed selection, and the methods of tobacco raising now practiced offer many opportunities for improvement. Although large quantities of fertilizers are often applied in farming, this is not done in an intelligent manner or with reference to supplying definite elements of plant food, and very little attention is given to other means of conserving or improving soil fertility.

Practically nothing has been done toward the development of agricultural education in Cuba as yet. The University of Havana has a department of agriculture, but this is evidently not very active or influential at present. The industrial school formerly located on the site of the station is the only attempt made to start an agricultural school, and as the agricultural feature has now been abandoned, the people are practically without facilities for instruction in agriculture.

The establishment of the experiment station on a liberal basis, and

the determination to secure a thoroughly competent director and corps of workers, is an evidence that the authorities have awakened to the needs and the opportunities for developing the great productive industry of the island and placing it upon a more rational and progressive basis. The development of the station under Director Earle will be followed with much interest by his many friends in this country.

The inauguration exercises of the new agricultural course at Mount Hermon School for Boys, near Northfield, took place April 18. The occasion was the annual commencement of the school, and the exercises served to give formal recognition and prominence to this new course, which was started last fall.

The principal address was made by Prof. L. H. Bailey, who spoke upon the place of agricultural instruction in the college and school curriculum. His remarks showed the steady growth of interest in the teaching of agriculture, the various forms which this is now taking, and the more general recognition accorded to it for its educational value and its utility as a preparation for daily life.

While the Mount Hermon agricultural course is in a sense an experiment, it is one in which the friends of agricultural education have great faith. The conditions afforded at the school for developing such a course seem in many respects ideal. A farm of a thousand acres is already at hand; the Northfield schools furnish a large market for its products; over 400 boys are in attendance, who are required to do a stipulated amount of manual labor every day about the college buildings or on the farm; and many of the boys come from country districts, with a desire to learn something which will be of direct advantage to them when they return to their homes. It only remains to make the labor required of the boys instructive and attractive, to systematize it, and to combine with it theoretical instruction which will teach the reason for the methods practiced.

It will require money to develop the new department, but under the old system the farm has been a source of considerable expense, and the saving which is being effected in the operating expenses and the increased returns from the improved system of farming will in part provide the necessary means. And in the past it has not been the rule at the Moody schools that new developments have been checked by lack of funds; a way has been found for providing means after the wisdom of the undertaking has become manifest.

In the death of Hon. Levi Stockbridge, of Massachusetts, a familiar landmark in the field of agricultural education has passed away. For nearly a quarter of a century he was a prominent and influential figure in the development of the Massachusetts Agricultural College, and in securing for it the recognition and financial support of the State. He was identified with the college from its inception, urging upon the

legislature the acceptance of the Federal land grant of 1862, assuming charge of the college property in 1866, and upon the opening of the college the following year becoming its first professor of agriculture one of the very few in the land at the time. He occupied that chair without interruption until 1882, and again in 1888–89, serving twice in the meantime as acting president. He was president of the college from 1880 to 1882.

It was no fault of his that those years included some of the darkest in the history of the college. It was rather the unreadiness of the times. Opposition was strong, often bitter, and the public mind was hardly prepared for this new kind of education. It is to the credit of the institution that it held its place as a distinctly agricultural college, and gradually gained recognition for its work and a public sentiment to bear it up. His strength and vigor and perseverance counted for much in those trying times.

Professor Stockbridge lived to see the teaching of agriculture gradually assume pedagogic form, many of the old ideas supplanted, and the subject so developed and specialized that instead of a single professor of agriculture a corps of specially trained men are required at the leading institutions; but the service which he and others of his type rendered in preparing the way for this development was of untold value and was fundamental in the evolution of this new branch of instruction.

As he was a leading spirit in the establishment of the agricultural college, so he was one of the prime movers for the experiment station. With Goessmann and Clark he conducted field and laboratory experiments which attracted wide interest and helped to show the practical value of experimental work to the farmer. The claims which he made in his urgent appeals for the experiment station have been more than justified with the passage of years; and the national growth and influence of the stations in this country, which probably surpass anything pictured by his keen and far-seeing imagination, is but another indication of the progressive times in which we live.

His was an active, earnest, useful life in the public service of agriculture. We glory in his having lived to see its advancement in so many directions. All honor to those pioneers like himself, who, with courage and perseverance born of their convictions, fought out the battles of our agricultural institutions in the darker days of their history, and paved the way for their present success and prosperity.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The direct determination of potassium in the ash of plants, E. M. EAST (*Jour. Amer. Chem. Soc., 26 (1904), No. 3, pp. 297–300*).—In the method proposed 2 to 3 gm. of substance is incinerated with ammonium nitrate, and the determination of potash in the ash thus obtained proceeds as follows:

"Transfer to a beaker with only a few drops of hydrochloric acid and heat to boiling. Add to the hot solution barium hydroxid solution saturated at 32°, sufficient to precipitate interfering salts. From 3 to 5 cc. are usually enough, providing the hydrochloric acid has been used sparingly. Digest one hour, filter hot, and wash with hot water. Precipitate the barium as sulphate by a sodium sulphate solution made up of strength equivalent to the barium hydroxid solution used. Digest 5 hours, filter, and wash. Evaporate down to about 25 cc. in a platinum dish. Add a drop or two of hydrochloric acid and the calculated amount of chlorplatinic acid needed to convert all the alkalis into chlorplatinates. Proceed as in the Lindo-Gladding method for fertilizers. Transfer all the double salt to the filter after the first addition of 10 cc. of the ammonium chlorid solution. The interfering salts of magnesium and calcium will all be dissolved on the first application. After transferring, 5 washings of 5 cc. each are sufficient to clear the double salt from impurities; then wash with alcohol, dry, and wash through the filter with hot water as usual."

A method for the direct determination of alumina, C. E. RUEGER (*Engineer and Min. Jour., 77 (1904), No. 9, pp. 357–359*).—A modification of Wöhler's method, in which alumina is precipitated from a slightly acid solution by means of sulphur dioxid, is described.

Eudiometric and gravimetric methods of determining ammonia, E. RIEGLER (*Ztschr. Analyt. Chem., 42 (1903), p. 677; abs. in Chem. Ztg., 28 (1904), No. 9, Repert. No. 2, p. 21*).—Methods based upon the fact that ammonia or ammonium salts when acted upon in alcoholic solution by an excess of iodic acid form ammonium triiodate $(NH_4)H_2(I_3O_9)$, which yields nitrogen when subjected to the action of hydrazin sulphate, are described. The nitrogen gas may be collected and measured in a Knop-Wagner azotometer, or the precipitated ammonium triiodate may be collected on a filter, dried, and weighed. The weight thus obtained multiplied by 0.0314 gives ammonia.

On the determination of nitrites in the absence of air, J. K. PHELPS (*Ztschr. Anorgan. Chem., 38 (1904), No. 1, pp. 113–116; abs. in Chem. Ztg., 28 (1904), No. 13, Repert. No. 3, p. 35*).—The author describes the apparatus used and methods followed in making this determination in an atmosphere of carbon dioxid.

The determination of total carbon in coal and soil, S. W. PARR (*Jour. Amer. Chem. Soc., 26 (1904), No. 3, pp. 294–297, fig. 1*).—Combustion of the substance is effected by means of sodium peroxid in a calorimeter by a method previously described by the author.[a] The resulting sodium carbonate after being boiled to free it from peroxid and oxygen is decomposed by sulphuric acid and the carbon dioxid evolved collected and measured in an eudiometer of special design, which is described

---

[a] Jour. Amer. Chem. Soc., 22 (1900), No. 10, pp. 646–652.

The fixation of atmospheric nitrogen, especially by means of electricity, F. von Lepel (*Die Bindung des atmosphärischen Stickstoffes insbesondere durch elektrische Entladungen. Greifswald: J. Abel, 1903, pp. 42*).—A review of recent progress in the investigation of various bacteriological, chemical, and electrical methods which have been proposed for the fixation of atmospheric nitrogen, especial attention being given to the method used by the Atmospheric Products Company of Niagara Falls (E. S. R., 14, p. 119), by Muthmann and Hofer,[a] and by the author (E. S. R., 15, p. 551) for causing the combination of the oxygen and nitrogen of the air by means of electrical discharges. The author claims that the efficiency of the process has been greatly increased and the expense lessened, the cost of preparing a kilogram of nitric acid by his method having been reduced to 13 pfennigs (about 1.5 cts. per pound), with a cost of 2 pfennigs (½ ct.) per horsepower per hour. The cost depends entirely upon the cheapness of the electric power.

Recent experiments on the fixation of atmospheric nitrogen by means of electrical discharges, F. von Lepel (*Mitt. Deut. Landw. Gesell., 19 (1904), No. 8, pp. 46, 47*).—A brief explanation of methods followed in oxidizing the nitrogen of the air by means of electricity.

The determination of hygroscopicity, H. Rodewald and A. Mitscherlich (*Landw. Vers. Stat., 59 (1904), No. 5–6, pp. 433–441, fig. 1*).—Hygroscopicity is determined by exposing dry or air-dry samples in shallow dishes over 10 per cent sulphuric acid in a vacuum until moisture equilibrium is secured and then determining the moisture taken up by Mitscherlich's method (E. S. R., 14, p. 127). Results of tests of this method on a variety of substances, including starches, soils, etc., are reported.

Results of investigations at the Sugar Experiment Station laboratory for 1903, C. A. Browne, Jr. (*Louisiana Planter, 32 (1904), No. 3, pp. 4751*).—In this paper, which was read before the Louisiana Sugar Planters' Association, the author summarizes some of the results of the investigations of the laboratory upon the chemistry of sugar cane and its products.

In studying the insoluble carbohydrates of the sugar cane, xylan, araban, and galactan were separated and identified. Araban was present in considerable quantities, and is noted as not hitherto reported in sugar cane. Pentosans prepared from sugar cane consisted of about 4 parts of xylose and 1 part of arabinose. Galactan was found only in small amounts, constituting in one instance only about 0.07 per cent of the whole cane. In normal cane juice the different gums did not usually exceed 0.2 per cent.

Analyses were made of the pith, fibrovascular bundles, and rind of sugar cane in a study of the utilization of bagasse for paper making. A process recently patented for the separation of the pith from the rest of the fiber and the manufacture of paper from this product, is noted.

Further studies (see E. S. R., 15, p. 285), upon the enzyms of sugar cane—namely, a diastase, an invertase, an oxidase, and a reductase or catalase, are briefly noted. It is believed that oxidizing enzyms, in addition to whatever part they may play in the vital processes of the plant, may serve also as a means of protecting the plant from invasion by fungi and bacteria.

Analyses are given of the juices from different parts of an immature cane, and from whole cane at different periods of growth. The juice from the green tops of the cane cut late in the evening had nearly twice as much sucrose as the tops of the cane cut early in the morning. During the past season canes with exceptionally high sucrose and low glucose content were observed.

Notes are given on the different fermentations of cane juice which have been observed. Different methods of extraction were compared, the composition of the

[a] Prometheus, 1902, No. 3, p. 145.

juices being determined. The methods included dry extraction, steam saturation, and saturation with cold water. In experiments in clarifying juices tests were made of the gelatinous hydrates obtained from the rare mineral monazite. The results were considered no better than those obtained by hydrated alumina, which is noted as having long been discarded as a clarifying agent in sugar manufacture. The electrical method of clarification was also tested.

Dry defecation in optical sugar analysis, W. D. HORNE (*Jour. Amer. Chem. Soc., 26 (1904), No. 2, pp. 186–192*).—In order to avoid the error due to the volume of the precipitate formed in clarifying sugar solutions with subacetate of lead, the author dissolves the normal weight of sugar in exactly 100 cc. of water and adds powdered anhydrous lead subacetate. Comparative tests of this method with the ordinary method are reported. "The dry defecation method has been employed for several months in 2 sugar refineries with perfectly satisfactory results and with the added advantages of greater speed of work, the elimination of volume measurements, and the simplification of calculations."

The hydrolysis of maltose and of dextrin by dilute acids and the determination of starch, W. A. NOYES ET AL. (*Jour. Amer. Chem. Soc., 26 (1904), No. 3, pp. 266–280*).—Studies were made of the rate of hydrolysis of maltose and dextrin under the conditions which obtain in the determination of starch by the method in common use. Several series of experiments are reported. After following the law of normal mass reaction approximately for a short time, the rate of hydrolysis became much retarded. The hydrolysis was apparently more nearly complete in a 2 or 4 per cent solution of hydrochloric acid than in a 0.5 per cent solution. A temperature of 111° C. was believed to possess a slight advantage over a temperature of 100°. The rate of hydrolysis for dextrin was about one-half of that for maltose. The reducing power of the products obtained by the action of extract of malt upon starch indicated a composition of 74 to 78 per cent of maltose and 22 to 26 per cent of dextrin.

"For the determination of starch we would recommend that, after filtration, 10 per cent by volume of hydrochloric acid (sp. gr. 1.125) should be added to the solution resulting from the action of extract of malt on the material under examination. After heating for 1 hour in a flask immersed in a boiling-water bath, making allowance for the time required for the solution to attain the temperature of the bath, the solution is cooled, enough sodium hydroxid is added to neutralize 90 per cent of the hydrochloric acid used, the solution made up to a definite volume, filtered on a dry filter if necessary, and the reducing power determined by Fehling's solution. One hundred parts of glucose found in this manner represent 93 parts of starch in the original material. The chemist should determine for himself, with pure glucose, the ratio between glucose and copper oxid or copper for the solutions and method which he uses."

Concerning the hydrolysis of cellulose with sulphurous acid, F. ZIMMER (*Mitt. Landw. Inst. K. Univ. Breslau, 2 (1902), No. 1, pp. 245–247*).—In view of the fact that alcohol is manufactured from sugar obtained from sawdust by treatment with sulphurous acid, the author studied the chemical action involved and found that the amount of sugar formed was directly dependent upon the concentration of the acid, the limit of sugar formation being 15 per cent. In making the calculations sugar was estimated as dextrose, but it was found to contain 8.56 per cent pentosan.

Investigation of the bodies called fiber and carbohydrates in feeding stuffs, with a tentative determination of the components of each, P. SCHWEITZER (*Jour. Amer. Chem. Soc., 26 (1904), No. 3, pp. 252–262*).—The crude fiber and nitrogen-free extract in a number of samples of feeding stuffs were determined by official methods, and the individual carbohydrates making up the total carbohydrate group were also determined by special methods which are very briefly

described. The values obtained are shown in the following table, calculated to an ash-free and a water-free basis:

Carbohydrates in a number of feeding stuffs (ash-free and water-free basis).

Feeding stuff.	Total carbohydrates.	Pure fiber.	Fibropentosan.	Pectose.	Pectopentosan.	Pentosan.	Sugar.	Starch.	Indefinite carbohydrates.

The determination of gliadin in wheat flour by means of the polariscope, H. SNYDER (*Jour. Amer. Chem. Soc., 26 (1904), No. 3, pp. 263–266*).—Briefly described, the proposed method for the determination of gliadin by means of the polariscope is as follows:

A weighed quantity of flour (15.97 gm.) is treated with 100 cc. of 70 per cent alcohol for 12 to 18 hours at a temperature of about 20° C., the flask being shaken moderately at intervals of one-half hour for the first 2 or 3 hours. The alcoholic solution is then filtered and polarized, using a 220 mm. tube. The reading on the sugar scale multiplied by 0.2 gives approximately the percentage of gliadin nitrogen. By shaking the solution mechanically and clarifying by means of a centrifugal machine, the time of extraction may be lessened. Excessive shaking gives cloudy filtrates which can not be polarized. This trouble is also observed if the alcoholic solutions are kept too long. According to the author some flours, particularly those from soft wheat, frequently give cloudy filtrates.

"The interpretation of results, particularly as to the amount of gliadin which a sample of flour shall contain for good bread-making purposes, is a separate feature of the problem of testing wheat and flour for commercial purposes. As yet only a limited number of gliadin determinations are available, and only tentative standards are possible. In general it can be said that flour of good quality should contain 12 per cent of total proteids (N×6.25), or about 11 per cent protein (N×5.7), and that from 55 to 65 per cent should be in the form of gliadin."

The precipitation of proteids by alcohol and certain other reagents, M. CHRISTINE TEBB (*Jour. Physiol., 30 (1903), No. 1, pp. 25–38*).—The precipitation of proteids of blood, egg white, muscle, and milk by alcohol was studied, as well as the precipitating action of ether, nitric, and hydrochloric acids. Some of the author's conclusions follow:

"It has been known for some time that serum globulin is composed of at least 2 proteids, one insoluble in water (euglobulin) and the other soluble in water (pseudoglobulin). The same is true of egg globulin.

"The true globulins (euglobulin) of serum and of egg white require considerably less alcohol to precipitate them than do the albumins.

"Although the pseudoglobulins are more readily salted out from their solutions than are the albumins and less readily than the euglobulins, the precipitability by alcohol does not run quite parallel to this. . . .

"The results obtained with the proteids of milk are a little unexpected; lactalbumin is precipitable by alcohol with difficulty, but caseinogen, which one would anticipate

to fall into line with the true globulins, requires also a considerable amount of alcohol to precipitate it all; most, however, is thrown out of solution by a comparatively small amount of alcohol.

"The two principal proteids of muscle are paramyosinogen and myosinogen. Both (and especially the first named) are readily salted out from their solutions, but v. Fürth pointed out that myosinogen is soluble in water and therefore not a typical globulin. Paramyosinogen appears to be the euglobulin of muscle, it is readily precipitable by alcohol; myosinogen, the pseudoglobulin, requires much more alcohol to precipitate it entirely. . . .

"Remembering the difference in salt precipitation and alcohol precipitation which obtain between the colloid carbohydrates, dextrins, and crystalline carbohydrates, the view is supported that the true globulins have larger molecules than the pseudoglobulins and albumins.

"The prolonged action of alcohol renders proteids insoluble. The euglobulins are most readily rendered insoluble, the pseudoglobulins and caseinogen come next, while of the proteids investigated, albumins are the most difficult to convert into insoluble modifications by alcohol. It was previously well known that proteids of still smaller molecular size (proteoses and peptones) not only require a large amount of alcohol to precipitate them entirely, but also are not rendered insoluble by prolonged contact with that reagent."

The results of biological studies of proteids and the use of such data in legal chemistry and the chemistry of food, A. PARTHEIL (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 20, pp. 923–927*).—A paper with discussion, summarizing bacteriological studies of blood, presented at a meeting of the Association of German Food Chemists. Some recent work was especially considered which has to do with the identification of blood by the method depending upon the fact that the blood of a rabbit inoculated with the blood serum of any given animal acquires the property of forming a precipitate with such serum.

Some experiments on biochemical synthesis, S. B. SCHRYVER (*Jour. Physiol., 30 (1904), No. 5–6, Proc. Physiol. Soc., 1903, pp. XLIV–XLVIII*).—Experiments with bases isolated from ox pancreas and bases from the liver led to the conclusion that bases from the organs play no part in condensation processes in the body.

A new method for the determination of cocoanut oil in butter, E. POLENSKE (*Arb. K. Gesundheitsamte, 20 (1904), No. 3, pp. 545–558, fig. 1; Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, pp. 273–280, fig. 1*).—In the determination of the Reichert-Meissl number insoluble fatty acids go over in part into the distillate with the soluble volatile acids. In the method described the insoluble acids in the distillate are separated by filtration, washed, dissolved in alcohol, and determined by titration with decinormal barium hydroxid, the number of cubic centimeters required for neutralization being designated a "new butter number." The Reichert-Meissl number is determined as usual in the filtrate.

The "new butter number" was found to bear a definite relation to the Reichert-Meissl number. Thirty-one samples of butter gave Reichert-Meissl numbers varying from 23.3 to 30.1, and "new butter numbers" varying from 1.5 to 3. Four samples of cocoanut oil gave Reichert-Meissl numbers of 6.8 to 7.7 and "new butter numbers" of 16.8 to 17.8. The addition of 10 per cent of cocoanut oil to pure butter fat increased the "new butter number" on an average about 1, the addition of 15 per cent about 1.6, and the addition of 20 per cent about 2.1, showing an increase in the "new butter number" of about 0.1 for each addition of 1 per cent of cocoanut oil within these limits. From the determinations of both the Reichert-Meissl number and the "new butter number" the amount of cocoanut oil in a sample of butter can be estimated approximately. Tables are given for this purpose.

A new method for the determination of the adulteration of butter by cocoanut oil and its different commercial forms, A. MÜNTZ and H. COUDON (*Ann. Sci.

Agron., 2. ser., 1904, I, No. 1, pp. 1–29, fig. 1).—A method for the determination of the water soluble and the insoluble volatile fatty acids is described in detail, and results obtained by the method on 40 samples of pure butter of different origin, 4 samples of cocoanut oil, 1 sample of oleomargarine, and various mixtures of butter and cocoanut oil are reported.

By this method the content of insoluble volatile fatty acids in the butter examined averaged 0.65 per cent as butyric acid, in cocoanut oil about 3.5, and in margarine 0.16 per cent. The proportion of the soluble to the insoluble acids in pure butter was 1:0.10 to 0.15, and in cocoanut oil 1:2.50 to 2.80. A sample of pure butter showed 5.34 per cent of soluble and 0.69 per cent insoluble acids, the ratio being 1:0.129; while the same butter adulterated with 10 per cent of cocoanut oil showed 4.90 per cent of soluble and 1.01 per cent of insoluble acids, the ratio being 1:0.206. The application of the method to the examination of adulterated butter is illustrated by numerous examples.

Some rare fixed oils, G. R. PANCOAST and W. GRAHAM (*Amer. Jour. Pharm., 76 (1904), No. 2, pp. 70, 71*).—The author classifies a number of fixed oils of limited importance commercially, and gives determinations of the specific gravity, acid number, and saponification number of several of these.

Examination of commercial peppers, J. W. GLADHILL (*Amer. Jour. Pharm., 76 (1904), No. 2, pp. 71–81*).—Determinations of ash, ether extract, piperin, and oleoresin were made on samples of 9 kinds of black pepper and 4 kinds of white pepper, the different peppers being described and the results discussed. The highest amount of ash found was 5.5 per cent for black pepper and 2.8 per cent for white pepper. In only one case did the ether extract exceed 9 per cent. The conclusion is drawn that the ash should not be above 6.5 per cent for black pepper and 3 per cent for white pepper; that the ether extract should be between 7.5 and 10 per cent for black pepper, and 6 and 9 per cent for white pepper; and that in a good black pepper, piperin should be present to the extent of from 5.5 to 9 per cent.

Existence of salicylic acid in wines, grapes, and other fruits, H. MASTBAUM (*Chem. Ztg., 27 (1903), p. 829; abs. in Analyst, 28 (1903), No. 331, pp. 293, 294*).—A review of the work on the natural occurrence of salicylic acid in plants, and a report of the author's recent investigations, which, in his opinion, indicate the presence of salicylic acid in wines and strawberries. In the case of grapes it was found principally in the stalks, and in the case of the strawberries in the fruit stalks and calices. Before flowering gallic acid, but no salicylic acid, was found in the stems, leaves, and roots. The fruit stalks of sweet and sour cherries, pears, apples, and bananas were not found to contain salicylic acid.

Thirty years' progress in water analysis, ELLEN H. RICHARDS (*Science, n. ser., 19 (1904), No. 481, pp. 443, 444*).—A brief historical summary showing how the wholesomeness of water is now considered to be more a matter of dangerous organisms than of organic matter.

Proceedings of the second annual meeting of the Association of German Food Chemists (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 20, pp. 913–975*).—The meeting was held at Bonn, August 3–4, 1903. Papers on the following subjects were presented and discussed: The Use of Yeast as a Reagent in Food Chemistry, by E. Prior; The Results of the Biological Investigations of Proteids in Regard to their Application to Food Chemistry, by A. Partheil (see p. 850); Sulphuric Acid in Wine, by L. Grünhut; Notes on the Control of the Sale of Edible Fungi, by K. Giesenhagen (for earlier work, see E. S. R., 14, p. 477); The Examination of Vinegar, by G. Popp (see p. 886); Spices, by A. Beythien (see p. 886); Homogenized Milk, by P. Buttenberg (E. S. R., 15, p. 714); and Observations in the Field of Water Examination, by H. Grosse-Bohle. The general discussion following each paper is summarized.

Physical and microscopical examination of commercial products, K. HAS-

SACK (*Physikalische und mikroskopische Warenprüfungen. Vienna and Leipzig: A. Pichlers Witwe & Son, 1903, pp. IV+145; rev. in Oesterr. Chem. Ztg., 6 (1903), No. 23, p. 540*).—A manual designed for self-instruction as well as laboratory use.

Practical physiological chemistry, J. A. and T. H. MILROY (*New York: Longmans, Green & Co., 1904, pp. XII+200, pls. 8*).—A text-book providing material for a course of approximately 3 months. The principal constituents of the animal body and of food stuffs are considered, and both qualitative and quantitative analysis are taken up. The appendix contains a number of tables.

Text-book of physiological and pathological chemistry, E. SALKOWSKI (*Practicum der physiologischen und pathologischen Chemie. Berlin: August Hirschwald, 1900, 2. ed., pp. XVI+310, pl. 1, figs. 10*).—This volume is especially designed for medical students and students of physiological chemistry, and takes up both qualitative and quantitative analysis. Under the section devoted to qualitative analysis the following topics are included: Inorganic and physiological-chemical analysis and reactions of metals and acids. Under quantitative analysis: Urine, feces, meat, milk, bread, blood, and similar topics are considered.

A practical guide to qualitative and quantitative urine analysis and the analysis of gastric juice, F. SIGMUND (*Praktischer Leitfaden der qualitativen und quantitativen Harnanalyse nebst Analyse des Magensaftes. Wiesbaden: J. F. Bergmann, 1904, pp. 91; rev. in Oesterr. Chem. Ztg., 7 (1904), No. 2, p. 34*).—An introductory text-book and laboratory manual.

Progress in the field of agricultural chemistry in 1903, A. STUTZER (*Chem. Ztg., 28 (1904), No. 14, pp. 149–152*).—A brief summary, with numerous references to literature, of investigations relating to soils and fertilizers, plant physiology, plant diseases, feeding stuffs and feeding, and methods of investigation.

Annual report of the progress in animal chemistry, R. ANDREASCH and K. SPIRO (*Jahresber. Tier-Chem., 32 (1902), pp. 1142*).—This contains abstracts of the literature of animal chemistry for 1902, with subject and author indexes.

Report of the division of chemistry, A. M. PETER (*Kentucky Sta. Rpt. 1899, pp. XI–XXIX*).—This includes analyses of 63 samples of butter, 5 of sorghum, 6 of soils, 4 of tobacco stems, 2 of an egg preservative, 1 of asphalt rock, 1 of petroleum, 1 of supposed gold ore, 1 of a ferment for ripening cream, 11 of mineral waters, and 43 of numerous species of forage plants and grasses.

Chemical division, B. C. ASTON (*New Zealand Dept. Agr. Rpt. 1903, App. I, pp. 3–24*).—This is a report upon the work done during the year and includes analyses of 266 samples of butter, 26 of milk and cream, 3 of poultry foods, 4 of limestone, 8 of sugar beets, 32 of soils, 40 of waters, and of numerous samples of miscellaneous materials. The average water content of the 266 samples of butter from the different districts of New Zealand was 10.33 per cent, only 10 samples showing a water content above 13 per cent.

Adulterated drugs and chemicals, L. F. KEBLER (*U. S. Dept. Agr., Bureau of Chemistry Bul. 80, pp. 47*).—The author classifies the adulteration of drugs as conventional, accidental or incidental, arbitrary to take advantage of certain standards, and intentional; and illustrates each class by numerous examples taken from his investigations. A sample of chimaphilla leaves was found to contain 25 per cent of stems. Numerous reagents labeled chemically pure contained varying quantities of impurities. The author considers that the term at present means nothing. Samples of potassium cyanid labeled 98 to 100 per cent pure contained from 22 to 74 per cent of sodium cyanid. A sample of beeswax was found to contain 33 per cent of cassava starch. It is stated that 25 per cent of all turpentine purchased in small packages is liberally adulterated with kerosene. In many instances the goods as delivered were much inferior to the samples submitted.

A study was made of rose geranium oil which was found to be frequently adulterated. The sense of smell is considered the most satisfactory procedure available at present for determining the quality of this oil.

The author reviews the history of phenacetin, describes the methods of manufacture, gives the numerous physical and chemical tests which have been employed in the examination of this substance, reports the results of an examination of 9 commercial samples, of which 1 was found to be adulterated with acetanilid, and comments on commerce in phenacetin.

BOTANY.

The maple sap flow, C. H. JONES, A. W. EDSON, and W. J. MORSE (*Vermont Sta. Bul. 103, pp. 43–184, pls. 17, figs. 6*).—This bulletin gives the results of an extended series of observations on the cause of maple sap flow, the various factors influencing it, and some of the problems of the sugar orchard.

The investigations were begun in the winter of 1896–97 (E. S. R., 11, p. 318). The work has been carried on from season to season, and in the present bulletin the results of the continued observations are given. Two phases of the general subject were studied, the physiological and the chemical. The work was carried only to the collection of the sap, the commercial features of the industry having been intentionally omitted. A review is given of the general structure and physiology of the maple tree, and attempts are made to account for the presence of the sugar, the causes of sap flow, and the relation of various internal and external factors to the flow of the sap.

Among the possible explanations of sap flow are considered sap pressure, movement, and bleeding. Gas pressure seems to exert a considerable effect on the flow of maple sap, but the authors state that the sudden cessation of sap flow at the end of the sugar season when there are not only wide temperature variations but also the highest water content, are strong arguments against a purely physical explanation of sap flow. It is believed that most of the phenomena of sap pressure and flow are due to the inherent activities of the living cells. The activity of the protoplasm is known to vary quickly and widely in response to physical and chemical changes, and alterations in temperature may influence the protoplasmic activity directly or indirectly through the disturbance of the gas tension and the resultant sap movement. A marked fluctuation in the sap flow was noted, a suction-like motion following a strong sap flow. This is attributed in a great degree to temperature changes, the suction being due possibly to the reabsorption of the bleeding cells of the sap exuded by them into the adjacent cells. The composition of the sap was found to be somewhat variable from day to day and even from hour to hour.

Among the problems of the sugar orchard considered are the location and conformation of the trees in relation to sugar production, the location of the tap holes, variations in quantity and quality of sap, etc. It was found that maple trees well exposed to sunlight gave more and richer sap than those grown in crowded, shaded situations. The quantity of sap obtained from a tree averaged slightly higher on the side bearing the largest and most numerous branches, although individual trees varied in this particular. Almost without exception the largest yields of sap and sugar were derived from the tissues nearest the bark. Fully four-fifths of the sugar was obtained from a 3-inch boring in large first-growth trees, or from 1 to 1.5 in. in smaller second-growth trees.

Considering the yield of the entire season, little advantage is likely to arise from too carefully adjusting the points of tapping to the points of the compass. On typical sap days a southern exposure as a rule yielded the most sap and sugar, but on cloudy days the outcome was more uniform between the different points. As a rule, the larger the hole the greater the yield of sap or sugar, but for obvious reasons it is not desirable to wound the tree to such an extent, and tapping the tree with a bit of three-eighths to five-eighths inch is recommended. The maximum flow of sap generally occurred between 9 and 12 o'clock noon. After this time there was a

gradual diminution until about 3 p. m., when the flow practically ceased. Wide variations are noted between different sugar orchards and between the same orchard in different seasons.

The effect of tapping at different heights was investigated, and the greatest amount of sap, as well as the best quality, was obtained when the trees were tapped at a height of about 4 ft. A tree tapped at 3 different levels gave 27 per cent of its sap from the roots, 51 per cent at 4 ft., and 22 per cent at 14 ft. above the ground.

Data are appended giving the weather conditions and temperature records for the seasons 1898–1901, details of studies on annual rings of growth, the water content of trees at different dates, gas and other pressures, the individual records of sap flow, composition, etc.

The maple sap flow, J. L. Hills (*Vermont Sta. Bul. 105, pp. 195–222, figs. 3*).—A popular edition of Bulletin No. 103 of the station noted above.

Range conditions and range improvement, J. J. Thornber (*Arizona Sta. Rpt. 1903, pp. 342–344*).—A description is given of the range conditions of Arizona and the experiments which are being conducted for range improvement. An abundant rainfall during the winter caused the rapid development of the spring grazing, the principal species being *Plantago fastigiata*, alfilaria, and slender fescue. Attention is called to one of the grama grasses, *Bouteloua rothrockii*, as a desirable grass on account of its drought-resisting qualities. This grass does best without any cultural operations, disking the surface apparently being injurious.

During the latter part of June of the season reported upon storm-water embankments were constructed so as to increase the area overflowed. The areas watered by these dams were disked and sown with seeds of native and introduced forage plants, the more important of which were *Andropogon leucopogon*, *Panicum texanum*, *Bouteloua curtipendula*, *B. rothrockii*, *B. oligostachya*, *B. hirsuta*, *Sporobolus wrightii*, *S. strictus*, *S. cryptandrus*, *Pappophorum apertum*, *Chætochloa composita*, *Eriochloa punctata*, and *Chloris elegans*.

The wheat grasses of Wyoming, A. and E. E. Nelson (*Wyoming Sta. Bul. 59, pp. 34, pls. 5, figs. 6*).—An account is given of observations made on the wheat grasses of Wyoming, a number of species of which are described at considerable length. These grasses, which belong to the genus Agropyron, are among the best forage grasses of the region covered by the investigation. They readily divide themselves into 2 groups, those forming a dense sod and those growing in bunches. The different species are found to be suitable to special conditions of soil and moisture, the special adaptations of each being shown.

Pathogenic fungi, E. Pinoy (*Bul. Inst. Pasteur, 1 (1903), No. 20, pp. 761–774, figs. 12*).—An attempt is made to briefly describe the morphology of many pathogenic fungi and to classify them according to their botanical characters.

FERMENTATION—BACTERIOLOGY.

The value of tests for bacteria of specific types as an index of pollution, H. W. Clark and S. DeM. Gage (*Separate from Massachusetts State Bd. Health Rpt. 1902, pp. 39*).—The results of prolonged investigations, covering a wide field on the subject of water contamination, are given. According to the authors the principal types of bacteria used as indices of pollution are the colon type, the sporogenes, sewage streptococcus type, and occasionally others. The colon type, which has received the most study, is most widely distributed and is of the most value as a positive indication of sewage pollution. In the filtration of polluted water bacterial tests are of more value than chemical analyses. Long continued comparisons have shown that the *Bacillus coli* test is a more delicate indication of filter efficiency than the tests of the total number of bacteria present in filtered and unfiltered water.

In the examination of spring waters the degree of purity of the samples when collected in a careful and proper manner is almost absolutely shown by chemical

analyses. In these waters, as sold on the market, chemical analyses did not reveal such slight accidental contamination as might be produced by the introduction of *B. coli*, and this contamination might be of considerable importance.

In an examination of waters from driven wells comparisons were made of the chemical, bacterial, and *B. coli* analyses, and in all of 128 samples the different examinations were in entire agreement. Polluted waters that may become unfit for consumption at any moment are more plainly indicated by a single chemical analysis than by single determinations of *B. coli*.

In the examination of shellfish from suspected sources the determination of such bacteria as the colon bacillus is of considerable importance as showing the purity or pollution.

Comparative tests for the relative viability of *B. typhosus* and *B. coli* show that there is a great similarity in the 2 germs under a great variety of conditions. Both appear to follow the general laws of the removal of bacteria by sand filters. Both organisms are destroyed rapidly by cold, either in fluid culture or when frozen in ice. In ice both germs will live in slowly reducing numbers for a considerable length of time, and when subjected to heat both appear to follow about the same rule, the typhoid germs being destroyed in about five minutes' exposure at a temperature of 45° C. and nearly all of the *B. coli* in the same exposure at a temperature of 50° C. The thermal death point of both lies between 80 and 85° C., a point somewhat higher than has hitherto been set for these species. Both are rapidly destroyed by sunlight, an exposure of 30 minutes to 1 hour usually being sufficient to sterilize the culture when spread in a thin layer.

The practical value of tests for Bacillus coli in water, G. C. WHIPPLE (*Tech. Quart., 16 (1903), No. 1, pp. 18–31, figs. 2*).—According to the author, the methods necessary for the certain identification of *Bacillus coli* in water are so complicated that they are not practical as working tests in connection with the supervision of water supplies. The fermentation of dextrose broth is said to furnish the most rapid and practical test for the presence of this organism in water. *B. coli*, if not itself widely distributed in nature, is said to so resemble certain common bacteria in all the points covered by the usual tests as to throw doubt upon the use of this organism as a conclusive test for fecal contamination. The methods described by the author furnish a useful test to determine the sanitary quality of water, and give results that agree well with chemical and biological analyses.

Water molds and lime purification, H. SCHREIB (*Wasserpilze und Kalkreinigung. Berlin: M. Krayn, 1904, pp. X+176, pl. 1, maps 2*).

Some problems in fermentation, J. H. LONG (*Jour. Amer. Chem. Soc., 26 (1904), No. 2, pp. 117–133*).—An address upon this subject delivered before the meeting of the American Chemical Society at St. Louis, December 30, 1903.

METEOROLOGY—CLIMATOLOGY.

Annual summary of meteorological observations in the United States, 1903 (*Mo. Weather Rev., 31 (1903), No. 13, pp. VII+625–652, charts 8*).—This number gives a table of contents, list of corrections, additions, and changes, and an index for volume 31; and a summary of observations on temperature, pressure, precipitation, wind movement, cloudiness, and other meteorological phenomena "based essentially upon data received from about 166 regular Weather Bureau stations, 33 regular Canadian stations, and from such climate and crop sections as have forwarded their annual summaries in time." A report of the Chief of the Weather Bureau for the year ended June 30, 1903, is included.

Monthly Weather Review (*Mo. Weather Rev., 31 (1903), Nos. 10, pp. 449–502, figs. 6, charts 11; 11, pp. 503–563, pl. 1, figs. 15, charts 12; 12, pp. 565–624, figs. 9, charts 12*).—In addition to the usual reports on forecasts, warnings, weather and crop conditions, meteorological tables and charts for the months of October, November, and

December, 1903, recent papers bearing on meteorology, etc., these numbers contain the following articles and notes:

No. 10.—Special contributions on Solar Radiation and Earth Temperatures (illus.), by C. G. Knott; Studies on the Circulation of the Atmospheres of the Sun and of the Earth—I.—The Circulation of the Sun's Atmosphere (illus.), by F. H. Bigelow; A Study of the Summer Fogs of Buzzards Bay, by F. W. Proctor; and A Photograph of Lightning at Havana, Cuba (illus.), by W. C. Devereaux; and notes on sun spots and the weather conditions on the earth, Weather Bureau men as instructors, sun-spot periods in meteorology, the noises made by projectiles and meteors, climate and mankind, reliability of high-wind records, the Philippine Weather Bureau, and long-range forecasting.

No. 11.—Special contributions on Studies on the Circulation of the Atmospheres of the Sun and of the Earth—II.—Synchronism of the Variations of the Solar Prominences with the Terrestrial Barometric Pressures and the Temperatures (illus.), by F. H. Bigelow; The Problem of the Cyclone (illus.), by F. J. B. Cordeiro; Clouds on the Cucamonga Mountains (illus.), by G. R. Rounthwaite; The Earthquake of December 5, 1903, at Washington, D. C., by C. F. Marvin; Mount Whitney as a Site for a Meteorological Observatory, by A. G. McAdie; Computation of the Altitude of Mount Whitney, by H. L. Heiskell; Mountain and Valley Breezes, by W. S. Tower; and Waterspouts at Cape May, N. J., August 24, 1902, by C. F. M. Leidy; and notes on Weather Bureau men as instructors, climatology of California, proposed pilot charts of the South Atlantic and of the South Pacific oceans, a daily weather map for the northern and southern hemispheres, the meteorological observatory at San Fernando, Spain, education of meteorologists, cooperation in Government work in science, aqueous vapor lines of the solar spectrum, seiches in Lake Garda, extremes of temperature and pressure in Montana, computation of the altitude of Mount Whitney, meteorology in the universities and normal schools, oscillations of temperature at any altitude, a waterspout, lightning phenomenon, the barometric disturbance in the Danish West Indies November 22–29, 1903, black rain in Clermont County, Ohio, August 19, 1903, vertical components of atmospheric motions, proportion of rainfall available for plant use, stationary and whirled psychrometers, meteor observed at South Bend, Ind., terrestrial globes, periodic floods in the Mississippi, island stations in the South Atlantic Ocean (illus.), and a new suggestion for thermometers.

No. 12.—Special contributions on The Use of Sounding Balloons for Meteorological Observations at Great Heights, by C. Renard; The Ascension of Closed Rubber Balloons, by H. Hergesell; Detailed Cloud Observations—A Progressive Phase in Weather Forecasting, by F. L. Odenbach; Methods of Forecasting the Weather, by J. M. Pernter; Kite Flying in the Tropics (illus.), by O. L. Fassig; Thunderstorms at Lincoln, Nebr., by J. H. Spencer; Recent Studies on the Solar Constant of Radiation (illus.), by C. G. Abbot; and The Polar Aurora of October 30–November 1, 1903, by J. Page; and notes on formation of hailstones (illus.), Weather Bureau men as instructors, meteorology and the art of flying, the thermophone applied to geodesy, periods in solar radiation and terrestrial temperatures, Southport exhibition of meteorological apparatus, the diffusion of odors in the atmosphere, low barometer during the "President" storm of March 12, 1841, the mischief of wrong theories, aurora and magnetic disturbances of October 30–November 1, 1903, storms on the southeast coast of Cape Colony, density of the atmosphere under different conditions, weather notes at West Cummington, Mass., international seismological association, meteorology in Hawaii, influence of continents and oceans on the atmosphere, and origin of the rare gases in the earth's atmosphere.

Meteorological observations, W. A. STOCKING, Jr. (*Connecticut Storrs Sta. Rpt. 1903, pp. 191–196*).—This is a record of observations on temperature, pressure, humidity, precipitation, and cloudiness during each month of 1902 at Storrs; rainfall during the 6 months ended October 31, 1902, at 21 places in Connecticut; monthly

mean temperature and monthly precipitation for 14 years (1888–1901); and dates of last and first killing frost for 14 years. The mean pressure for the year at Storrs was 30.01 in.; total precipitation, 52.12 in.; number of cloudy days, 142. The average rainfall for the State during the 6 months ended October 31 was 27.21 in. The mean annual temperature for 14 years has been 46.9°, the annual precipitation 46.99 in., the average length of growing season 147 days.

Meteorological summary for 1899, V. E. MUNCY (*Kentucky Sta. Rpt. 1899, pp. XXXV–XL*).—Tabular monthly summaries are given of observations at Lexington, Ky., on atmospheric pressure, temperature, precipitation, cloudiness, and wind. The mean barometric pressure for the year was 29.02 in., the highest 29.61, lowest 28.56; mean temperature 63.8° F.; highest 98, Sept. 6; lowest —20, February 13; total annual precipitation 40.24 in.

Meteorological observations in Jamaica (*Ann. Rpt. Dept. Pub. Gardens and Plantations and Bd. Agr. [Jamaica], 1903, pp. 9, 10*).—Tabular summaries are given of observations from April, 1902, to March, 1903, inclusive, at Hope, Castleton, and Hill Gardens on pressure, temperature, precipitation, dew-point, humidity, etc.

Meteorology of the fall of 1903, G. GINESTOUS (*Bul. Dir. Agr. et Com. [Tunis], 9 (1904), No. 30, pp. 138–159*).—Observations at a number of places in Tunis on rainfall, temperature, humidity, cloudiness, wind movement, etc., are summarized for the months of September to November, 1903.

WATER—SOILS.

Rural water supply, C. D. HOWARD (*West Virginia Sta. Bul. 89, pp. 163–213, pls. 5, figs. 2*).—This bulletin explains the danger from contamination of the water supply and the importance of providing pure water for domestic use, and reports and discusses analyses of water from various springs and wells in and around Morgantown, West Virginia, as well as from a small stream which was first used as a public water supply for the town, and from the Monongahela River, which is now used for that purpose. The wide variations in the volume and character of the water of this river are pointed out and the importance of employing means of purification is explained. The relation of water supply to typhoid epidemics is discussed and a list of publications relating to the general subject of water supply is given.

Poison in water from a gold and silver mill, P. A. YODER (*Utah Sta. Bul. 81, pp. 199–202*).—An analysis of a sample of water from the tail race from a gold and silver mill, which was supposed to have poisoned a number of cattle, is reported. This showed the water to contain 35 parts of lead, 5.1 parts of copper, and 166.6 parts of arsenic trioxid in 100,000 parts of water. "The water was so highly charged with arsenic that an ordinary drink for man or beast would contain sufficient to kill."

Results of rain, river, and evaporation observations made in New South Wales during 1900, H. C. RUSSELL (*Sydney: Dept. Pub. Instruction, 1903, pp. LXVI+139, maps 3, dgms. 4*).

Soil surveys in the United States, J. A. BONSTEEL (*Cornell Countryman, 1 (1904), No. 4, pp. 107–109*).—A brief historical review of soil-survey work in the United States, with a short account of the work of the Bureau of Soils of this Department, especially that done in cooperation with the agricultural colleges and experiment stations.

Fourth and fifth annual reports on the soils of Dorset, J. PERCIVAL and C. M. LUXMOORE (*Univ. Ext. Col. Reading [England], Agr. Dept., Ann. Rpt., Soils, Dorset, 1903, pp. 28, 19*).—A report is given of results of examinations of the fourth and fifth installments of 21 and 19 samples, respectively, of Dorset soils investigated under the terms of an agreement explained in an earlier report (E. S. R., 11, p. 327). The report gives the results of laboratory examinations and field observations.

The fertility balance in soils, S. GUÉRAUD DE LAHARPE (*Jour. Agr. Prat., n. ser., 7 (1904), No. 8, pp. 259–262*).—A discussion of an example of the maintenance of

soil fertility by the use of manures and fertilizers, by rotation, and by using on the farm purchased feeding stuffs, etc., rich in fertilizing constituents.

On the importance of certain physical properties of soils and soil-forming minerals in plant culture, W. BAGGER (*Inaug. Diss., Albertus-Univ. Königsberg, 1902, pp. 84, pls. 2*).—Studies of the physical properties of soils as based upon investigations of the size, character, and arrangement of the soil particles in a large number of soils are reported. The results of an attempt to trace a relation between the mechanical condition of the soil (size of soil particles) and the potash content are also reported.

The main conclusions reached are as follows: (1) Apparently only the crystalline substances in soils remain in suspension. (2) The arrangement of the mineral particles is determined to a large extent by their form. (3) The water capacity of a soil increases with a decrease in the size of the soil particles. It is clearly dependent upon the form of mineral and the resulting arrangement of soil particles. (4) The permeability declines uniformly with the decrease in size of particle, but not with decreasing compactness of arrangement of particles. (5) Cohesion in fine-grained soils increases with the decrease in the size of the particles. The form and the adhesive properties of the mineral constituents have an important influence on the cohesion. There is no clear distinction between sand and loam. In an agricultural sense sand may be defined as a collection of soil particles of varying size resulting from incomplete disintegration of amorphous or crystalline substances. Loam may be defined as a collection of small soil particles derived from complete disintegration of crystalline substances. (6) The mechanical properties (size of particles) of a soil furnish no index of potash content.

A review of the more important fertilizer experiments on black soil, W. VON WIENER (*Landw. Vers. Stat., 59 (1904), No. 5–6, pp. 397–409, pl. 1*).—Experiments on typical steppes black soil underlaid by loess, at the agricultural experiment station and on a farm near Nowossil, Government of Tula, Russia, are reported. The physical and chemical properties of the soil are described. A large number of crops, including cereals, leguminous plants, root crops, fiber plants, etc., and various combinations of fertilizing materials as well as manure, were experimented with. In all cases phosphoric acid was the element of plant food which gave best results. Nitrogen and potash were practically without effect. Barnyard manure gave better results than mineral fertilizer, the most effective form being fresh horse dung. The best returns from the fertilizers and manures were obtained when their use was accompanied with deep and thorough culture.

Factors of availability of potash and phosphoric acid in soils, G. S. FRAPS (*Science, n. ser., 19 (1904), No. 481, p. 443*).—This is an abstract of a paper presented at the St. Louis meeting of the American Association for the Advancement of Science. "In the determination of plant food in soils, chemists have usually considered only that part which is soluble in the common solvents. Solubility is not, however, the only factor of fertility in the soil. The rate of decomposition or weathering of the soil is of great importance, as is also the power of the plants to assimilate. Weathering has received little or no attention. It is known to be of great importance with nitrogenous bodies, but in regard to phosphorus and potash no data can be given. Experiments show that there is a slight increase in both phosphoric acid and potash when the soil is kept moist, and a great increase in potash when organic matter is present. This accounts for the necessity for vegetable matter in soils. Another factor is the difference in the solvent powers of plants. A soil may contain sufficient food for one plant, but not enough for another."

Reply to an address: Present status of soil investigation, F. K. CAMERON (*Science, n. ser., 19 (1904), No. 478, pp. 343–347*).—This is in reply to criticisms of Bulletin 22 of the Bureau of Soils by C. G. Hopkins and others (E. S. R., 15, p. 329).

The nitrogen of the soil, VIBRANS (*Mitt. Deut. Landw. Gesell., 19 (1904), No. 8, pp. 47, 48*).—A brief discussion of practical means of maintaining the nitrogen balance in cultivated soils.

Bacteriological studies of the soil, T. REMY (*Centbl. Bakt. u. Par., 2. Abt., 8 (1902), Nos. 21, pp. 657–662; 22, pp. 699–705; 23, pp. 728–735; 24, pp. 761–769; abs. in Centbl. Agr. Chem., 33 (1904), No. 2, pp. 75–79*).—This is a report of a series of culture tests with organisms from different kinds of soil to study nitrifying capacity, denitrifying action, the relation of bacteria content of the soil to productiveness, and similar questions.

Reclamation of salt and alkali lands, T. H. MEANS (*Forestry and Irrig., 10 (1904), No. 3, pp. 123–130, figs. 6*).—A discussion of this subject based upon recent observations in Egypt, showing the applicability of the methods followed there to similar problems in the United States. (See also E. S. R., 15, pp. 22, 234.)

Reclamation of alkali land near Salt Lake City, Utah, W. H. HEILEMAN (*U. S. Dept. Agr., Bureau of Soils Circ. 12, pp. 8*).—An account is here given of experiments made in cooperation with the Utah Station on a 40-acre tract of alkali land lying between Salt Lake City and Salt Lake, in which an attempt was made to demonstrate the practicability of reclaiming such land by means of underdraining and flooding. The operations began in 1902. The system for the 40 acres included 8 lateral drains of 4-in. and 3-in. drain tile, and 1 main drain of 10-in. tile. "Over the great part of the tract the drains were laid at a depth of 4 ft. In that part nearer the lake a somewhat shallower depth was necessitated in order to obtain a gravity outlet for the drainage water. The drains were laid on a grade of not less than one-tenth foot in 100 ft., except where 3-in. tile was used, when the grade was somewhat higher." The cost of the installation was about $660.

"Flooding has been carried on systematically, the land being divided into checks and plats by levees, and each plat treated in rotation. During each flooding water has been added to an average depth of 4 in. . . . During the last season (1903) the land was flooded once each week, with occasional longer intervals. . . . The land, at the time work was commenced, was all strongly impregnated with alkali salts, and had nothing growing upon it except a few alkali weeds, the most prominent of which was greasewood (*Sarcobatus vermiculatus*). The land was considered valueless by the farmers of the neighborhood."

Data are given which show "that between September, 1902, and the following May, 3,171 tons of salt had been removed from the soil to a depth of 4 ft., and that between September, 1902, and the following October, 5,430 tons had been removed, or 82 per cent of the alkali originally in the first 4 ft. of soil. It is also seen that a greater proportion of the alkali has been washed out of the surface foot than out of the lower depths, and that the movement of the salts is less pronounced as the depth increases. . . .

"The total volume of drainage was 5,651,776 cu. ft., or 51.8 per cent of the water added to the tract. This 51.8 per cent drainage water carried 3,648 tons of salts over the outlet weir. The remainder of the salts removed from the tract have passed into the deeper subsoil and been carried away by the natural subdrainage.

"The results so far obtained indicate the ultimate complete reclamation of the land. The single season's operations produced marked improvement in the land, not only in the alkali content, as shown by the soil tests made, or as shown by the salts in the drainage, but also as shown in the improved tilth of the soil and the favorable changes that have taken place in its physical properties.

"The indications are that the greater part of the tract is at present sufficiently sweetened to allow the growing of shallow-rooted crops."

The geomorphogeny of the Upper Kern basin, A. C. LAWSON (*Univ. California Bul. Dept. Geol., 3 (1904), No. 15, pp. 291–376, pls. 15*).

FERTILIZERS.

A treatise on manures, A. B. GRIFFITHS (*London: Whittaker & Co.; New York, 1903, 3. ed., rev. and enl., pp. XVI+453, pls. 3, figs. 17*).

Green manuring on the better class of soils, W. SCHNEIDEWIND (*Deut. Landw. Presse, 31 (1904), No. 7, pp. 45, 46*).—A brief account of the results of experiments made at Lauchstädt.

The preparation and use in agriculture of lime nitrogen, M. GERLACH (*Mitt. Deut. Landw. Gesell., 19 (1904), No. 8, pp. 45, 46*).—A brief account is given of methods of preparing this substance and of field experiments to test its fertilizing value. Earlier experiments by Wagner and the author (E. S. R., 15, p. 25), showing that the availability of this form of nitrogen is very nearly the same as that of nitrogen in form of ammonia salts and nitrate, are referred to. It is pointed out, however, that more recent farm trials have not shown so high a degree of availability, being on an average only about three-fourths of that of nitrogen in form of nitrate. It was found also that later applications were more effective than earlier applications, and that on certain soils (for example, moor soils) the lime nitrogen had an injurious effect, due, it is suggested, to the formation of dicyandiamid, which is apparently poisonous to vegetation.

Sulphate of ammonia or nitrate of soda? LILIENTHAL (*Fühling's Landw. Ztg., 53 (1904), No. 4, pp. 129–134*).—Comparative tests with potatoes on light sandy soil of nitrate of soda and sulphate of ammonia, with and without the addition of lime, are reported. The results with the sulphate were equal to and in some cases superior to those with the nitrate.

Under what conditions and by what means may ammoniacal nitrogen be made most effective? P. WAGNER (*Jahrb. Deut. Landw. Gesell., 18 (1903), pp. 37–49*).—A general discussion of the fertilizing value of the nitrogen of ammonium salts under various conditions.

Pot experiments on the influence of liming and marling on the yield of serradella, R. ULBRICHT (*Landw. Vers. Stat., 59 (1904), No. 5–6, pp. 425–432, pls. 2*).—The method used in experiments during 1900 and 1901 was the same as that followed in earlier experiments (E. S. R., 14, p. 129). Burnt lime and magnesite, marl, and ground limestone were experimented with. Applications of lime in all forms decreased the yield, showing that the growth of serradella, like that of lupines, is injuriously affected by this substance. The addition of magnesia to the lime still further decreased the yield.

On precipitated superphosphate as a substitute for Thomas slag, A. EMMERLING (*Deut. Landw. Presse, 31 (1904), No. 14, pp. 107, 108*).—Various methods of preparing precipitated phosphate by mixing superphosphate with calcium carbonate (chalk) and combining this mixture with potash and nitrogen salts are described. Analyses and field experiments with the various mixtures are reported. The results show that very effective fertilizers may be prepared in this way.

The use of crude potash salts in German agriculture in 1898 and 1902, G. SIEMSSEN (*Arb. Deut. Landw. Gesell., 1904, No. 88, pp. 24, map 1*).—Detailed statistics are given. The total amount used in 1898 is reported to be 7,604,754 kg. (8,365.23 tons); in 1902, 10,788,625 kg. (11,867.49 tons).

Progress in the potash industry in 1903, M. HAGEN (*Chem. Ztg., 28 (1904), No. 18, pp. 206–209*).—A brief review with references to literature.

FIELD CROPS.

Field experiments, F. C. BURTIS and L. A. MOORHOUSE (*Oklahoma Sta. Bul. [illegible], pp. 22*).—The results obtained in 1900 with sugar beets and mangels showed the value of soaking beet and mangel seed before planting. Two varieties each of sugar

beets and mangels were planted without previously soaking the seed, and in neither case was a stand secured, while a perfect stand resulted from old sugar-beet seed soaked over 24 hours before planting. The seed was planted April 16 and the beets, yielding at the rate of 9.81 tons per acre, were harvested the last week in November.

In 1901 Mammoth Long Red and Golden Tankard mangels and White Improved sugar beets gave a good average yield. The next year the varieties and yields were as follows: Mammoth Long Red 17.5 tons, White Kleinwanzlebener 14.1 tons and Golden Tankard 13.3 tons per acre. Freezing of the soil on December 3 injured the Mammoth Long Red mangels, which grow largely above the surface, while it did but little damage to the White Kleinwanzlebener, which seemed to be protected by a very heavy top and by a deeper growth. The following yields were obtained in 1903: Golden Tankard, 13 tons, and White Kleinwanzlebener 7.27 tons, Long Red mangel, 7.2 tons per acre. The treatment of these root crops under experiment is described and general directions are given for the culture of sugar beets and mangels in Oklahoma.

Kafir corn from 1900 to 1903, inclusive, on heavy upland soil produced on an average for the 4 years on manured ground 51 per cent more stover and 19.7 per cent more grain, and on unmanured ground 59.2 per cent more stover and 48.5 per cent more grain than corn. Samples of Kafir corn and corn stover from the crop of 1902 contained 75.80 and 80.22 per cent of dry matter, respectively. The culture and uses of Kafir corn are discussed.

In 1900 Texas Red oats drilled March 2 at the rate of 3.2 bu. per acre and harvested June 16, yielded at the rate of 72 bu. of grain and 2.19 tons of straw per acre. The following year this same variety on 2 manured and 2 unmanured plats produced on an average 54.5 bu. of grain and 1.24 tons of straw and 28.6 bu. of grain and 0.54 tons of straw per acre, respectively. Lincoln, Culberson, and Texas Red, compared in 1902, yielded 57.5, 46.4, and 45.3 bu. of grain and 1.29, 1.03, and 1.13 tons of straw per acre, respectively. Texas Red has in general given the best results. In 1903 oats in rotation produced a larger yield of straw, but 1.48 bu. of grain per acre less on plats manured for cotton the year before than on unmanured plats.

In addition to these tests experiments on the time of seeding and the preparation of the seed bed were carried on. The seedings were made March 17–20, March 28–31, and April 7–9. The early seeding gave the lowest yield of straw and the highest yield of grain and also the heaviest weight of grain per bushel. In early seeding plowing gave larger yields of grain than plats receiving surface cultivation only by disking. With the later seedings the reverse was the case, but the yield of straw was larger on the plowed plats. The more luxuriantly growing crop on the plowed plats seemed the most subject to rust.

Results obtained in 1903 from trial plats of grain, fodder corn, field roots, and potatoes, W. SAUNDERS (*Canada Cent. Ext. Farm Bul. 44, pp. 63*).—This bulletin is the customary annual report of cooperative variety tests now in progress for 9 years at the Canada Experimental Farms (E. S. R., 14, p. 751). The yields of the different crops at the several farms are given in tables. The varieties producing the largest crops in 1903, taking the average results obtained on all the experimental farms and giving them in the order of their productiveness, were as follows:

Oats.—Abundance, White Giant, Wide Awake, Sensation, Danish Island, Lincoln, Banner, Golden Tartarian, Waverly, Thousand Dollar, Improved Ligowo, and Twentieth Century. Average yield per acre, 90 bu. 30 lbs. *Two-rowed barley.*—Invincible, French Chevalier, Canadian Thorpe, Standwell, Beaver, and Danish Chevalier. Average yield per acre, 53 bu. 46 lbs. *Six-rowed barley.*—Mansbury, Brome, Odessa, Trooper, Oderbruch, and Nugent. Average yield per acre, 60 bu. 35 lbs. *Spring wheat.*—Advance, Roumanian, Wellman Fife, Byron, Monarch, Preston, White Connell, White Fife, Goose, Chester, Crawford, and Clyde. Average yield per acre, 33 bu. 18 lbs. *Peas.*—English Grey, Macoun, Early Britain, Archer, Crown, Alma, German White,

Pride, Arthur, Mackay, Wisconsin Blue, and Mummy. Average yield per acre, 40 bu. 59 lbs. *Indian corn.*—Early Mastodon, Thoroughbred White Flint, Eureka, Angel of Midnight, Giant Prolific Ensilage, and Superior Fodder. Average yield per acre, 20 tons 753 lbs. *Turnips.*—Mammoth Clyde, New Century, Emperor Swede, Jumbo, Hartley Bronze, and Perfection Swede. Average yield per acre, 37 tons 929 lbs. *Mangels.*—Mammoth Long Red, Mammoth Yellow Intermediate, Half Long Sugar White, Selected Yellow Globe, Giant Yellow Intermediate, and Lion Yellow Intermediate. Average yield per acre, 36 tons 1,732 lbs. *Carrots.*—Ontario Champion, Giant White Vosges, Mammoth White Intermediate, New White Intermediate, Improved Short White, and White Belgian. Average yield per acre, 22 tons 3 lbs. *Sugar beets.*—Red Top Sugar, Improved Imperial, Danish Red Top, and Danish Improved. Average yield per acre, 28 tons 285 lbs. *Potatoes.*—Seedling No. 7, Vanier, Rose No. 9, Rochester Rose, Carman No. 1, Enormous, Late Puritan, Burnaby Seedling, Everett, Uncle Sam, Canadian Beauty, and Pearce. Average yield per acre, 425 bu. 32 lbs.

Emmer was grown last season at all of the experimental farms with yields varying from 17 bu. 20 lbs. to 43 bu. 44 lbs. per acre.

The average results of the various crops for a series of years are also given. The following varieties, taking the average of the yields obtained on all the experimental farms, have been the most productive: *Oats.*—Danish Island, Banner, Mennonite, New Zealand, American Beauty, White Giant, Thousand Dollar, Black Beauty, Holstein Prolific, Improved American, Buckbee Illinois, and Golden Tartarian. Average yield per acre, 76 bu. 6 lbs. *Two-rowed barley.*—French Chevalier, Dunham, Canadian Thorpe, Danish Chevalier, Clifford, and Beaver. Average yield per acre, 45 bu. 29 lbs. *Six-rowed barley.*—Manshury, Claude, Mansfield, Yale, Odessa, and Brome. Average yield per acre, 50 bu. 43 lbs. *Spring wheat.*—Roumanian, Clyde, Laurel, Preston, Goose, Monarch, Wellman Fife, Rio Grande, White Fife, Huron, Red Fife, and Weldon. Average yield per acre, 34 bu. 20 lbs. *Peas.*—Crown, Pride, English Grey, Early Britain, German White, Pearl, Carleton, Picton, King, Arthur, Paragon, and Agnes. Average yield per acre, 35 bu. 41 lbs. *Indian corn.*—Early Mastodon, Superior Fodder, Thoroughbred White Flint, Salzer All Gold, Red Cob Ensilage, and Early Butler. Average yield per acre, 19 tons 867 lbs. *Turnips.*—Perfection Swede, Imperial Swede, Halewood Bronze Top, Selected Purple Top, Magnum Bonum, and Hall Westbury. Average yield per acre, 31 tons 927 lbs. *Mangels.*—Giant Yellow Intermediate, Yellow Intermediate, Lion Yellow Intermediate, Mammoth Long Red, Mammoth Yellow Intermediate, and Gate Post. Average yield per acre, 31 tons 1,514 lbs. *Carrots.*—New White Intermediate, Giant White Vosges, Ontario Champion, Mammoth White Intermediate, Improved Short White, and Half Long White. Average yield per acre, 22 tons 84 lbs. *Sugar beets.*—Danish Red Top, Danish Improved, Red Top Sugar, and Improved Imperial. Average yield per acre, 24 tons 932 lbs. *Potatoes.*—Uncle Sam, Seedling No. 7, Irish Daisy, American Wonder, Rose No. 9, American Giant, Late Puritan, Country Gentleman, Carman No. 1, Burnaby Seedling, Penn Manor, and State of Maine. Average yield per acre, 377 bu. 53 lbs.

Alfalfa, sorghum, soy beans, and other forage plants, J. F. DUGGAR and J. M. RICHESON (*Alabama Canebrake Sta. Bul. 20, pp. 20*).—Alfalfa sown broadcast March 20 yielded, from 3 cuttings made June 16, July 15, and September 3, a total of 4,634 lbs. of hay, being at the rate of 8,424 lbs. per acre. The land was upland prairie of a fair degree of fertility, and the results are considered very good for the first season of spring-sown alfalfa. The soil on which the crop was grown seemed to have been inoculated from adjacent fields on which alfalfa and melilotus had been produced. The culture and value of alfalfa in the canebrake region are noted.

The yields of a number of summer-growing forage crops on a dark upland prairie soil, all planted in drills about May 1 and giving good stands, except the teosinte, are shown in the following table:

Yields of various forage plants per acre.

Crop.	Date of each cutting.	Green forage per acre.	Weight of hay per acre when stored.	Yield of hay calculated as 40 per cent of green weight.
		Lbs.	*Lbs.*	*Lbs.*
Amber sorghum, first cutting	Aug. 11	27,040	20,640	10,816
Amber sorghum, second cutting	Oct. 12	15,648	8,256	6,259
Amber sorghum, total	....	42,688	28,896	17,075
Orange sorghum, first cutting	Aug. 17	34,606	23,360	13,862
Orange sorghum, second cutting	Oct. 26	14,080	8,832	5,632
Orange sorghum, total	....	48,736	32,292	19,494
White Kafir corn	Sept. 8	19,712	11,584	7,885
Red Kafir corn	....do....	17,552	13,728	8,721
Pearl or Cattail millet	Aug. 17	17,216	8,640	6,886
Welborn corn (for grain) stover	Oct. 4	....	1,680	....
Teosinte	Aug. 27	5,888	3,200	2,355
German millet	Aug. 6	6,464	4,032	2,155
Yellow soy beans	Sept. 8	27,136	13,568	9,405
Whippoorwill cowpeas	Aug. 27	11,088	4,672	3,696
Wonderful cowpeas	Sept. 19	15,872	7,456	5,291
New Era cowpeas	Aug. 27	7,872	2,976	2,624

On dark pebbly land which had produced a crop of poor wheat, a mixture of 3 pecks of Amber sorghum and 5 pecks of cowpeas sown broadcast yielded 5,760 lbs. of hay per acre, the weight being taken after 8 days of curing. In this same series of plats Mexican June corn yielded 2,288 lbs. of stover and 19.25 bu. of corn, but this crop occupied the land until October while the other crops occupied it only for 67 days.

In a test of crops suitable for hog feeding, Welborn corn yielded 21.1, yellow soy beans 34.1, Spanish peanuts 58.3, Virginia peanuts 116.5, and sweet potatoes 64.3 bu. per acre. In the same experiment 800 lbs. of sunflower seed were obtained per acre. A plat of late sorghum without fertilizer produced 11,200 lbs. of green forage, while another plat receiving 70 lbs. of nitrate of soda per acre yielded 18,272 lbs. Seed of the Newman bean, obtained from this Department and sown March 28, gave a yield of 20,398 lbs. of green crop or 8,158 lbs. of cured material by September 8. In addition to the different crops mentioned melilotus, hairy vetch, and Dwarf Essex rape were grown and produced good yields.

The hay meadow with special reference to culture and irrigation, W. Quitzow (*Inaug. Diss., Ver. Friedrichs-Univ. Halle-Wittenberg, 1902, pp. 29, map 1*).—A discussion of this subject with reference to conditions around Seehausen.

The work of the Community Demonstration Farm at Terrell, Texas, S. A. Knapp (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 51, pt. 2, pp. 8*).—A brief account of a demonstration experiment on a farm which had been in corn and cotton continuously for 28 years, and was in an impoverished condition. Thorough preparation and cultivation were given, and complete fertilizers containing admixtures of cotton-seed meal were applied freely. Corn and cotton were the crops grown. As a result of the demonstration, the farm manager announced at the end of the season that "he had cleared $700 more than would have been made under the ordinary methods of farming employed in that section."

Experiments with cotton and corn in 1903, J. F. Duggar and J. M. Richeson (*Alabama Canebrake Sta. Bul. 21, pp. 20*).—In the culture tests reported with cotton,

land plowed 6½ in. deep yielded 76 lbs. of seed cotton and 16 lbs. of lint more per acre than land plowed 3½ in. deep. Subsoiling did not materially affect the yield of lint. Cotton planted on ridges yielded 344 lbs. of lint per acre as compared with 272 lbs. when planted on beds in the usual way. Ridge planting, however, is considered more likely to suffer from drought. The use of a cultivator gave practically as large a yield as the use of the sweep. An additional cultivation given September 19 apparently increased the yield of lint cotton per acre by 40 lbs. over a plat laid by August 26.

Slag phosphate and acid phosphate each applied at the rate of 200 lbs. per acre on black slough land failed to increase the yield but hastened maturity to some extent. Different forms of potash were also used without material effect. In a test with nitrogenous fertilizers, plats receiving 160, 80, and 40 lbs. of nitrate of soda per acre yielded 112, 64, and 48 lbs. of lint cotton more per acre than the check plat. The increase in yield from 100 lbs. of cotton-seed meal per acre was the same as that obtained from 40 lbs. of nitrate of soda. An application of 3,200 lbs. per acre of barnyard manure apparently increased the yield of lint by 80 lbs., and the same application of corn stover by 16 lbs. per acre.

The best-yielding varieties of corn under test were Shaw Improved, Blount Prolific, and Cocke Prolific, producing 37.7, 35.4, and 34.9 bu. of corn and 2,176, 1,360, and 1,840 lbs. of stover per acre, respectively. Two plats subsoiled on April 4 yielded on an average 2.5 bu. per acre less than 2 plats not subsoiled. No material difference resulted from different methods of preparing the soil and planting. In a cultivation test the best yield was obtained from the use of the 12-in. sweep at the first cultivation and the subsequent use of the 20-in. sweep. Owing to a very wet season the continuous use of the turnplow gave very good results.

Among different fertilizer applications, 88 lbs. of nitrate of soda per acre applied at the second cultivation gave the largest increase in yield. The same increase was obtained from 44 lbs. nitrate of soda and 100 lbs. of cotton-seed meal applied together at the first cultivation. The increase obtained from 88 lbs. of nitrate of soda per acre applied at planting was smaller by 2 bu. than when the application was given at the second cultivation. Manure applied before planting at the rate of 2,702 lbs. per acre yielded a return of $2.20 per ton. In a second test 5,408 lbs. of manure per acre gave an increase of only 4 bu., while 200 lbs. of cotton-seed meal and 80 lbs. of nitrate of soda increased the yield by 7.1 and 7 bu. per acre, respectively. Nitrate of soda was applied at the third cultivation, June 12, 2½ months after planting.

Direct application of nitrate of soda and cotton-seed meal failed to increase the yield of Mexican June corn, but the residual effect of 1,600 lbs. of cotton-seed meal applied to the immediately preceding crop of oats showed a gain of 7.2 bu. per acre. Subsoiling apparently decreased the yield.

Selecting and improving corn, A. M. Soule (*Univ. Tennessee Record, 7 (1904), No. 1, pp. 13–27, figs. 10*).—The value and methods of selecting and improving corn are discussed at some length, and results of planter and variety tests are reported. The planter tests indicate that uniformity in the size of kernels insures uniformity in the number of kernels dropped by the machine, and consequently tends to produce an even stand. Attention is called to the importance of selecting varieties adapted to the locality, by the fact that on the University farm the varieties leading in yield in 1901, a dry year, were not among the leaders the following season, which was favorable, and others not represented in either year had a better average for the 2 seasons. The vitality test showed a low percentage of germination for butt, tip, and deformed kernels and soft corn. A score card for judging corn in the ear, in use at the College of Agriculture, is presented.

Cowpea hay, C. L. Newman (*Arkansas Sta. Bul. 80, pp. 69–82*).—The average yield at the station of cowpea hay for 5 years, from 1899 to 1903, as computed from all plats and all varieties recorded, was 3,169.4 lbs. per acre. This in general did not include the weight of peas and hulls. In 1902, 16 plats yielded over 6,000 lbs.

of hay per acre, and on 8 of these either no ripe peas or only a small quantity was produced. The highest yield of hay for this season, 8,750 lbs. per acre, is recorded for Clay, and the lowest, 750 lbs. per acre, for New Era and Extra Early Black Eye. The yields of shelled peas were 2.9 bushels and 1,337 and 1,025 lbs. per acre, respectively.

Since 1898 over 550 plats, including about 50 varieties, have been cut for hay. It was found that young or vigorously growing vines are always difficult to cure, while mature vines are cured much more rapidly. Varieties producing few or no peas are the most difficult to cure because they continue to grow until checked by frost. Late shallow cultivation prolongs the period of growth and the author recommends that cultivation should cease when the first pods appear, if the crop is grown for hay. Vines bearing a fair or full crop of peas well ripening together are easily cured when about one-fourth of the peas are ripe and no second growth is taking place, while if the peas ripen through a prolonged period the plants continue in vigorous growth and are difficult to cure unless the weather is most favorable.

Cowpea seed of the same varieties but obtained from different sources showed great variations in the yield of hay. At the station, Clay cowpeas from Virginia and Arkansas-grown seed in adjoining plats yielded 3,800 and 8,700 lbs. of hay per acre, respectively. Black Eye from Indiana produced 800 lbs., and the same variety from North Carolina 4,000 lbs. of hay per acre. New Era from Maryland seed yielded 700 lbs. of hay and 22 bu. of peas, and from home-grown seed 1,900 lbs. of hay and 19 bu. of peas per acre. Yields of hay for all varieties and seed from different sources are tabulated, and reference is made to previous work along this line (E. S. R., 15, p. 666).

In another experiment cowpeas were mown at different stages of growth to observe the effect of the degree of maturity on the curing of the vines for hay. The varieties under test ripened their first pods as follows: Warren New Hybrid August 15, Warren Extra Early August 20, Whip-poor-will August 28, Taylor September 8, and Clay September 14. The first mowing, made when the varieties were forming their first pods, proved unsuccessful for haymaking. The second mowing, made when the first pods ripened, gave good hay from Warren New Hybrid and Warren Extra Early. The first and second mowings of Clay and Taylor were failures, but good hay was produced from Taylor mown when half or all of the pods were ripe. The number of days from sowing until the first ripe pods appeared was as follows: Warren New Hybrid 67, Warren Extra Early 72, Whip-poor-will 80, Taylor 90, and Clay 97 days. Clay is a late grower and did not prove to be a very successful variety for hay.

In 1903, 12 varieties were planted on May 13 and July 8, and both varieties were mown at the same time. Of the different varieties New Era, Black Eye, and Warren Extra Early ripened a full crop of peas and the vines cured well. Brown Eye, California Black Eye, Large Black Eye, and Whip-poor-will ripened a fair quantity of pods and the vines cured into very good hay; while Brown Crowder, Clay Crowder, Conch, Lady, and Red Ripper were in vigorous growth with only a few ripe pods when mown, and produced a very inferior hay.

The results of four years' experiments with Whip-poor-will cowpeas show that the quantities of seed producing the largest yields of hay were in no case below 12.5 lbs. nor above 25 lbs. per acre, the average being about 16 lbs. Varying with 6 varieties in 1903, using from 6.25 to 100 lbs. per acre, the highest average yield of hay was produced from 25 lbs. of seed. Whip-poor-will in this test produced the heaviest yield from 12.5 lbs. per acre, Taylor from 100, and Warren New Hybrid from 25 and from 75 lbs. From 100 lbs. of seed Taylor yielded only 350 lbs. of hay more than from 37.5 lbs. The best yields of shelled peas were secured from not less than 12.5 nor more than 37.5 lbs. of seed per acre. Directions for harvesting and curing cowpea hay are given.

Observations on potato culture, A. Carré (*Prog. Agr. et Vit. (Éd. L'Est), 25 (1904), No. 8, pp. 235–242*).—The culture of the potato in France is discussed, sta-

tistics on the production given, and the results of experiments reported. A fertilizer test was made on a sandy, noncalcareous clay soil. The first or check plat received no fertilizer, the second received barnyard manure only, the third 400 kg. of superphosphate per hectare in addition to the manure, and the fourth 160 kg. of nitrate of soda per hectare in addition to the manure and the superphosphate. The increase per hectare in financial results on the second plat over the first was 120 francs, and on the third and fourth plats 105 and 210 francs, respectively, over the second. The average results of a cooperative experiment carried on by 24 farmers on this same plan gave an increase of 3,548 kg. of potatoes per hectare in favor of the application of commercial fertilizer.

Potato trials of 1903, E. S. BROWN (*Amer. Gard., 25 (1904), No. 473, pp. 133, 134*).—Of nearly 100 varieties tested the following are considered the most promising: Extra early varieties—Eureka, Early Snowball, Early Whiton, and Krine Lightning; early to medium varieties—Early Ohio, White Ohio, New Queen, Irish Cobbler, Red Triumph, Early Puritan, Early Michigan, Early Thorburn, and Peck Early; medium to late varieties—Potentate, Vornheim, King of Michigan, Chicago Market, and Great Divide; late and general purpose varieties—Green Mountain, Bonanza, Whiton Mammoth, and Yellow Elephant. Descriptive notes on these and on other leading varieties are given.

A method of storing potatoes, E. SCHRIBAUX (*Jour. Agr. Prat., n. ser., 7 (1904), No. 7, pp. 214, 215*).—The experiments here described are essentially trials of storing and growing potatoes in pulverized soil or sand kept in the dark. Early in June potatoes were planted in wooden boxes filled with moist potting earth and placed in a dark basement where the temperature varied but little from 15° C. The tubers were planted 6, 12, and 18 cm. deep in the same boxes. Practically no care was given them until the boxes were examined in December, when it was found that a crop of new potatoes amounting in weight to one-half that of the tubers planted had been produced near the surface of the soil.

The tubers of the new crop were all at the same level, although the planting had been at different depths. It was noticed that at a depth of 20 cm. some tubers produced only a few tender sprouts, and that by placing them somewhat deeper they can be kept without change, excepting a reduction of the starch content, until August. If placed too deep the tuber is deprived of oxygen, intramolecular respiration is substituted for normal respiration, and decomposition results.

Thickness of seeding in its relation to the yield and the development of the head of spring rye, E. GROSS (*Fühling's Landw. Ztg., 53 (1904), No. 2, pp. 57–60*).—Three series of plats were seeded with rye in the spring. Different quantities of seed were used, and the results obtained are shown in the following table:

Results with spring rye sown at different rates.

Seed per hectare.	Yield per hectare.		Weight per hectoliter.	Weight of stem.	Weight of head.	Weight per head.		Length of head.	Number of grains per head.	Grains per centimeter.
	Grain.	Straw.				Grains.	Chaff.			
Kg.	*Ql.*	*Ql.*	*Kg.*	*Gm.*	*Gm.*	*Gm.*	*Gm.*	*Cm.*		
160...	25.90	61.93	71.4	1.631	1.109	1.177	0.232	11.39	36.2	3.18
200...	24.78	68.18	70.4	1.590	1.316	1.093	.223	11.11	35.5	3.15
240...	24.20	66.27	69.9	1.495	1.132	.909	.223	10.95	29.4	2.69

Weather in its relation to the yield and quality of sugar beets, GROHMANN (*Deut. Landw. Presse, 31 (1904), No. 11, pp. 83, 84*).—Weather conditions in relation to sugar-beet culture are discussed and meteorological data, together with the average yield and quality of sugar beets for the years 1892 to 1900 inclusive, are given.

The observations of the author lead to the conclusion that sunshine is not very effective in the sugar production in the beet when the development of the plant has not been normal, but that otherwise the sugar content of the beet mainly depends upon the duration of sunshine during the last months of the vegetative period of the crop. Of the different factors affecting the yield of beets, moisture conditions are considered the most important. The production of sugar in the beet is influenced mainly by the duration of sunshine, and largely by favorable temperatures. Attention is called to the fact that heavy yields of beets often more than offset a low sugar content. The richest beets in this series of years were produced in 1900, but the yield of sugar per hectare was less than in 1894, when the sugar content of the beets was lowest.

The increase in the sugar content of pulled beets when topping is delayed, T. Remy (*Deut. Landw. Presse, 31 (1904), No. 15, pp. 119, 120*).—The composition of fodder beets and sugar beets topped immediately after pulling and stored in heaps covered with earth, was compared with that of beets pulled, placed in piles with their leaves exposed on the exterior of the piles, and topped 3 weeks later. The late-topped beets showed an increase in the percentage of dry matter and of sugar over the beets topped at the time of pulling. This increase was unimportant in the fodder beets, but in the sugar beets it amounted to 0.8 per cent, which, in the opinion of the author, is sufficient to merit consideration. The disadvantages of the method as pointed out are the loss of the leaves for fodder, the increase in labor, and the danger of frost injury in the unprotected heaps.

Annual report of the Bureau of Sugar Experiment Stations for the year 1902–3 (*Brisbane, Queensland: Bureau of Sugar Expt. Stas., 1903, pp. 39*).—This report contains accounts of laboratory work on soils of the Province, and experiments with varieties, methods of culture, fertilization, and irrigation of sugar cane, and on the manufacture of sugar from cane.

Sweet potatoes from seed (*Queensland Agr. Jour., 14 (1904), No. 2, p. 90*).—A report is here given of the growing of sweet potatoes from seed. The vines grown from seed were not very productive, but the tubers which were obtained were large and sound. Among some of the vines were a few lilac-colored stalks. These were planted out with the result that a potato having a different color and a leaf of different shape was obtained. It is thought probable that the vines thus grown from seed may be more resistant to the usual sweet potato diseases in the district than the ordinary sorts.

Ridge and level culture of swedes, G. L. Sutton (*Agr. Gaz. New South Wales, 15 (1904), No. 1, pp. 79, 80*).—The average yields per acre gave an increase of 18 cwt. and 23 lbs. in favor of level culture, but the crop on the ridges matured earlier.

Wheats and flours of Aroostook County, C. D. Woods and L. H. Merrill (*Maine Sta. Bul. 97, pp. 143–180, figs. 2*).—Maine-grown wheats represent Maine varieties grown within the State, and the samples of flour under test were obtained from 3 Aroostook County mills. The composition and heat of combustion of these flours are compared with those of flours obtained from Minneapolis. The results show that 8 samples of flour from Maine-grown wheats contained 3 per cent less protein than the flours from the western wheats, i. e., the western wheats contained one-fourth more protein than the Maine wheats. The dry matter of the western flour also contained one-fourth more fat and crude fiber, and 3½ per cent less starch and other carbohydrates than the samples from Maine-grown wheats. The heat of combustion was practically the same.

Baking tests showed that the Aroostook-milled flours were deficient in wet gluten as compared with the flour adopted as a standard by one of the Minneapolis mills. This defect is believed to be largely due to milling, and not solely to a lower gluten content of the grain.

The following table shows the differences in composition of wheats grown in different sections of the country:

Average composition and heat of combustion of Maine and western grown wheats, calculated to a water-free basis.

Wheats.	Nitrogen.	Protein (N×5.7).	Fat.	Crude fiber.	Nitrogen-free extract.	Ash.	Heat of combustion per grain.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Calories.*
16 Maine wheats	2.14	12.20	2.56	2.70	80.52	2.02	4.424
12 western wheats	2.55	14.52	2.53	2.76	77.98	2.21	4.437
25 Minnesota wheats	2.47	14.09	2.30	2.53	78.92	2.16	4.328

Two experiments in growing northwestern wheat in Maine are reported. In the first seed of Lamona wheat from Washington and Wellman Fife and Blue Stem from Minnesota was sown. The resulting crop showed an increase in the weight of kernel in every case, amounting to almost 50 per cent with Blue Stem. Lamona, which has a heavy kernel, was only slightly affected in this particular but showed a marked decrease in protein, amounting to 21 per cent of the original. Fife also lost in protein, while Blue Stem made a slight gain. These 2 varieties also gained in gluten, but this gain was much too small to offset the loss in Lamona. The results in this first test were regarded as contradictory, and a second experiment on a larger scale was made under more favorable conditions. In this second test plats of some of the wheats were also grown in Minnesota for comparison. The results obtained again proved inconclusive. The principal differences appeared in the protein content and the weights of the kernels. The average protein content for the northwestern-grown wheats was 15.28 per cent and for the Maine-grown wheats from the same seed 14.27 per cent.

Milling tests were made to study the loss in Maine milling. The results show that it is possible to obtain from 72 to 75 per cent of the wheat in the form of flour. In one of the tests with Minnesota-grown wheat only 57.4 per cent of the wheat was recovered as flour, while in an experiment with Minnesota wheat at Minneapolis 73.1 per cent was recovered. The flour obtained in the first test carried 51 per cent of the nitrogen of the grain, and that obtained in the other, 69.6 per cent. The yield of flour in the other milling tests ranged from 70.2 per cent to 72.4 per cent in the Maine-grown wheats, 72.8 per cent in No. 1 Northwestern, and 68.4 per cent in No. 2 Northwestern wheat. Baking tests of the flours from these experiments revealed imperfections in the product, due to milling. Notes on the improvement of wheat are given.

HORTICULTURE.

Improvements in vegetables, J. O. THILOW (*Amer. Florist, 22 (1904), No. 824, pp. 316, 317, figs. 6*).—The author enumerates the various improvements which have taken place in recent years in the form, color, and quality of the following vegetables: Artichoke, asparagus, beans, beets, cabbage, celery, sweet corn, cucumbers, endive, lettuce, melons, onions, peas, radish, squash, and tomatoes. Some illustrations are given which show in outline the improvements which have been made with beans, beets, carrots, peppers, parsnips, and peas.

Standard varieties and interesting novelties (*Amer. Agr., 73 (1904), No. 6, p. 140*).—The experiences of a number of growers are here summarized as to the results secured with a number of vegetables, field crops, and small fruits. Varieties especially commended and described are the Brittle Wax beans, Fordhook Famous cucumber, Halbert Honey watermelon, Dwarf Stone and Early Trojan tomatoes, Mammoth Yellow Flint corn, White Evergreen and Troy Market sweet corn, Great White Maine oats, Iowa raspberry, and Hartford pear.

A new late cabbage from Russia (*Amer. Agr., 73 (1904), No. 6, p. 142*).—This is a variety of cabbage called the Volga which has been grown on Long Island during the past 9 years. The crop of 1903 was the fourth one from seed grown in this country. The heads of this variety are reported to weigh from 10 to 15 lbs. In shape it is midway between the Danish Ball Head and the Flat Dutch. It is considered one of the best for shipping and for kraut. It is a rapid-growing variety, valuable for a second crop. When planted the same time as the earliest varieties of Flat Dutch it made a solid head fully two weeks earlier than Early Summer, and 25 per cent larger. The heads are very uniform in size. In a field of 4 acres grown for seed purposes less than 1 per cent had to be thrown out. The variety is especially recommended as a quick-growing late sort.

Cantaloupe seed, B. K. Blinn (*Colorado Sta. Bul. 85, pp. 8, pls. 4*).—The author states that it is a common custom in the region where the Rocky Ford cantaloupes are grown in Colorado to use all those melons for seed at the close of the shipping season which may be green, overripe, large, or small. These are gathered without any attempt at selection, and run through the melon seeder. As a result of this method of selection a large percentage of melons grown at Rocky Ford are unmarketable either on account of size, form, defective netting, thin rinds, soft flesh, or other reasons. Illustrations are given showing the outward appearance of a desirable type of Rocky Ford melons produced by careful seed selection.

A typical Rocky Ford melon should be "slightly over 4 in. in diameter, and about 4⅝ in. long; it should have silver-gray netting that stands out like thick, heavy lace, practically covering the entire melon save the well-defined slate-colored stripes; these should run the whole length of the melon, clear cut as if grooved out with a round chisel, and terminating at the blossom end in a small button. The interstices in the netting should be light olive green, that turns slightly yellow when the melon is ready for market. A melon with a black skin under the netting is not so attractive in appearance. . . .

"The flesh should be thick and firm, of a smooth texture, and free from watery appearance, rich and melting in flavor. The shipping and keeping qualities depend largely on the solidity of the melon, so the seed cavity should be small and perfectly filled with seed. The color of the flesh near the rind should be dark green, shading lighter toward the seed cavity, which should be salmon or orange in color. The flesh is often mottled with salmon, and not uncommonly the entire flesh is of that color. The flavor is usually quite uniform, though it is sometimes affected by the health of the vines or other conditions of growth."

Directions are given for the different steps to be observed in selecting melons for seed. It has been found that it takes about one crate of melons to produce a pound of seed, and this fact should be made the basis of the price of selected cantaloupe seed. Melons should be selected from extra prolific hills and among those that ripen earliest in the season. With attention to the careful selection of seeds it is believed that practically all the melons produced can be marketed.

Growing cauliflower seed in Denmark (*Amer. Florist, 22 (1904), No. 824, p. 330, fig. 1*).—A description is given of the methods observed in Denmark in growing cauliflower seed for the trade.

Ginseng to date, F. O. Harrington (*Trans. Iowa Hort. Soc., 38 (1903), pp. 222–227*).—The author notes that by failing to mulch ginseng in Iowa during the winter of 1898 and 1899 one plat was wholly destroyed and another partially destroyed by the severe cold. Artificial shade was not used. Very successful results have been obtained by planting among evergreens and also in walnut groves. Seed produced during the summer of 1902 was sold at an average net price of 66 cts. per 100 seeds. It is estimated that the value of the seed obtained from one-seventh of an acre of genseng was $2,500. Some seed heads of 5-year-old plants produced from 100 to 166 seeds. The dried roots sold for $6.60 per pound.

With seed selling for the price mentioned, or at even half this amount, it is believed more profitable to grow seed than to dig the roots for drying. Special attention is called to the desirability of planting ginseng among shallow-rooting shade trees. The Scotch pine has proved especially valuable for shading purposes. It is sufficiently open to let the sunlight through almost everywhere, and it sheds a large amount of foliage for mulching material. White pine has also proved fairly good when the trees were not too numerous. Cedars and spruces should not be used at all. Beds under walnut trees have done very well. With the approach of winter the beds are now regularly covered over with about 3 in. of evergreen needles.

Field culture of tomatoes, A. GUY (*Prog. Agr. et Vit. (Éd. L'Est), 25 (1904), No. 4, pp. 113–118*).—An account is here given of the field culture of tomatoes in the southern part of France for the London market. Directions are included for handling the crop and shipping.

Watermelon growing, A. J. McCLATCHIE (*Arizona Sta. Bul. 47, pp. 302–307, fig. 1*).—Popular directions are given for the culture of watermelons in Arizona, special attention being given to varieties, irrigation, and cultivation. While all varieties of watermelons thrive in Arizona, the variety Augusta is considered most desirable as an early melon. Next in earliness is the Alabama. For the main crop the Florida and the Rattlesnake are most in favor. Sweetheart and Blue Gem are also grown to a considerable extent for the home market and for shipping. The Chilean is considered an excellent late melon.

Subirrigation in the greenhouse, W. M. MUNSON (*Amer. Agr., 73 (1904), No. 8, p. 201, fig. 1*).—Several methods of subirrigation in the greenhouse are described. In an experiment with radishes the percentage germination of the seed was about the same, whether subirrigation or surface irrigation was practiced. The yield, however, of first-class roots on the subwatered section was about 15 per cent greater than on the surface-watered section. In another experiment the number of marketable bunches obtained on the subwatered section was more than twice as great as the number obtained from the surface-watered section.

Principles of plant growth, A. T. ERWIN (*Trans. Iowa Hort. Soc., 38 (1903), pp. 233–236*).—Special attention is called in this article to the desirability of heading apple trees low in Iowa. With low-headed trees there is less sun scald, the trees do not dry out as much in winter, the wind can not get so great a leverage on them and thus blow them down, the fruit in falling is not bruised to so great an extent, spraying is more easily performed, and harvesting can be done much more rapidly and easier than where high heading is practiced. One of the disadvantages of low heading is the difficulty of cultivating close to the trees; but since with mature trees the feeding rootlets are at considerable distance from the trunk, it is believed that cultivation close to the body of the tree is not nearly as essential as it is generally thought to be.

An experiment was made in storing fruit by putting Wealthy and Wolf River apples in a cellar at harvesting time, and also storing in sheds. Those placed in the cellar decayed much more quickly than those put in sheds, owing to the fact that the cellar kept warm much longer than the shed above ground.

Production of new varieties, G. A. IVINS (*Trans. Iowa Hort. Soc., 38 (1903), pp. 345–348, pl. 1*).—The author gives an account of growing a large number of seedling strawberries, plums, apples, and grapes.

With strawberries the greatest success has been achieved in crossing on the Bubach variety. Two new varieties have been thus secured, one of which produces very large berries. The picking season of both continues about 3 weeks. They are staminate varieties and are considered good plant makers. A seedling of Beder Wood proved earlier, of better quality, higher color, and fully as productive as that variety. Another of Haverland proved more productive than the mother plant. Only one pistillate variety has been secured which is considered promising. It is a very large berry with nearly black foliage and has been named "Mary E."

The characteristics of a number of seedling apples which have been secured are noted in some detail. Some of these are of exceedingly fine quality and very hardy. The Rankin has been the best late fall apple grown by the author. The Hinkley is believed to be hardier than the Longfield. None of the author's seedling grapes have yet fruited.

A method of increasing the size of fruit (*Proskauer Obstbau-Ztg., 8 (1903), No. 6, p. 90*).—Directions are given for increasing the size of long-stemmed fruits such as apples, pears, etc., by grafting to the stem by approach a vigorous sprout growing near the fruit.

Origin of Black Ben Davis (*Nat. Nurseryman, 12 (1904), No. 2, pp. 18, 19*).—This is a report of a committee appointed by the Arkansas State Horticultural Society to investigate the origin of the Black Ben Davis. The committee stated that Black Ben Davis originated in Washington County, Arkansas, on a farm owned by Alexander Black; and that while it is of the Ben Davis type and has some of the characteristics of the apple known as Gano, it is a separate and distinct variety.

Thinning fruit, E. R. BENNETT (*Connecticut Storrs Sta. Rpt. 1903, pp. 28–32, fig. 1*).—A general discussion is given of the desirability of thinning different varieties of fruit, with an account of an experiment in thinning Baldwin apples. Five medium-sized trees were used in the experiment. On one tree about one-third of the fruit was removed, on another one-fourth, while on another the thinning was mostly done on heavy-laden limbs. Two trees were used as checks. In every case the thinning was done July 15, after the usual early dropping of the fruit was past.

The number of first and second grade fruits obtained and the total value of the fruit is recorded in a table. The increased value of the fruit due to thinning varied from 77½ cts. to $1.83 per tree. Thinning had a tendency to increase the size of the first-grade fruit; thus while it took 570 apples for a barrel of first-grade fruit in the case of the unthinned trees, it required but 536 to make a barrel of first-grade fruit from thinned trees. Suggestions are given on how to thin fruit and when to thin.

According to the author, peaches should be thinned to 6 or 8 in. apart. Plums should not be left close enough to touch each other when they are full grown. It is usually not desirable to thin until after the early periods of falling are past, which in the northern States occurs from the middle of June to the middle of July.

It is recommended that all discarded fruits be removed from the orchard and destroyed, either by burning or burying, as a means of controlling injurious insects and diseases.

Pruning of tree and bush fruits, W. N. HUTT (*Utah Sta. Bul. 83, pp. 33, figs. 28*).—Detailed directions are given for pruning all the more important orchard and small fruits, especial attention being given in each case to a discussion of the principles underlying the pruning operations to be performed with each fruit.

Pruning the peach, C. P. CLOSE (*Delaware Sta. Bul. 62, pp. 16, figs. 21*).—This bulletin discusses the value and best methods of pruning peaches in Delaware and is accompanied by a large number of photographs illustrating the text. Various subdivisions treat of the method of pruning roots at planting; pruning the top immediately after planting; pruning first, second, and subsequent years; renewing old orchards, etc. Low heading of peach trees is advocated.

Peach growing in Arkansas, E. WALKER (*Arkansas Sta. Bul. 79, pp. 43–68, dgm. 1*).—According to the author, peach growing is rapidly increasing in importance in Arkansas. The larger part of the orchards are located in the western half of the State on the higher grounds. The soils which are becoming popular for peaches are largely those which were coming to be considered "worn-out" cotton lands. Land so worn as to be unprofitable in cotton is giving very satisfactory results with peaches. Of the varieties grown throughout the State the medium and late ones are most profitable.

The early varieties come in competition with those from Georgia, Texas, and elsewhere, and are unprofitable. It is believed that Mountain Rose and Family Favorite

are as early varieties as will prove generally profitable in the State when planted in shipping quantities. The chief demand at the present time in Arkansas seems to be for yellow free-stone peaches. The varieties of peaches that have proved profitable for shipping are in order of commercial value Elberta, Salway, Mountain Rose, Emma, Family Favorite, and Heath Cling. Detailed directions are given for the location of peach orchards, and the planting, growing, harvesting, and marketing of the fruit.

Relative to the root pruning of young trees at transplanting, the author states that as a result of trials, close root pruning, such as is observed in the Stringfellow method, has proved less satisfactory at the station than planting with only moderate pruning of the roots.

A lesson in pollination, C. G. Patten (*Trans. Iowa Hort. Soc., 38 (1903), pp. 372–374*).—Pollen of Winter Nellis pears was put up by the author in California, shipped to Iowa, and used to fertilize blossoms of Keiffer pears about 30 days later. The pollen was spread out on unprinted paper as soon as gathered, and placed in a darkened corner of a room near a stove, where it was left until fully ripened and dried. This required about 35 hours. It was then placed in several envelopes to exclude the air, and shipped. The blossoms of the Keiffer pears fertilized with this pollen were the only ones that matured fruit on the tree during the season.

The Calimyrna fig, G. C. Roeding (*Pacific Rural Press, 67 (1904), No. 6, p. 84*).—The author states that the California crop of Calimyrna figs in 1903 was 65 tons. The cost of distributing Capri figs throughout the orchards for the purpose of pollinating the Smyrna figs was $1.15 per acre. The cost of drying and handling the Smyrna figs is stated to be considerably less than that required for Adriatic figs. The opening prices for dried Adriatics in 1903 was 3½ cts. per lb., while that for Calimyrna figs was 6 cts. per lb. The top grafting of California Adriatic figs with Smyrna varieties is recommended.

The date-palm orchard, R. H. Forbes (*Arizona Sta. Rpt. 1903, pp. 324–328, figs. 2*).—A further report of progress is given on the condition of the date-palm orchard up to July, 1903 (E. S. R., 14, p. 761). During the year the number of new suckers increased from 321 to 422, 60 trees blossomed, and the 4 varieties, Rhars, Deglet Noor, Amari, and Arechti fruited. The Rhars variety produced the bulk of the crop, which began to ripen August 30 and matured mostly between October 1 and 10. This appears to be a soft date of good flavor, but required drying to about 85 per cent of its original weight in order to keep and handle well. This may be done either artificially or in dry, quiet weather on the tree. It is now thought probable that the Deglet Noor variety will not ripen in the Salt River Valley.

The Amari variety has proved to be a small, dark date of very ordinary quality. About 60 per cent of the importations from Arabia and Beluchistan in June, 1902, have died and it is thought that about 10 per cent more will be lost. This heavy loss is believed to be due to the small size of the suckers imported. They averaged only 5 lbs. in weight, and it is believed that 30 lbs. is about the weight best suited for importation, combining economy in freight with a high-growing percentage.

In a summary of all the work thus far done at the station with imported dates, it is shown that 41 per cent of all the trees imported have been lost. Specimens of 68 varieties are now growing on the station grounds. The losses from a commercial point of view are heavy. On the basis of the station work it has cost, under favorable circumstances, not less than $4 each to deliver 25-lb. suckers from Africa to the station. On account of this excessive cost it is believed that many growers will prefer to plant seeds in the expectation of obtaining a small percentage of good fruit-bearing palms. Relative to the growing of palms from seed, the author states that "the seeds may be made to grow promptly by first stratifying them for 3 or 4 months. This consists in burying them under about 20 in. of well-drained moist sand or sandy soil, and keeping them moist for the time stated. They will then be

well softened and, being planted, will sprout promptly instead of waiting weeks or months before appearing above ground. Very alkaline ground should not be used to start seedlings, which are much less resistant to salts than mature trees."

Strawberry culture, A. J. McClatchie (*Arizona Sta. Bul. 47, pp. 297–299*).—Popular directions are given for the culture of strawberries in Arizona. The 2 most commonly cultivated varieties in Arizona are the Arizona Ever-Bearing and Michel Early. The Ever-Bearing gives the better results on heavy soils, while the Michel is better adapted for more sandy soils. The Michel is the earlier berry of the two, and endures heat and drought better.

The native shrubs of Iowa, B. Shimek (*Trans. Iowa Hort. Soc., 38 (1903), pp. 453–468, pls. 10*).—A botanical key is given for identifying the native shrubs of Iowa, and in addition descriptive notes on 97 of these shrubs. Plate illustrations are also given in a number of instances.

Beautifying the home grounds, L. C. Corbett (*U. S. Dept. Agr., Farmers' Bul. 185, pp. 24, figs. 8*).—Directions are given for the laying out and the beautifying of home grounds by the use of shrubs, flowers, vines, and trees. Cultural suggestions are given, as well as directions and diagrams for the planting of various shrubs in groups. Some notes are also given on planting to produce immediate effects and on the maintenance of lawns.

Roses and their cultivation, T. W. Sanders (*London: W. H. & L. Collingridge, 1904, pp. 162, figs. 59; rev. in British Med. Jour., 1904, No. 2254, p. 611*).—This purports to be a full account of English methods of growing and managing roses, with descriptions of varieties and other matter of interest to rose growers.

Comparative fertilizer experiment with the commercial fertilizer "Heureka" and the Wagner fertilizer "WG" with pelargoniums and fuchsias, R. Otto (*Gartenflora, 53 (1904), No. 3, pp. 58–61*).—The details are here given of a test to compare the relative values of these two commercial fertilizers in the pot culture of pelargoniums and fuchsias. The "Heureka" fertilizer was supposed to contain 7 to 10 per cent of nitrogen, 7 to 10 per cent of phosphoric acid, and 7 to 10 per cent of potash; all in an easily assimilable form. The fertilizer "WG" was supposed to contain 13 per cent of nitrogen, 13 per cent of phosphoric acid (12 per cent of which was water soluble), and 11 per cent of potash.

With pelargoniums the "Heureka" fertilizer proved much the better of the two. The leaves of the plants fertilized with this material were larger, deeper green, earlier, more numerous, and the flowers were more highly colored than where the fertilizer "WG" was used. With fuchsias, however, the results were considerably in favor of the "WG" fertilizer. All in all, the author considers that these two fertilizers stand very close to each other as regards their relative value in garden and flower culture.

FORESTRY.

Tests of forest trees, A. Dickens and G. O. Greene (*Kansas Sta. Bul. 120, pp. 85–131, pls. 12*).—Tests of forest trees were among the first experiments begun at the Kansas Agricultural College, and an account is given of a number of the plantings which took place between 1886 and the present date. The different species planted are described at some length, their adaptability to conditions and rate of growth being indicated. Among the trees reported upon are ash, black walnut, Osage orange, ailanthus, various maples, box elder, cottonwoods and poplars, elms, oaks, and various conifers.

In 1896 a cooperative experiment with the Bureau of Forestry of this Department was begun to test the hardiness of tree seedlings. Seeds from different localities were sown and observations made to test their resistance to the climatic conditions of the station. While considerable difference was noted in the individual trees, there was nothing to indicate great differences in species received from different States.

A second report is given of cooperative tree planting carried out in 1896-7, the rate of growth of the different trees being shown. The species in this experiment were aspens, red cedars, and various pines.

Planting trees for posts, fuel, and wind-breaks, O. M. MORRIS (*Oklahoma Sta. Bul. 60, pp. 19, figs. 6*).—Directions are given for the collection of seed, propagation and care of seedlings, cultivation in the nursery, preparation of the land, and transplanting of trees for the different purposes indicated in the title. The first tree planting made at the station was begun in 1898. A brief account is given of the different species of trees planted, and a report is made of those still living in December, 1903. The adaptability of a number of species for planting in Oklahoma is described, including the American white ash, box elder, catalpa, white elm, hackberry, black locust, honey locust, soft maple, Osage orange, Russian mulberry, sycamore, and black walnut.

The measurement of saw logs, A. L. DANIELS (*Vermont Sta. Bul. 102, pp. 35-40, charts 2*).—The author gives a formula for determining the actual number of board feet in the average log, and compares the results obtained by this system of measurement with the log rules in common use. There seems to be good reason for believing that this rule, which is designated as the "Universal log rule," offers distinct advantages over any of the others now in use.

Some of the sources of error of other rules are pointed out and comparisons made between the estimated contents of the log and the actual amount as shown by the sawed lumber. The universal rule, which can be used for logs of any size, is as follows: From five-eighths of the diameter in inches subtract 2 and multiply by the diameter. The error in this rule, so far as tested, is only about 1 part in 200.

SEEDS—WEEDS.

Clover and alfalfa seeds, A. D. SELBY and J. F. HICKS (*Ohio Sta. Bul. 142, pp. 111–130, pls. 4*).—The results of examination of 28 samples of red clover seed, 15 of alfalfa, 6 of alsike clover, and 3 of crimson clover. Attention is called to certain impurities which were found in many of the samples, the presence of dodder in red clover and alfalfa being especially commented upon.

The detailed results of the examinations of the different lots are given in tabular form, and the presence of foreign seeds in the different samples is indicated. The vitality tests showed that the seed for the most part was of fairly good quality, but wide differences were noted between soil tests and those conducted in a seed-testing apparatus. In order to remove the danger from the introduction of dodder, the authors recommend that no alfalfa seed be sown until it has been thoroughly screened through a sieve of 20 meshes to the inch to remove the dodder seeds.

Some weeds of Iowa, L. H. PAMMEL (*Iowa Sta. Bul. 70, pp. 295–545, figs. 169*).—This is a more technical and expanded edition than the popular edition previously noted (E. S. R., 15, p. 372). The information regarding the different weeds is given in greater detail, and comprehensive accounts are included of the distribution and migration of weeds, and the means of dissemination of plants. A number of poisonous plants are described at length, particular attention being paid to poisoning from cowbane (*Cicuta maculata*). The effect of weeds on crops, their duration, and the different species of weeds which are associated with different crops are discussed.

Weeds used in medicine, ALICE HENKEL (*U. S. Dept. Agr., Farmers' Bul. 188, pp. 45, figs. 31*).—A popular bulletin describing the methods of collecting and curing drugs, roots, barks, etc., and giving suggestions for their disposal. A number of species of plants which occur more or less as weeds are described, and their utilization by preparing them for the drug trade is suggested.

Weed prevention experiments, J. A. VOELCKER (*Jour. Roy. Agr. Soc. England, 63 (1902), pp. 359–361*).—A report is given of experiments carried on for the eradica-

tion of wild poppy, wild oats, wild onion, and the annual chrysanthemum. In the experiments for wild poppy eradication, spraying with copper-sulphate solutions was again tried. Shortly before the poppies came into flower they were sprayed with a 2 per cent solution. In one case the solution was distributed over the upper side of the leaves, while in the second an attempt was made to thoroughly spray it on the under side of the foliage. When copper-sulphate solution was applied so as to well cover the under side of the leaves the plants were to a great extent destroyed.

The experiments for wild oats eradication consisted of a top-dressing of nitrate of soda and sulphate of ammonia. In 1901 the effects of basic slag and lime were tried, the wild oats being sown with barley. The slag did not seem to produce any benefit, but with the application of lime there was a marked reduction in the wild oats and an accompanying increase in the barley crop.

For the eradication of the wild onion a 5 per cent solution of carbolic acid was tested with promising results. In the experiments for the eradication of the annual chrysanthemum, the application of lime was tested at the rate of 2 tons per acre. The application was followed by a decided reduction in the amount of wild chrysanthemums present, but the results were not sufficiently marked to lead to the conclusion that a single application of lime at the rate indicated would be sufficient for the eradication of this weed.

DISEASES OF PLANTS.

A few common plant diseases in Delaware, C. O. Smith (*Delaware Sta. Bul. 63, pp. 19–28, pls. 3, fig. 1*).—Notes are given on corn blight, Lima bean mildew, bean anthracnose, and bean and watermelon anthracnose. During 1903 many complaints were received at the station regarding the blighting of corn. Investigation showed that the trouble was due to the fungus *Helminthosporium inconspicuum*, which produces discolored elongated spots on the leaves, the width often being limited by the veins of the leaf. The fungus makes its appearance ordinarily during July and August, and thus far has not been reported as injuring corn seedlings. The spore characters and germination are described, and the results of some artificial infection experiments are given.

In many respects this disease is said to resemble a destructive disease of maize in southern Europe, which is attributed to *H. turcicum*, and the 2 organisms are described as probably identical. As this disease occurs upon the corn in an advanced stage of growth there appears to be no practical remedy for its prevention. Rotation of crops is recommended, and as it is probable that spores would live after passing through the alimentary canal of animals, the use of manure from corn-fed animals on land intended for corn is cautioned against.

The mildew of Lima beans due to *Phytophthora phaseoli* is described. This disease seems to be entirely confined to the Lima bean, and has been the subject of considerable investigation at different stations. Hitherto the fungus has not appeared in sufficient abundance to be very troublesome, but a warning is given for the protection of fields in case of a wet summer and fall.

The bean anthracnose (*Colletotrichum lindemuthianum*) is described, the spore characteristics, mycelium, etc., being characterized. On account of various experiments which have been carried on to prove the identity of similar diseases, the author gives an account of inoculation experiments between the species of Colletotrichum growing on the bean and watermelon. These inoculations were made with spores on cucumber, pumpkin, squash, muskmelon, watermelon, and bean, and while the results are not considered conclusive, the failure to produce the disease leads the author to believe that the two fungi are distinct, *C. lindemuthianum* growing on the bean and *C. lagenarium* upon the cucurbits. For the prevention of this disease spraying with Bordeaux mixture has given satisfactory results.

Treatment of certain plant diseases, F. D. CHESTER (*Delaware Sta. Bul. 63, pp. 29–32*).—A brief report is given of experiments in spraying grapes, treating asparagus rust, and plum rot.

The experiments in spraying grapes were conducted to test the effect of different applications of Bordeaux mixture, and the relative value of Bordeaux mixture with and without the addition of resin soap. The different rows of vines were given 1 to 4 sprayings of the different fungicides. Two sprayings gave nearly as good results as 4 sprayings and at half the cost. The yield was approximately doubled as the result of the first 2 sprayings, and no special advantage would be gained by further sprayings in the average seasons, but the persistence of warm, damp weather would justify a third application 2 weeks after the second.

While the results did not show that the addition of the resin soap offered any advantage over the use of plain Bordeaux mixture, it is thought to make the spray finer and cause a more even distribution of the fungicide. Certain plants, as asparagus and plum, seem to require the addition of soap to cause a proper spread of the fungicide. On this account the author describes the method of preparing resin soap, which consists in heating 35 gal. of water and 42 lbs. of sal soda to the boiling point in a water-tight barrel by means of steam until the soda is dissolved, adding 60 lbs. of melted resin, and continuing the boiling for an hour or two, until a homogeneous mixture is obtained. Two quarts of this mixture are to be used with each barrel of Bordeaux or other fungicide. Where steam is not available, the boiling may be carried on in a kettle or boiler over a fire.

An account is given of spraying experiments for the treatment of asparagus rust, which demonstrate that the disease can be controlled by the use of Bordeaux-resin-soap mixture. The first application should be made about the 1st of July and followed by a second early in August. Ordinarily these 2 sprayings will carry the plants over without injury to the next year's crop.

In experiments in the treatment of plum rot the Bordeaux-resin-soap mixture was tested with fairly satisfactory results. So long, however, as mummy fruits are allowed to remain on the trees but little benefit will be derived from the spraying. The author recommends the removal of all such sources of infection, and winter spraying with strong copper-sulphate solution, followed by sprayings during the season as required.

Some experiments with fungus diseases in 1903, L. F. HENDERSON (*Idaho Sta. Bul. 39, pp. 257–272*).—The 3 most serious diseases of fruits in the vicinity of the Idaho Station are said to be the fire blight of the pear, apple scab, and powdery mildew of the gooseberry. During 1903 experiments were conducted to test the efficiency of a gasoline spraying engine, the value of 2 sprayings of Bordeaux mixture for the prevention of apple scab, the efficiency of potassium sulphid in preventing gooseberry mildew, and pruning for the fire blight of the pear.

The gasoline engine was not found to be wholly satisfactory, due partly to the steep hillside of the orchard, certain mechanical difficulties, and the cost of the machine. Where the land is not too steep and competent help is at hand for running the engine, which is kept in good condition, the cost of the machine should not be considered as it is said to effect a great saving in manual labor, being more powerful and rendering a finer spray, with less liability of the fungicide to clog the nozzle. It is thought doubtful whether a gasoline spraying engine would prove a success in the majority of the orchards in the Palouse country.

Experiments for the prevention of gooseberry mildew were carried on with 3 or 4 applications of sodium sulphid of 2 strengths, 1 oz. and one-half oz. per gallon of water. The results obtained show conclusively the efficiency of protecting fruit against the mildew by this treatment, although the tips of some of the young shoots at the end of the season showed the presence of the fungus. In order to stamp out the disease the spraying should be continued late into the summer.

The experiments for the prevention of apple scab were carried on in 2 orchards, the fungicide used being Bordeaux mixture, but the almost entire absence of scab from the unsprayed trees led to rather negative results. It is thought that the pruning and cleaning up of the orchards and their thorough cultivation aided very materially in suppressing the apple scab. The use of lime-sulphur spray for apple scab was tested, and it was found that a single application of this fungicide would not prevent the occurrence of the disease, although such a claim has been made for it.

A brief account is given of the pruning of pear trees for the destruction of the fire blight. The trees in question were severely pruned during the early summer, and although the variety Winter Nellis is particularly subject to the disease, the trees examined in October did not show a trace of the blight either on the fruit, young branches, shoots, or leaves.

Crown gall, W. PADDOCK (*Colorado Sta. Bul. 86, pp. 7, pls. 3*).—A popular account is given of the crown gall of fruit trees and other plants, and a warning against its spread from infested nurseries. In Colorado the disease does not seem to be particularly destructive where irrigation is not practiced, but its abundance in other districts is shown by the fact that few shipments of nursery stock have been received from points outside of the State which were entirely free from the disease. The preventive measures of inspection, rejection of affected stock, pruning of diseased portions of old trees, and covering them with the fungicide are described.

ENTOMOLOGY.

Thirty-fourth annual report of the Entomological Society of Ontario, 1903 (*Rpt. Ontario Ent. Soc. 1903, pp. 116, pls. 5, figs. 60*).—This report contains the proceedings of the fortieth annual meeting of the society, held at Ottawa September 3 and 4, 1903. During the different sessions of the society various papers on economic entomology were presented, some of which are briefly mentioned in the following notes:

Reports were made to the society by the Entomological Council and by its various branches and sections, and brief accounts were given on the insects of the year by C. H. Young, C. E. Grant, and J. A. Balkwill. The president, W. Lochhead, in his annual address (pp. 22–26) discussed the progress of economic entomology in Ontario. The subject was presented in a historical manner and notes were given on the economic entomological investigations of greatest importance.

A paper on the transmission of yellow fever by mosquitoes was read by L. O. Howard (pp. 26–30). W. Lochhead (pp. 31–36) gave an account of the injurious insects of the season, including Hessian fly, wheat midge, pea weevil, codling moth, beet leaf miner, plum curculio, tussock moth, gooseberry fruit worm, asparagus beetles, etc. Some notes on various injurious insects were given by C. Stephenson and A. H. Kilman. The habits and life history of the cottony maple scale were described by C. J. S. Bethune (pp. 40–42), and the same author discussed the economic relations of the great leopard moth (pp. 46, 47). A key to the insects affecting small fruits (pp. 74–79) was given by the same author, who also discussed the present condition of the San José scale in Ontario (pp. 42–45). In the last-named paper notes are given on the use of crude petroleum, whale-oil soap solution, carbolic wash, and lime-sulphur-salt wash.

The insects injurious to linden were discussed by A. Gibson (pp. 50–61). The pests of this tree were classified according to the particular part of the tree affected and according to their systematic position.

J. Fletcher presented a general account of insects injurious to Ontario crops in 1903 (pp. 62–71). In this paper notes were given on wheat-stem maggot, fall webworm, Hessian fly, clover-seed midge, white grub, onion maggots, carrot rust fly, asparagus beetles, cucumber beetles, San José scale, etc.

Report of the government entomologist, C. Fuller (*Natal Agr. Dept. Rpt. 1902, pp. 53-58*).—A general account of the author's work during the year 1902. Notes are given on the distribution of locusts in various parts of Natal and on the work of the agricultural department in destroying these pests. The Government furnishes free of charge arsenic, soda, and sugar for the preparation of poison baits in the destruction of locusts.

Report on the injurious insects and other animals observed in the Midland Counties during 1903, W. E. Collinge (*Birmingham: Cornish Bros., Ltd., 1904, pp. 16, figs. 16*).—Brief descriptive biological and economic notes are given on the red spider, currant gall mite, myriapods, woolly aphis, plum aphis, flour beetles, pear midge, carrot rust fly, onion maggot, cabbage maggot, diamond-back moth, gooseberry sawfly, *Limax agrestis*, etc.

A report on the injurious insects for 1902, C. Schröder (*Allg. Ztschr. Ent., 8 (1903), No. 1, pp. 9-11*).—Economic and biological notes on cutworms, frit fly, nematodes, pear-leaf blister mite, *Anthomyia funesta*, etc.

The migration and dispersal of insects, J. W. Tutt (*London: Elliot Stock, 1902, pp. 132*).—The author presents in a systematic manner the facts which have been recorded in entomological writings regarding the causes and conditions of the migration of various species of insects.

Recent practical entomological literature, A. Tullgren (*Ent. Tidskr., 24 (1903), No. 4, pp. 233-245*).—The author briefly summarizes the results announced in recent literature concerning methods of spraying and insects injurious to fruits, garden vegetables, field crops, and ornamental trees.

Statistical data concerning the causes of white-head condition in grasses in Finland, E. Reuter (*Ent. Tidskr., 24 (1903), No. 2-3, pp. 113-125*).—The disease known as white head in grasses was carefully studied in various parts of Finland, for the purpose of arriving at a conclusion regarding the insects which were most concerned in producing this condition. The statistics which are reported by the author were collected during the years 1889 to 1901 and indicate that the pests chiefly concerned in bringing about white head are the following: *Pediculoides graminum*, *Tarsonemus culmicolus*, *Aptinothrips rufa*, *Eriophyes cornutus*, etc.

Descriptions of some new species and varieties of Canadian butterflies, J. Fletcher (*Proc. and Trans. Roy. Soc. Canada, 2. ser., 9 (1903-4), Sec. IV, pp. 207-216, pl. 1, figs. 2*).—Descriptive and economic notes are given on a number of butterflies of Canada described as new under the following names: *Phyciodes hanhami*, *Thecla strigosa liparops*, *T. heathii*, *Lycæna pseudargiolus argentata*, *L. pseudargiolus nigrescens*, and *Pamphila manitoboides*.

Diffusion of the hawk moths in North America, F. M. Webster (*Canad. Ent., 36 (1904), No. 3, pp. 65-69, fig. 1*).—According to the author, the majority of North American species belonging to this family appear to have migrated northward from Mexico and the Antilles into various parts of the United States, especially along the Atlantic and Pacific coasts.

Precocious development of the pupal and adult organs in the larvæ of Lepidoptera and Coleoptera, H. J. Kolbe (*Allg. Ztschr. Ent., 8 (1903), Nos. 1, pp. 1-9; 2-3, pp. 25-30, figs. 12*).—The precocious development of various insect organs were studied with special reference to the histology of these structures. Particular attention is given to a study of these questions in the case of *Dendrolimus pini*, which is injurious to pine trees.

A revision of the Nearctic Chrysopidæ, N. Banks (*Trans. Amer. Ent. Soc., 29 (1903), No. 2, pp. 137-162, pl. 1*).—A brief account is given of the habits, life history, and economic importance of these insects. The greater part of the article is occupied with a detailed account of the various species of this family which occur in North America. Several of these species are described as new. A bibliography of the subject is appended to the article.

A revision of the Anophelinæ, G. M. GILES (*London: John Bale Sons & Danielsson, Ltd., 1904, pp. 47, pl. 1, figs. 13*).—This constitutes the author's first supplement to the second edition of his Handbook of the Gnats. Notes are given on the names, habits, and life history of a number of species in the subfamily Anophelinæ, and descriptions are presented of several new species.

The cotton bollworm, A. L. QUAINTANCE (*U. S. Dept. Agr., Farmers' Bul. 191, pp. 24, figs. 7*).—A brief historical statement is given regarding the previous investigations referring to this insect. It appears that planters have thus far made little practical use of the effective remedies which have been discovered. Notes are given on the extent of injury from this insect in Texas in 1903, and also upon its general distribution, habits, life history, food plants, etc. The number of annual broods appears to vary from 4 to 7, with an average of about 5. The preferred food plant is corn, but no practical remedies have been devised for combating the insect upon this plant. The chief injury to cotton from the bollworm appears with the August brood of caterpillars. Observations on the egg-laying habits of the moths showed that the majority of eggs are deposited upon the leaves. The effect of infestation of the squares is to cause them to flare.

Among the ineffective remedies which have been tried or recommended the author mentions trap lanterns, poisoned sweets, burning of sulphur, and the use of resistant varieties. No varieties of cotton immune to attacks by the bollworm are known. During the season of 1903 experiments were made in early planting, spraying with arsenicals, and using corn as a trap crop. As the result of these experiments it is recommended that an early variety of cotton be used, and that this be planted as early in the spring as possible and given good cultivation. Corn may be advantageously used as a trap crop provided it is planted so as to be in silk not later than August 1. Considerable benefit may be obtained from spraying with arsenicals, which are most effective if applied about August 1. The arsenicals may be applied dry or in water, but from the standpoint of convenience the dusting method is preferred.

Information concerning the Mexican cotton-boll weevil, W. D. HUNTER (*U. S. Dept. Agr., Farmers' Bul. 189, pp. 31, figs. 8*).—In this bulletin a historical account is presented of the introduction and distribution of this pest in the United States, with a special account of the territory infested at present, the amount of damage, and a plan of the investigations of the Division of Entomology. Notes are given on the life history and habits of the insects, and on local restrictions regarding the shipment of infested cotton seed in Alabama, Georgia, North Carolina, Mississippi, and Louisiana. The author states that certain dealers have raised the price of cotton seed alleged to be of northern origin far beyond the actual value of the seed, and in some cases when the seed concerned was not of northern origin.

As a result of the investigations thus far made in combating this insect, it is concluded "that there is not even a remote probability that the boll weevil will ever be exterminated." The belief is expressed, however, that the insect can be sufficiently controlled to allow the production of profitable crops by practicing a number of preventive measures, such as early planting, the use of seed of early varieties, thorough cultivation of the fields, planting the rows far apart, destroying all the cotton stalks in the fields when the weevils become so numerous that all the fruit is being punctured, and more extensive use of fertilizers.

Sesamia fusca (*Transvaal Agr. Jour., 2 (1904), No. 6, pp. 220–222, pl. 1*).—The life history and habits of this insect are briefly discussed. Some damage is done to corn wherever the insect is found. The best methods for controlling the pest consist in the proper rotation of crops, late planting, fall plowing, and burning of corn stubble.

The climbing cutworm in the Hawkesbury District, H. W. POTTS (*Agr. Gaz. New South Wales, 14 (1903), No. 12, pp. 1203–1206, figs. 4*).—The climbing cutworm is reported as having caused great injury to wheat fields during the past season. The

leaves and heads in infested fields were entirely destroyed. The best results in combating the pest were obtained from the use of brush harrows and ditches about 9 in. deep provided with deeper holes at intervals of 10 yds.

Cankerworms in Ohio, A. F. Burgess (*Ohio Dept. Agr., Div. Nursery and Orchard Inspection Bul. 2, pp. 13, figs. 7*).—Notes are given on the habits, life history, and distribution in Ohio of the fall and spring cankerworms. Attention is called to the influence of unfavorable weather conditions upon the prevalence and distribution of the insect, and brief notes are given on the natural enemies of the cankerworm and on artificial remedies, such as banding the trees and spraying with arsenicals.

Insects injurious to the apple, G. H. French (*Trans. Illinois Hort. Soc., n. ser., 37 (1903), pp. 530–535*).—The author discusses briefly the habits, life history, and means of combating codling moth, flat-headed apple-tree borer, and scale insects.

The curculio and the apple, C. S. Crandall (*Trans. Illinois Hort. Soc., n. ser., 37 (1903), pp. 176–189*).—The injuries of the plum curculio, apple curculio, and plum gouger are briefly described. Spraying experiments were made, during which applications of standard Bordeaux mixture and Paris green were given to apple trees at 3 periods, viz, when the buds were bursting, just after the petals had fallen, and 1 week later. The results indicated that the injury from the plum and apple curculios is considerably reduced by this treatment. Notes are also given on the habits and life history of these insects.

The ribbed cocoon maker of the apple, M. V. Slingerland and Philena B. Fletcher (*New York Cornell Sta. Bul. 214, pp. 69–78, pls. 4, figs. 3*).—This is a new name proposed by the authors in place of the one which has hitherto been in use, viz, apple bucculatrix. The pest is apparently increasing in number in New York orchards. Descriptive notes are given on the cocoons, caterpillars, and adult insects. The moths of the first brood emerge about the middle of May. They seldom fly except when disturbed. The number of eggs deposited by each female is 4 or 5, and they hatch within from 6 to 10 days. A gradual migration of caterpillars takes place from the upper to the lower branches. In the southern part of New York there are 2 broods per year. The apple appears to be the preferred food plant. Pear, plum, peach, and cherry trees seem to be immune. A number of parasitic insects are mentioned as assisting in the control of this pest, which is also attacked by birds and spiders. There is a large mortality of the pupæ during the winter. In experiments with remedies it was found that the pupæ of this pest could be killed by spraying with whale-oil soap at the rate of 1 lb. per gallon of water. Good results were also obtained by the use of lime-sulphur-salt and mechanical mixtures of kerosene and water.

The peach-tree borer, F. Sherman, Jr. (*North Carolina Dept. Agr., Ent. Circ. 7, pp. 5, fig. 1*).—Brief notes are given on the habits and life history of this insect, together with recommendations concerning the most promising methods of combating it.

The Coccidæ of Ceylon, III, E. E. Green (*London: Dulau & Co., 1904, pp. 171–249, pls. 33*).—In this part of the author's monograph of the Coccidæ of Ceylon the subfamily Lecaniinæ is considered. A synopsis is given of the various genera belonging to this subfamily, and detailed descriptive notes are presented on 33 species of Lecanium.

Treatment of the San José scale in cities, A. F. Burgess (*Ohio Dept. Agr., Div. Nursery and Orchard Inspection Bul. 1, pp. 8, pl. 1, fig. 1*).—Brief descriptive notes on the San José scale, together with an account of its life history, distribution in Ohio, natural enemies, and food plants. Formulas are presented for preparing the insecticides most commonly used in destroying this pest.

A new method of destroying the woolly aphis, E. André (*Rev. Hort. [Paris], 76 (1904), No. 4, pp. 83, 84*).—In an orchard infested with the woolly aphis it was noticed that trees in close proximity to walnut trees were comparatively immune.

Experiments were made to test the possible action of the active principle of walnut trees in the control of these insects. Good results were obtained from pouring a decoction of the leaves of *Juglans regia* upon the woolly aphis and in the soil about the roots of infested trees.

The destruction of grapevine flea-beetles, J. Bonhomme (*Bul. Agr. Algérie et Tunisie, 10 (1904), No. 1, pp. 15, 16*).—According to experiments reported in this paper grapevine flea-beetles may be quite successfully controlled by infection with *Botrytis bassiana.* Cultures of this fungus were distributed on leaves upon which the larvæ were feeding. Upon examination of the larvæ later it was found that the spores eaten by them had germinated and caused death by gradual infection of all the internal organs.

A new organ in Phylloxera vastatrix, H. Stauffacher (*Allg. Ztschr. Ent., 8 (1903), Nos. 2–3, pp. 30–35; 4, pp. 57–60, pl. 1, figs. 4*).—In studying the anatomy of this insect the author discovered a new organ on the ventral side of the body between the first and second thoracic segments. The organ is paired and is believed to be the organ of hearing. The gross and microscopic anatomy of this structure is described in detail.

Extensive outbreaks of Lymantria monacha during the years 1898-1902, J. Meves (*Ent. Tidskr., 24 (1903), No. 4, pp. 225–229*).—Detailed notes are given on the occurrence of this insect in various parts of Sweden during the past 4 years. In forests composed of large trees there is no practical means of combating the insect, except by felling and removing infested trees. Eradication may be somewhat assisted by infectious diseases. Vigorous trees under 3 years of age are rarely attacked. In cases where the insect is present only in small numbers the outbreak may be checked to a considerable extent by collecting the eggs and destroying the moths.

Lasiocampa pini as a forest insect, J. Meves (*Ent. Tidskr., 24 (1903), No. 1, pp. 61–64, pl. 1*).—The habits and life history of this insect are briefly mentioned with special reference to suitable means of combating it. The insect attacks pine and spruce trees of all ages. Experiments showed that the larvæ were capable of withstanding a temperature of —10° C., and it is believed that the pest winters over to a considerable extent in the larval condition.

Studies of the life history, habits, and taxonomic relations of a new species of Oberea (O. ulmicola), F. M. Webster (*Bul. Illinois State Lab. Nat. Hist., 7 (1904), Art. 1, pp. 1–14, pls. 2*).—This species has thus far been found only in a single town in Illinois, where it appears to be confined to one section of the city. The technical description of the species is given by F. H. Chittenden, and the account of the habits and life history is largely based on observations by E. S. G. Titus.

The insect appears to be confined in its feeding habits to the American elm. There is only 1 generation annually, and the larvæ hibernate in the twigs. The pupal period occupies from 22 to 29 days. The eggs are deposited from May 20 to June 15. The effect of the attack of this insect upon elms is to cause the development of clusters of small twigs upon the sides of the branches, and to bring about the premature falling of the leaves.

The method by which young willows protect themselves against the attacks of Dichelomyia rosaria, P. Speiser (*Allg. Ztschr. Ent., 8 (1903), No. 10–11, pp. 204–206, fig. 1*).—In studying willows attacked by this gall-forming insect, the author found that affected branches grew downward in a spiral manner, and that the growth of the affected twig was continued by means of the rapid development of the bud lying immediately below the affected one.

Galls on Abies pectinata, K. Escherich and E. Wimmer (*Allg. Ztschr. Ent., 8 (1903), No. 6–7, pp. 119–122, figs. 4*).—A detailed description is given of the galls on the needles of this tree which are due to the attacks of a species of Lestodiplosis.

Pulex vagabunda, E. Wahlgren (*Ent. Tidskr., 24 (1903), No. 2–3, p. 219*).—Brief

descriptive and economic notes are given on this species, which is said by the author to be referable to the genus Ceratophyllus.

Plant-house Aleurodes, L. R. Cary (*Maine Sta. Bul. 96, pp. 125–144, figs. 11*).—A description is presented of the embryonic stages of this insect, and notes are given on the anatomy of the adult form. Hydrocyanic-acid gas was found to be a successful remedy for combating this species in greenhouses.

The red spider, A. Tullgren (*Ent. Tidskr., 24 (1903), No. 4, pp. 246–249*).—The habits and life history of this pest are briefly described, and notes are given on the use of various insecticides in controlling it. These insecticides include sulphur, potassium sulphid, kerosene emulsion, lysol, antinonnin, and decoction of tomato leaves.

Studies of the habits and development of Neocerata rhodophaga, F. M. Webster (*Bul. Illinois State Lab. Nat. Hist., 7 (1904), Art. 2, pp. 15–25, pl. 1*).—This insect was reported as injuring roses under glass in the vicinity of Chicago. The pest appears to prefer the Meteor rose, but attacks also other varieties, especially Wooton, Bride, Madame Chatenay, etc. No injury is done in rose houses between November and May. The habits of the insect are not well understood. It seems not to attack native species of wild roses, and is therefore considered not to be a native species of insect. The author is not certain whether the name as provisionally adopted for the species will prove to be the correct one.

Spraying apples and pears, F. Sherman, Jr. (*North Carolina Dept. Agr., Ent. Circ. 6, pp. 7*).—As the result of observation of orchards in North Carolina and correspondence with orchardists, it is concluded that careful and persistent spraying of apple and pear trees with Bordeaux mixture and Paris green furnishes the most effective means of restoring the orchards of the State to a productive condition. Notes are given on the insect pests and fungus diseases which may be controlled by these remedies, and also on the manner of preparation and methods and time of application of the remedies.

A supposed remedy for fruit-tree pests: Gunpowder, sulphur, niter, sulphate of iron, mixed and inserted into the tree, C. T. Musson (*Agr. Gaz. New South Wales, 14 (1903), No. 12, pp. 1206, 1207*).—These substances were mixed in equal quantities, and an ounce of the mixture was inserted in holes ¾ in. in diameter bored into trees at a height of 2 ft. from the ground. An application was made upon wattle and plum trees. The holes were blocked with clay. After a period of 6 months there was no evidence that this remedy had had any effect upon the insect pests of these trees.

The nurseries inspection and quarantine bill, C. P. Lounsbury (*Agr. Jour. Cape Good Hope, 24 (1904), No. 2, pp. 188–195*).—The author gives the text of a quarantine bill which has been under consideration for a number of years. It is believed that the bill will be introduced into the colonial parliament during the coming season, and on this account the author urges the desirability of such a law in order to protect the nurserymen and fruit growers of South Africa.

The Columbacs fly, L. von Aigner-Abafi (*Allg. Ztschr. Ent., 8 (1903), Nos. 5, pp. 93–96; 6–7, pp. 124–127*).—The habits and life history of this species of fly are described in detail. The fly belongs to the family Tipulidæ and is generally distributed in southeastern Europe. The females lay from 5,000 to 10,000 minute eggs in running water. The larvæ require from 6 to 8 weeks for development.

The adult insects appear in swarms and attack cattle, horses, sheep, and hogs, which animals are frequently killed by the flies. The losses of live stock are especially serious in parts of Servia and Hungary. In animals which are not killed outright by the attacks of the flies a fever and other abnormal conditions are produced. In protecting animals against this pest the author recommends that animals should be allowed to graze only between sunset and sunrise, and that smudges or substances giving off disagreeable odors be maintained in connection with the stables. Ani-

mals may be protected to some extent from the bites of the flies by covering them with rank smelling oils, etc.

Ten generations of the house fly under different conditions, E. A. Bogdanow (*Allg. Ztschr. Ent., 8 (1903), No. 14–15, pp. 265–267*).—In one series of experiments the wings of the common house fly were clipped for a series of 10 generations in order to determine the effect of this operation upon the flies. No permanent effect was produced by clipping the wings. In a second series of experiments flies were maintained for 10 generations with no food except meat mixed with increasing quantities of the flowers of tansy. No effect was produced by this unusual food.

Mosquitoes, C. Fuller (*Natal. Agr. Jour. and Min. Rec., 7 (1904), No. 1, pp. 50–56, figs. 7*).—A brief account of the habits, life history, and means of combating these pests. The use of permanganate of potash in infested pools and growing eucalyptus trees for the purpose of keeping away mosquitoes are condemned as absolutely valueless. The usual remedies, such as covering the pools with kerosene and draining stagnant water, are recommended.

Termites and termitophilous insects of Central America, F. Silvestri (*Redia, 1 (1903), No. 1, pp. 1–234, pls. 6, figs. 57*).—A detailed technical description is given of the various species of white ants known to occur in Central America. The author also describes the habits of these insects and presents a discussion of the biology of the various members of the colonies of white ants, the duration of the life of individuals, feeding habits, nests, and the relationship of white ants to agriculture. As a rule these species are injurious only to dead trees or timber, but sometimes attack living trees.

In the second part of the author's article notes are given on the various species of mites, scale insects, flies, beetles, Hemiptera, etc., which are known to inhabit the nests of white ants.

Sex determination in bees and ants, W. E. Castle (*Science, n. ser., 19 (1904), No. 479, pp. 389–392*).—A brief popular account of the theories concerning parthenogenesis in bees, in which the author supports the theory of Dzierzon.

Bee keeping, F. Sworder (*Transvaal Agr. Jour., 2 (1904), No. 6, pp. 139–148, pls. 4*).—Various forms of comb foundation are described and notes are given on the methods of preventing the falling of brood comb in young swarms. The author also discusses in a brief manner the location and general management of apiaries, hives, section honey, and the most suitable methods for hiving bees.

Bees and their benefit to the farmer, J. D. Pike (*Ohio State Bd. Agr. Rpt. 1902, pp. 506–509*).—A general account is given of the problems concerned in apiculture with special reference to the importance of bees in fertilizing fruits.

Apiculture in Italy (*Ann. R. Scuola Superiore Agr. Portici, 2. ser., 3 (1902), pp. 691–702*).—A brief statistical account is presented of the quantity of honey produced in various parts of Italy and of the import and export trade in this product. Attention is called to the importance of apiculture, and especially to the agency of bees in the fertilization of fruit trees.

Studies and observations on bumblebees, S. Bengtsson (*Ark. Zool., 1 (1903), No. 1–2, pp. 197–222*).—The author reports the results of his observations on the habits and life history of bumblebees, with special reference to the species *Bombus distinguendus* and *B. hypnorum*. The parasitic and predaceous insects which attack bumblebees are also briefly considered. The author discusses the nature and function of various individuals of the bumblebee colony.

Annual report of the Royal Sericultural Station of Padua (*Ann. R. Staz. Bacol. Padova, 31 (1902), pp. 140, pls. 3*).—An account of the general principles which should govern silk raisers in the selection of races of silkworms most suitable for any given locality is presented by E. Verson.

Experiments were undertaken by E. Quajat for the purpose of devising a method

by which it would be possible to distinguish the sex of silkworm eggs and larvæ. Numerous determinations were made on the specific gravity of eggs and the variations thus observed were noted, particularly with reference to the sex of the eggs as determined by rearing adult moths. It was found that the eggs could be divided roughly into 2 classes, with low and high specific gravity, respectively. No differences were observed in the vigor of the larvæ obtained from these different classes of eggs and no constant relation was observed between the specific gravity of the eggs and the sex. In general, however, there seemed to be a slight preponderance of female eggs among those of low specific gravity. Experiments with larvæ showed that while the actual weight of the larvæ could not be depended upon as indicating the sex, nevertheless about 72 per cent of the heavier larvæ and 29 per cent of the lighter larvæ proved to be females.

Detailed anatomical notes are given on the postembryonic development of the cephalic and thoracic segments of silkworms, by E. Verson. The comparative vigor of the first and last eggs fertilized by the same male moth was studied by E. Quajat. The results obtained indicate that the eggs of a large number of females may be fertilized by a single male, and that no differences are demonstrable in the fertility or vigor of the eggs. Experiments were made by the same author for the purpose of determining the influence of turpentine upon the vitality of silkworm eggs. The action of the fumes of turpentine upon the eggs was found to vary somewhat according to the temperature of the air. The injury was greatest in eggs of the White Japanese breed of silkworms and less so in the eggs of Korean, Chinese, and native races. Immersion of the eggs in pure turpentine killed a large majority.

The influence of external conditions of environment upon the physical properties of the cocoons was investigated by E. Verson, the results of observations carried out in various places in Italy being presented in tabular form. A bibliography of literature relating to sericulture published during the years 1902 and 1903 is appended to the report.

FOODS—NUTRITION.

Review of the literature of composition, analysis, and adulteration of foods for the year 1902, A. J. J. VANDEVELDE (*Separate from Bul. Serv. Surveill. Fabric. et Com. Denrées Aliment., 1903, pp. 95*).—This is the third annual volume reporting titles of articles on analytical methods, apparatus, water, milk and cream, fats and oils, cheese, flours and their derivatives, spices and colonial products, sugar, alcoholic beverages, vegetables and fruits, meats and meat products, preservatives, and related topics. In many cases the bibliographical data are accompanied by brief notes regarding the scope of the articles.

Report of State analyst, E. N. EATON (*Illinois State Food Com. Rpt. 1902, pp. 120–211, figs. 8*).—Of the 924 samples of food analyzed during the year 1902, 397 were found to be adulterated. In addition to other topics, grape juice, soda water, and soda-water sirups are discussed.

Pure food law and rulings of the food commissioner, E. F. LADD (*North Dakota Sta. Spec. Bul. 1, pp. 11*).—The State pure food law is quoted, and the author makes some suggestions for those who would comply with its provisions. The bulletin also includes the rulings of the State pure food commissioner regarding labels, standards, preservatives, etc.

Breakfast foods, J. B. WEEMS and C. E. ELLIS (*Iowa Sta. Bul. 74, pp. 101–114*).—A number of samples of breakfast foods, biscuits, hulled beans, split peas, potato chips, and other food materials were analyzed, and their relative nutritive value is discussed. In the case of some of the materials for which the claim is made by the manufacturers that they are in a sense predigested, the amount of soluble carbohydrates was determined and found to vary from 0.24 per cent to 13.23 per cent, being

in the majority of cases less than 2 per cent. This would indicate, according to the authors, "that the soluble sugars are present only to a limited extent in the breakfast foods. Those who are not troubled with indigestion should not desire predigested foods, and those who have indigestion should consult the family physician."

The general conclusions which were drawn from the investigation follow:

"The breakfast foods are put up in an attractive form and many of them are pleasing to the taste. The statements printed on the packages are greatly exaggerated and little reliance can be placed in many of them.

The cost of the prepared foods is 10 to 16 cts. per pound and the unprepared 6 to 7 cts. per pound. These products do not possess any nutritive value in excess of ordinary food materials. The attractive features are the packages and the palatableness of the food. The claims made for many of the predigested foods are of little or no value. The breakfast foods are not medicines and no reliance should be placed in statements which claim that they are a remedy for any disease."

Breakfast foods, J. B. Weems and C. E. Ellis (*Iowa Sta. Bul. 74, popular ed., pp. 101–106*).—An abridged form of the above bulletin.

On the relation between gluten and total nitrogenous matter in different kinds of wheat, E. Fleurent (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 26, pp. 1313–1315; Bul. Agr. Algérie et Tunisie, 9 (1903), No. 24, pp. 544–546; abs. in Rev. Sci. [Paris], 5. ser., 1 (1904), No. 2, p. 57*).—According to the author the wheats at present grown on a large scale in France have a lower gluten content than those formerly grown. Estimating the total amount of nitrogen in the wheat is not regarded as a satisfactory method for judging of its value. To learn this the amount of gluten should be determined.

The chemical composition of cooked vegetable foods, Katharine I. Williams (*Jour. Amer. Chem. Soc., 26 (1904), No. 3, pp. 244–252*).—Analyses of a number of cooked vegetable foods are reported, the data including sulphur and phosphorus in addition to the usual determinations. It was found that in almost every case the cooked foods contained more water than the raw. However, with broccoli the weight of the raw and cooked material was practically the same, and in the case of asparagus there was a considerable loss in weight due to cooking which was ascribed to a loss of soluble nitrogenous constituents. The large percentage of waste, both before and after cooking, makes asparagus expensive. Raw-green burr artichokes are tough, and in the process of cooking absorbed a larger proportion of water than the other vegetables studied.

The food value of fruit, W. R. Lazenby (*Columbus Hort. Soc. Rpt. 1903, pp. 126–129*).—A number of points in connection with the food value of fruits are discussed.

The adulteration of foods and medicines, G. McCarthy (*Bul. North Carolina Bd. Health, 18 (1904), No. 11, pp. 124–131*).—Food adulteration and food preservatives are discussed, and some of the work of the North Carolina department of agriculture is summarized.

The composition of poultry, W. O. Atwater (*Connecticut Storrs Sta. Rpt. 1903, pp. 147–158*).—Analyses are reported of a number of sorts of fresh and preserved poultry and poultry products.

Poultry as food, R. D. Milner (*Connecticut Storrs Sta. Rpt. 1903, pp. 159–175*).—Noted from another publication (E. S. R., 15, p. 701).

Cold storage of eggs, H. V. Jackson (*Agr. Gaz. New South Wales, 14 (1903), No. 8, pp. 713–715*).—It is stated that the attempts made by the department of agriculture of New South Wales to preserve eggs in cold storage have been very successful. The method employed is briefly described.

Preserving eggs in water-glass solution (*Agr. Gaz. New South Wales, 14 (1903), No. 7, p. 676*).—In an article quoted from the *Mark Lane Express* concise directions are given for the use of water glass in preserving eggs, which, it is stated, are based on the results of 5 years' experience.

Preserving eggs (*Mark Lane Express, 88* (*1903*), *Nos. 3729, p. 335; 3730, p. 371*).—Brief directions are given for preserving eggs by a number of methods.

The caffein content of coffee infusion, J. Katz (*Arch. Pharm., 242* (*1904*), *No. 1, pp. 42–48*).—Using 300 gm. of water to 15 gm. of coffee, containing on an average 1.26 per cent caffein, an infusion was prepared in a number of ways and analyzed. The drip coffee which was made with a special apparatus contained 96.5 per cent, the infused coffee 85.2 per cent, and the coffee made by allowing the water to filter through the ground berry 60.3 per cent of the caffein originally present.

The amount of extract matter in the infusion was, generally speaking, proportional to the caffein content. Judged by the caffein content and the extract matter in the infusion, distilled water and hydrant water gave practically the same results, but when a little sodium bicarbonate was added to the water used for coffee making, the coffee was a little more thoroughly extracted. According to the author's calculations a cup of coffee (150 cc.) contains about 0.1 gm. caffein.

Concerning spices, A. Beythien (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6* (*1903*), *No. 20, pp. 957–964*).—A paper with discussion, presented at a meeting of the Association of German Food Chemists. The adulteration of mace, pepper, and other spices is discussed on the basis of analytical data.

Judging vinegar, G. Popp (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6* (*1903*), *No. 20, pp. 952–956*).—A paper with discussion, presented at a meeting of the Association of German Food Chemists. Experiments are reported which have to do with the establishment of a standard of strength for vinegar. As shown by tests in which vinegar was added to food, that containing a small amount of acetic acid (1.14 per cent) was as satisfactory as stronger vinegar (containing 2.4 per cent acetic acid). In other words, weak vinegar, the author concludes, is as satisfactory as a condiment as stronger vinegar.

From artificial digestion experiments with pepsin it appeared that neither vinegar containing 2 per cent acetic acid nor that containing 4 per cent had any effect upon digestibility. Vinegar with less than 2 per cent acetic acid was not found to be a satisfactory preservative for meat, etc., for short periods. On the other hand, vinegar with 2 per cent or more acetic acid was satisfactory.

Composition of fruit juice, K. Farnsteiner et al. (*Ber. Hyg. Inst. Hamburg, 1900–1902, p. 61; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7* (*1904*), *No. 5, p. 309*).—The expressed and strained juice of a number of sorts of berries was analyzed.

Concerning the marmalade industry, F. Strohmer (*Ber. Chem. Tech. Vers. Stat. Zent. Ver. Rübenz. Ind. Oesterr.-Ung., 1902, pp. 5, 6; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7* (*1904*), *No. 5, pp. 308, 309*).—Examination showed that the English jams and marmalades did not contain glucose, though this substance was found in similar goods of local manufacture.

The nutrition investigations of the Storrs Experiment Station, W. O. Atwater (*Connecticut Storrs Sta. Rpt. 1903, pp. 99–102*).—A brief historical account of the nutrition investigations of the station, particularly those carried on in cooperation with this Department.

The conservation of energy in the living organism, W. O. Atwater (*Connecticut Storrs Sta. Rpt. 1903, pp. 103–122*).—The author discusses the conservation of energy on the basis of his experiments with the respiration calorimeter. Considering the total number of experiments with man at work and at rest, covering in all 143 days, there was a difference of only 53 calories between the total income and total outgo of energy. The author believes, therefore, that the experiments demonstrate that the law holds good with the living body.

The demands of the body for nourishment and dietary standards, W. O. Atwater (*Connecticut Storrs Sta. Rpt. 1903, pp. 123–146*).—On the basis of a considerable amount of data summarized from his own experiments and those of other investigators, the author discusses dietary standards and proposes tentative

standards suitable for persons performing different amounts of work. The fact is emphasized that many more dietary studies, metabolism experiments, and special feeding tests are necessary before definite standards can be determined upon. "The standard must vary not only with the conditions of activity and environment, but also at the nutritive plane at which the body is to be maintained. A man may live and work and maintain bodily equilibrium on either a higher or lower nitrogen level or energy level;" but the most advantageous level needs to be determined.

The fact that appetite is not necessarily the measure of the demand for nutriment is pointed out, and the need of caution in basing general theories of nutrition upon the results of special experience is emphasized.

While recognizing the value of tables of composition of food materials, dietary standards, and daily menus showing the proportions of different food materials required to furnish an adequate diet, the author protests against the too mechanical use of such numerical data.

The conservation of energy in those of advancing years, J. M. TAYLOR (*Pop. Sci. Mo., 64 (1904), No. 4, pp. 343–350*).—In addition to other topics food and diet are discussed with special reference to old age. The author regards moderation in eating and drinking as of the utmost importance.

The A B–Z of our own nutrition, H. FLETCHER (*New York: Frederick A. Stokes Co., pp. XXXVI+426, figs. 10*).—On the basis of personal experience the author believes that overeating should be avoided, and that health may be maintained by eating a comparatively limited amount of food and taking pains to masticate it as thoroughly as possible, the normal appetite being a guide as to kind and amount of food required. The volume contains an explanation of the author's theories, and quotes a number of articles by different writers of interest in connection with the subjects under discussion.

The function and digestion of foods, G. G. NASMITH (*Assoc. Executive Health Officers' Rpt., Ontario, 1903, pp. 109–117*).—A discussion of the theories of nutrition, including results of Pawlow's recent work on digestion (E. S. R., 14, p. 789).

How we are fed, J. F. CHAMBERLAIN (*New York: Macmillan Co., 1904, pp. XIV+214, figs. 63*).—A reader for primary schools, the subject-matter of which concerns the origin of common food products and similar topics.

The action of X-rays upon nutrition, LÉPINE and BOULUD (*Lyon Méd., 1903, Dec. 13 and 20; abs. in British Med. Jour., 1904, No. 2251, Epit., p. 31*).—A series of experiments on animals and animal organs and tissues showed that the X-rays induced or increased glycolytic power under certain conditions. For instance, a portion of the pancreas of a dog exposed to the action of X-rays for an hour and 30 minutes caused increased conversion of starch to sugar, the proportion of sugar to that found in a control test with pancreas not thus acted upon being 471: 413. The action on the starch was continued for 4 hours in each case. In the experiments with animals it was found that the interposition of an aluminum plate prevented the oppressive lassitude and anorexia, which the direct action of the rays tends to produce.

Food and cookery for the sick and convalescent, FANNIE M. FARMER (*Boston: Little, Brown & Co., 1904, pp. XIV+289, pls. 42, figs. 3*).—Some of the principal subjects discussed are infant feeding, child feeding, and food for the sick. Chapters are devoted to the principal foods and beverages and a large number of recipes are given. Throughout the volume the author has included data regarding the composition of foods and has discussed the subjects under consideration to a large extent from the standpoint of nutritive values and the general theory of nutrition.

Food for the tropics, T. M. MACKNIGHT (*London: Thacker & Co., 1904, pp. 126; rev. in British Med. Jour., 1904, No. 2254, p. 611*).—Tropical foods and their uses are described, the general plan being to note the various tropical products which may replace those more familiar in other regions. A list of tropical vegetables and methods of cooking them is given, as well as similar lists of fruits and condiments.

Some thoughts on market hygiene, H. B. BASHORE (*Sanitarian, 52 (1904), No.*

412, pp. 243, 244).—The need of improvement in marketing and handling food is discussed, the fact being recognized that it may readily become contaminated by dirt and micro-organisms, including disease germs, when marketed under the conditions which often prevail.

Concerning human pancreatic juice, K. GLAESSNER (*Ztschr. Physiol. Chem., 40* (*1904*), *No. 5–6, pp. 465–479, dgms. 4*).—A surgical operation which necessitated the insertion of a drainage tube into the pancreatic duct of a patient afforded the author the opportunity of collecting and studying pancreatic juice. According to his observations, the amount secreted varied from 500 to 800 cc. per day. It did not contain trypsin, but a precursor of this, which was rendered active by the intestinal juice.

The action of the fat-splitting and diastatic ferments was increased by gall and intestinal juice, but especially by the latter. The cleavage of starch stopped with maltose. Disaccharids (milk sugar and cane sugar) were not acted upon by pancreatic juice, but were split up into simpler bodies by intestinal juice. The amount of digestive juice and of ferment and the alkalinity were least when the subject was fasting. These factors increased rapidly after food was taken, reached their maximum in about 4 hours, and diminished until the eighth hour of the digestive process.

A study of the variations in the course of the nitrogen, sulphate, and phosphate excretion, as observed in short periods following a small increase in the proteid ingested, P. B. HAWK and J. S. CHAMBERLAIN (*Amer. Jour. Physiol., 10* (*1904*), *No. 6, pp. 269–289, figs. 5*).—Continuing work recently reported (E. S. R., 15, p. 494), the authors were the subjects of experiments to determine the effect of adding a small amount of protein to a uniform basal ration, as shown by the excretion of nitrogen, phosphorus, and sulphur.

It was found that the rate of excretion of nitrogen, measured by 3-hour periods, showed 2 maxima daily. When measured by shorter periods, 3 maxima were observed.

"The rate of excretion of sulphates followed in general a parallel course to that of nitrogen, the main difference being that the minimum rate of excretion was reached after the morning meal, and the maximum late in the afternoon. Frequently 3 maxima were observed on normal days with 3-hour periods. The phosphates differed decidedly in their rate of excretion from either the nitrogen or the sulphates. Two very distinct rises were shown each day, and in one instance . . . an indication of a third rise was seen. . . .

"After the ingestion of a small extra amount of proteid food at the morning meal, the rate of excretion of nitrogen reached its maximum within three to four and one-half hours, after which it fell to its normal rate; in one case slowly, after 4 days, and in the other rapidly, after 2 days. It would seem that the time required to reach the maximum excretion of nitrogen, after increasing the proteid of a diet, was more or less directly proportional to the amount of proteid ingested, the length of time being greatest when the quantity was large.

"With each subject the maximum rate of sulphate excretion differed from that of nitrogen only in reaching its highest point about 6 hours later. In one subject the ratio of nitrogen to sulphates was lowest on the day of increased proteid ingestion; in the other, on the day after the ingestion. The maximum rate of phosphate excretion due to the increased proteid ingestion fell in a period between those in which the maxima of nitrogen and sulphate occurred. . . .

"The ratio between the heat of combustion of the urine and its nitrogen content was lower on the day of increased proteid ingestion than on normal days."

The effect of certain common essences on the cerebral circulation, A. D'ORMEA (*Arch. Ital. Biol., 40* (*1903*), *No. 1, pp. 141–160; abs. in British Med. Jour., 1904, No. 2251, Epit., p. 31*).—It was found in experiments with a dog that the essences of aniseed, lemon, mint, cinnamon, and camphor had a very decided effect on the cerebral circulation. These observed facts are of interest since some of the materials experimented with are commonly used for flavoring foods, etc.

ANIMAL PRODUCTION.

Range forages, R. H. Forbes and W. W. Skinner (*Arizona Sta. Rpt. 1903, pp. 348–350*).—Analyses are reported of greasewood (*Sarcobatus vermicularis*), paloverde twigs, water grass (*Chloris elegans*), 2 varieties of grama grass (one fresh the other old and weathered), and several varieties of saltbush. The composition of a number of these is shown in the following table:

Composition of a number of feeding stuffs.

Feeding stuffs.	Water.	Protein.	Ether extract.	Nitrogen-free extract.	Crude fiber.	Ash.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Greasewood (*Sarcobatus vermicularis*)	4.55	19.81	2.45	34.28	24.50	14.41
Paloverde twigs	5.10	10.94	3.20	39.05	36.01	5.70
Water grass (*Chloris elegans*)	7.60	8.88	1.61	36.53	33.62	11.76
Grama grass (*Bouteloua oligostachya*), fresh sample	6.98	6.50	1.82	42.45	28.19	14.06
Grama grass (*B. rothrockii*), sample 1 year old, dead and weathered	7.35	2.56	1.22	50.58	33.62	4.67

"Greasewood and paloverde twigs are instances of the 'browse' forage upon which animals so largely depend in semiarid country when grass is short. These are of surprisingly nutritious character, as indicated by the analyses here given, being rich in protein, fat, and carbohydrates. The sample of greasewood is especially good, being considerably richer in protein and fat than a sample of alfalfa hay from the station farm.

"The low protein in old, weathered 'grama' grass, as compared with fresh grasses of the same general nature, bears out the low estimate generally placed upon weathered grass as forage."

Commercial feeding stuffs in the Connecticut market (*Connecticut State Sta. Bul. 145, pp. 59*).—In accordance with the provisions of the State feeding stuff law analyses are reported of cotton-seed meal, linseed meal, wheat bran, middlings and mixed feed, maize meal and bran, gluten meals and feed, hominy meal, rye feed, brewery and distillery products, oat feeds, buckwheat middlings, miscellaneous mixed feeds, poultry feeds, proprietary, dairy, stock, and condimental feeds. The different classes of the feeding stuffs analyzed are discussed.

Regarding the proprietary, dairy, and stock feeds, the author notes that these feeding stuffs were made up of such materials as oat, wheat, and corn products, cotton-seed meal, linseed meal with fenugreek, carob beans, and common beans in addition in the case of one of the materials examined. The most concentrated of these mixtures contained 24.6 per cent protein and the others ranged from 7.81 to 20.06 per cent. The prices varied from $21 to $70 per ton.

"A mixture of 1,000 lbs. of gluten feed and 1,000 lbs. of mixed wheat feed made at home would cost at present retail prices $24.76. It would contain a good deal more protein than could be bought for the same money in any of these factory-mixed feeds and would have a higher feeding value. It would also have this added advantage, that the feeder would know exactly what his animals were eating.

"In other words, the cost of most of these factory-mixed feeds is quite out of proportion to their feeding value."

Commercial feeding stuffs, J. L. Hills, C. H. Jones, and F. M. Hollister (*Vermont Sta. Bul. 104, pp. 187–192*).—In order to learn how the actual compared with the guaranteed composition, a number of analyses were made in accordance with the State feeding stuff law of cotton-seed meal, linseed meals, gluten meals and feed, dried distiller's grains, oat and other commercial feeds, provenders, wheat offals, and condimental feeds. In most cases protein was the only constituent determined. The

authors also made an attempt to learn the ingredients used in compounding the condimental feeds examined.

"The claims made for these feeds are essentially, first, that they are appetizers, promoting and improving digestion, and therefore increasing production, be it work, flesh, milk, or wool, and, second, that they possess medicinal virtues of a high order. Touching the first claim it may be said that there is no valid evidence to the effect that condiments or spices increase the digestibility of food or enlarge production, while such evidence does exist to prove the contrary. As to the second claim it may be remarked that the drugs commonly present are simple and well-known remedies, which may do good at times, which are quite harmless, and in cases of more than slight indisposition doubtless quite as ineffectual as harmless."

Methods of discriminating between Egyptian and Bombay cotton-seed cakes, J. A. VOELCKER (*Analyst, 28 (1903), No. 330, pp. 261–263, figs. 6*).—A method of distinguishing between Egyptian and Bombay cotton-seed cakes is suggested, which depends in part upon microscopical, physical, and chemical characteristics. According to the author, the Bombay cake almost invariably contains borax and the percentage of sand (matter insoluble in hydrochloric acid) is considerably higher than in Egyptian cake.

The microscopic examination of American cotton-seed cake, A. L. WINTON (*Analyst, 29 (1904), No. 335, pp. 44–47*).—According to the author, there is no entirely satisfactory method of discriminating between Sea-island cotton-seed and upland cotton-seed cake.

"So far as concerns the mere detection of excessive amounts of hulls or starchy adulterants, microscopic examination, especially if coupled with determinations of nitrogen and fiber, is all that could be desired."

This investigation was suggested by that noted above.

Results of analysis of manures and of feeding stuffs for feeding experiments, S. H. COLLINS (*County Council Northumberland, Education Com., Rpt. 1903, pp. 92–94*).—Analyses are reported of a number of feeding stuffs and fertilizers.

Experiments on the digestibility of rye and wheat bran of different grades, A. KÖHLER ET AL. (*Landw. Vers. Stat., 58 (1903), No. 5–6, pp. 415–432*).—Using 2 sheep the digestibility of different sorts of wheat and rye bran was studied. Some of the brans selected were typical of the goods obtained by modern methods of milling; the others contained a larger percentage of starch, and were considered typical of the bran obtained from old-fashioned mills. The materials under investigation were fed with meadow hay, the digestibility of the bran alone being calculated from the results obtained for the whole ration. It appeared that the rye bran was more thoroughly digested by both sheep than the wheat bran. From the data as a whole the conclusion is drawn that the bran obtained by modern milling has a lower nutritive value than old-fashioned bran.

The effect of drying upon the solubility of protein of feeding stuffs in pepsin-hydrochloric acid, J. VOLHARD (*Landw. Vers. Stat., 58 (1903), No. 5–6, pp. 433–437*).—After preliminary experiments with fresh hay and fresh and dried clover had shown that drying diminished digestibility, the author made a systematic study of the effect of temperature upon the nitrogen content and the digestibility of the protein in a number of feeding stuffs, the results obtained being summarized in the table below. The samples were dried for 48 hours at 40, 60, and 100° C. Brewers' grains and distillery refuse, it is pointed out, are materials which are subjected to a fairly high temperature in the process of preparation. Such is not the case with the other feeding stuffs examined.

Effect of heating upon the digestibility of protein.

Kind of feed.	Total nitrogen in fresh feed.	Coefficient of digestibility of protein— Of undried feed.	Of feed dried at 40°.	Of feed dried at 60°.	Of feed dried at 100°.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Meadow hay	1.750	74.3	70.9	67.4	61.6
Palm-nut cake	2.924	82.8	80.7	81.6	80.1
Cotton-seed meal	7.296	94.8	93.0	88.5	91.5
Peanut meal	7.946	96.7	95.2	94.8	93.7
Cocoanut cake	3.441	91.8	90.9	90.8	90.4
Rye	1.669	92.4	89.0	88.7	88.7
Wheat	2.186	95.9	92.0	92.1	91.5
Vetch	4.534	95.3	92.9	93.9	94.2
Maize	1.817	88.6	83.7	84.5	85.0
Peas	3.968	95.5	93.5	93.2	93.4
Brewers' grains	3.416	76.2	75.8	74.2	58.3
Distillery refuse	4.991	60.4	56.1	59.1	44.8

The results are summarized as follows: Drying diminishes the digestibility of protein, the effect being proportional to the degree of heating. If the temperature employed is not over 60°, the digestibility is not markedly lowered. Heating lowers the digestibility of the protein of materials which have been heated in the process of manufacture, such as dried brewers' grains and distillers' grains.

Comparative tests of digestibility of protein by artificial and natural methods, K. von Dambski (*Inaug. Diss., Univ. Breslau, 1903, pp. 69*).—The literature of the subject is summarized at considerable length and experiments reported which compare the digestibility of protein by the Stutzer and the Kühn methods with the results obtained in natural digestion experiments with sheep.

The rations tested included meadow hay alone and with wheat bran, clover hay alone and with peanut cake, and meadow hay with dried beet chips. One of the points especially considered was the effect of heat employed in drying feces upon the protein present, and in this connection some tests were also made with horse and cow feces. The author's general conclusion is that natural and artificial digestion experiments do not give absolutely concordant results, since certain variations are unavoidable. The smallest discrepancies were observed when the metabolic products in the feces were determined by the Stutzer method with pepsin and trypsin. He believes, therefore, that the Stutzer method is the most satisfactory method for determining coefficients of digestibility in artificial digestion experiments.

Numerous tests are included in the above investigation on the effect of different amounts of digestive ferment and the effect of the time element on the reaction.

Concerning the nitrogen content and the solubility in pepsin-hydrochloric acid of the protein of fresh and dried sheep manure, C. Beger (*Ztschr. Physiol. Chem., 40 (1903), No. 3-4, pp. 176-181*).—In the experiments reported sheep were fed in the different periods hay, hay plus peanut oil, hay plus straw, a fat-free mixed ration, and a mixed ration containing oil. The amount of digestible protein in the fresh and the dried feces was determined by the pepsin-hydrochloric acid method. It was found that considerably higher values were obtained with the fresh than with the dried feces. The author believes that it is best, therefore, to retain the usual method and use fresh feces for the determination of the nitrogenous material insoluble in pepsin-hydrochloric acid. This is especially important in determining the coefficients of digestibility of a mixed ration.

Fate of proteids introduced through the alimentary canal and otherwise, C. Oppenheimer (*Beitr. Chem. Physiol. u. Pathol., 4 (1903), pp. 263-278; abs. in Jour. Chem. Soc. [London], 84 (1903), No. 493, II, pp. 738, 739*).—Experiments with rabbits showed that when foreign proteids (serum from other animals and egg white) were injected intravenously or intraperitoneally, they were directly utilized and only

small and variable amounts were excreted in the urine. The amount so excreted showed no relationship to preciptin formation.

On the digestion and absorption of albuminoids in the stomach and in the first part of the duodenum, E. Zunz (*Beitr. Chem. Physiol. u. Pathol., 3 (1902), pp. 339–364; abs. in Bul. Soc. Chim. Paris, 3. ser., 30 (1903), No. 23, p. 1285*).—Using sulphate of zinc as a reagent for fractional precipitation, the author studied the contents of the stomach and duodenum in an experiment with a dog fed cooked beef.

Concerning the origin in the animal body of metabolic products containing sulphur, I, J. Wohlgemuth (*Ztschr. Physiol. Chem., 40 (1903), No. 1–2, pp. 81–100*).—From experiments in which cystein was given to rabbits per os, it appeared that this body in so far as it is resorbed is converted into taurin and at least in part appears as taurocholic acid in the gall. Since cystein normally accompanies the pancreatic digestion of proteid, the author considers that the origin of taurin in the animal organism is explained. As he points out, it remains to be seen whether cystein is solely a product of tryptic digestion, or whether it is also formed, which he believes is more probable, by autolysis with the aid of tissue ferments.

Combustion of the muscular carbohydrate and the influence of the pancreas on it, I, O. Cohnheim (*Ztschr. Physiol. Chem., 39 (1903), No. 3–4, pp. 336–349*).—From experiments made with dogs without a pancreas and tests with the cell-free juices of muscle and pancreas, the conclusion was drawn that the combustion of dextrose in the body requires the cooperation of muscles and pancreas. Combustion is attributed to a muscle ferment which is rendered active by an internal secretion from the pancreas. One gram of muscle can break down 5 to 8 gm. of dextrose. The action is inhibited by blood serum.

Experiments on the intermediate metabolic products of carbohydrates. I, Concerning ethylenglycol and glycolaldehyd, P. Mayer (*Ztschr. Physiol. Chem., 38 (1903), No. 1–2, pp. 135–156*).—The author presents a critical discussion of methods of experimenting and emphasizes the need of looking for intermediate products, as well as end products of cleavage. Experiments are reported in which rabbits were fed ethylenglycol and glycolaldehyd, which led to the conclusion that when ethylenglycol was burned by the rabbit glycolic and oxalic acids were the intermediate products. When 10 gm. of glycol was fed about one-fourth of it appeared as glycolic acid. As regards the glycolaldehyd, the author considered it probable that it was directly condensed in the body to glucose.

The effect of feed upon the character of body fat, O. Lemmermann and G. Linkh (*Landw. Jahrb., 32 (1903), No. 4, pp. 635–653*).—An experiment with pigs is reported in which the effect of maize and palm-nut cake on the character of body fat was studied, and also the effect of substituting palm-nut cake for maize for 2 to 6 weeks before slaughtering, the ration in every case having a wide nutritive ratio. In no case were the pigs overfed, since they were still growing.

The bacon from those fed palm-nut cake throughout the whole period was harder than that of the other pigs, otherwise no marked differences were noted. With all the animals the back fat had the lowest melting point, and the highest iodin number and refraction index; and next to this the belly, kidney, and intestinal fat, in the order mentioned. The further from the surface, the lower the oleic acid content of the fat and the higher the melting point and vice versa. Judged by its chemical and physical properties the fat of the pigs fed palm-nut cake was of better quality than that from pigs fed maize, though the differences were not very great. Substituting palm-nut cake for maize for 2 to 6 weeks did not exercise any favorable effect on the quality of the fat under the experimental conditions.

The absorption of fat, B. Moore (*Physiol. Lab. Univ. Col., Liverpool, 1903; abs. in British Med. Jour., 1904, No. 2252, Epit., p. 36*).—According to the author, fatty acid and fat have the same appearance in the basal parts of the epithelial cells of the small intestine after appropriate staining. Therefore, the method commonly

employed does not show conclusively that fats are split into fatty acids and glycerin and absorbed either as fatty acid or soap; however, chemical studies which he carried on are believed to have established the correctness of the above theory. Washed and scraped mucous membrane obtained from a digesting animal contained 15 to 35 per cent of its fat in the form of fatty acid, while in the fluid of the lacteals 96 per cent of the fatty material was present as neutral fat. The synthesis, therefore, was completed in the mucous membrane of the intestine.

Meat on the farm, A. Boss (*U. S. Dept. Agr., Farmers' Bul. 183, pp. 39, figs. 35*).—Various subjects connected with the butchering, curing, and preservation of meat on the farm are discussed, including such topics as the selection of animals, preparation for slaughter, killing and dressing cattle, sheep, hogs, and poultry; cooling and cutting the carcass; preservation of fresh meat, and curing meat. In connection with the subject of preserving meat a number of recipes are given, as well as detailed directions for salting and smoking.

Marketing live stock, C. S. Plumb (*U. S. Dept. Agr., Farmers' Bul. 184, pp. 40*).—The subject of marketing live stock is discussed and suggestions are offered for facilitating the marketing of farm animals. The topics discussed include, among others, buying and selling in country districts, periodical auction sales, rules and methods in Chicago horse market, stock yards, live-stock exchanges, inspection of stock, the abattoir and packing house, the market classification of live stock, shipment of stock by railway, and the export trade. The bulletin contains much statistical and general information pertaining to the subjects discussed.

The use of branding fluid, G. H. True (*Arizona Sta. Bul. 47, pp. 314–317*).—A fluid which was tested for branding cattle, in the author's opinion, did not give as satisfactory results as are generally obtained with the branding iron..

The food cost of raising calves, C. L. Beach (*Connecticut Storrs Sta. Rpt. 1903, pp. 187–190, figs. 4.*)—For several years records have been kept of the feed consumed by heifer calves from birth until about 6 months old. They were fed whole milk at first and later skim milk. Rowen hay was always supplied and grain in some cases during the last 2 months of the feeding period.

The gains noted, 1.25 lbs. in 1900 and 1.31 lbs. in 1899 per head per day, were regarded as satisfactory for animals designed for the dairy herd. The cost of feed required for 6 months' feeding was 44.6 cts. per week in one year and 47.3 cts. in the other. On the basis of observed data the cost of raising calves from birth to maturity (a little over 2 years) was $33.20.

"Kälberrahm" with skim milk as a milk substitute in calf feeding, J. Käppeli (*Landw. Jahrb. Schweiz, 17 (1903), No. 8, pp. 401–418, figs. 3*).—As shown by feeding experiments with calves "Kälberrahm," a commercial feeding stuff designed as a substitute for milk fat, did not give as satisfactory results as whole milk, 14.54 liters of "Kälberrahm" and skim milk being required per kilogram of gain as compared with 10.9 liters of whole milk or 16.4 liters of skim milk. When the quality of the flesh was taken into account the results, the author states, were even more unfavorable to the "Kälberrahm" and skim milk.

Live stock. Steer feeding, H. E. Stockbridge (*Florida Sta. Rpt. 1902, pp. 13–16*).—Notes are given regarding the live stock kept at the station, and feeding experiments with steers are briefly reported. Two grade oxen, fed chiefly on velvet-bean forage, made a gain of 3.5 lbs. per head per day, as compared with 2.17 lbs. made by a pair of native oxen under similar conditions, the profit in the 2 cases being $7.61 and $7.31 per ox. The time covered by the test was 60 days.

In a second test velvet-bean pods were compared with cassava and cassava pulp (refuse from a starch factory). Lot 1 (2 steers) was fed 3 bu. of velvet beans in pods; lot 2 (3 steers) was fed 30 lbs. of cassava and 5 lbs. of cotton-seed meal; and lot 3 (3 steers), 18 lbs. of cassava pulp and 5 lbs. of cotton-seed meal, all the animals receiving cowpea-vine hay in addition to the feeding stuffs mentioned. In the 60

days of the test the steers in lot 1 (velvet-bean pods) made a total gain of 120 lbs.; in lot 2 (cassava) of 324 lbs., and in lot 3 (cassava pulp) of 304 lbs.

"Velvet beans alone with roughage are inferior to a ration in which cassava is the predominating ingredient. In this connection it is well to note that the general appearance of lot 1 was deceptive, the oily character of the bean, or some other property, giving a glossy appearance to the coat and imparting a general smoothness of exterior indicative of better condition than actual weights justified. The conclusion seems to be warranted, therefore, that the addition of cassava to the ration of steers ranging on velvet-bean pasture in the winter would be a material advantage.

"The refuse pulp from the starch factories is a valuable feed stuff closely approximating the results obtained from cassava root."

Methods of steer feeding, T. I. Mairs and A. K. Risser (*Pennsylvania Sta. Bul. 64, pp. 8*).—Continuing earlier work (E. S. R., 15, p. 171), the relative merits of feeding steers in barns and open sheds was tested with 2 lots of 12 animals each, weighing about 830 lbs. Lot 1 was fed in a large pen or box stall in the college barn, and lot 2 in a yard with a shed.

The test began November 26 and covered 18 weeks. Both lots were fed similar rations of corn stover and clover hay, with corn-and-cob meal and cotton-seed meal 12:1 in addition during the first part of the test, and later corn meal and cotton-seed meal in the same proportion. In the case of the steers fed in the barn the average daily gain was 2.12 lbs. and the cost of a pound of gain 9.53 cts. Similar values for the animals fed in a shed were 1.97 lbs. and 10.372 cts. The amount eaten by the lot fed in the shed was somewhat the greater, 6.07 lbs. of coarse fodder and 8.53 lbs. of grain being required per pound of gain as compared with 5.57 lbs. of the coarse fodder and 7.83 lbs. of grain in the case of the lot fed in the barn. Self-registering thermometers were used throughout the experiment to record the temperature in the shed and in the barn. As was to be expected, the lower temperature was found in the shed.

According to the authors, "the general result of all these comparisons may be summarized in the statement that the lot fed in the open shed produced a slightly smaller gain and produced it at the expense of a somewhat greater amount of food. It is not so clear, however, that the lower temperature to which lot 2 [fed in the shed] was exposed was the cause of the difference. . . .

"On the whole, while the barn-fed lot appears to have given slightly better results, the differences are not very marked, and in view of the wide difference observed between individual animals in each lot it is not at all impossible that the selection of the animals, and the conditions other than temperature which surrounded them, had quite as much to do with the differences as the mere exposure to cold. In other words, the results of a single trial of this sort are never decisive, and they are presented here simply as a record of progress. It is proposed to continue the experiments through several seasons in the hope of securing conclusive results."

Feeding experiments with gluten feed and other feeds, D. A. Gilchrist (*County Council Northumberland, Education Com., Rpt. 1903, pp. 76–82*).—Using 4 lots, each made up of 2 blue-grey heifers, 1 blue-grey steer, and 1 Shorthorn steer, the author studied the relative feeding value of Buffalo gluten feed, rough cotton-seed cake, and barley meal 1:1, decorticated cotton-seed cake and barley meal 1:1, and linseed cake and barley meal 1:1. "The first 2 of these [rations] are practically the same in chemical composition, but the last 2 are richer." Three to 6 lbs. of concentrated feeds were fed per head daily in addition to a basal ration of 8 to 10 lbs. of hay with 28 lbs. of turnips.

At the beginning of the test the animals in each lot weighed not far from 525 lbs. each. In the 7 months of the trial the gains ranged from 1.73 lbs. with the lot fed rough cotton-seed cake and barley meal, to 1.93 lbs. with the lot fed decorticated cotton-seed cake and barley meal. The greatest profit was also obtained with the lot

fed gluten feed. "There is a prejudice in favor of linseed cake for feeding young cattle, but both rough and decorticated cotton cakes have given considerably better financial results than linseed cake."

As regards the relative value of the different breeds the results, according to the author, "are distinctly in favor of the 4 Shorthorn bullocks, which increased on the average 32 lbs. in weight more than the blue-grey bullocks during the time of the experiment."

Cattle-feeding experiment, T. H. MIDDLETON (*Cambridge [England] Univ., Dept. Agr., Rpt. Expts. Crops and Stock 1903, pp. 80–87*).—Using 2 lots of 4 heifers each, 5 to 6 lbs. per head per day of gluten feed was compared with a like amount of a mixture of bruised wheat and decorticated cotton-seed cake 2:1, the concentrated feed being supplemented in each case by mangel-wurzels with hay or hay and straw chaff.

The feeding period varied somewhat with the different animals, being on an average 111.5 days. On gluten feed the total gain was 260.75 lbs. and on wheat and cotton-seed cake 246.75 lbs., the cost of feed per head per day in the 2 cases being 15 cts. and 16 cts. The carcass yield of the lot receiving gluten feed was the greater, but the flesh was thought to be inferior in quality. Considering the test as a whole the 2 rations are regarded as of nearly equal value.

The value of roots in cattle feeding, T. H. MIDDLETON (*County Council Northumberland, Education Com., Rpt. 1903, pp. 42–55*).—In an experiment carried on in 1900–1, a lot of cattle was fed 56 lbs. of roots, chiefly swedes, per head per day in addition to other feed, and a second lot was fed 28 lbs. of the same sort of roots per head per day with 2.75 lbs. clover hay, 0.5 lb. maize meal, and 0.5 lb. of molasses in place of the remaining amount of roots. Satisfactory gains were made by both lots, but the ration containing the full amount of roots was considerably cheaper.

In 1901–2 a test was carried on under practically the same conditions. Two lots of 8 young cattle which had gained respectively 1.68 lbs. and 1.73 lbs. per head per day since birth, were fed for 7 months the same basal ration made up of grain, hay, and a little molasses. In addition lot 1 was fed 28 lbs. of Swedish turnips per head per day, while lot 2 was given 0.5 lb. of maize meal, 0.25 lb. molasses, and 2.75 lbs. clover hay in place of the roots. The average daily gain per head on the ration containing Swedish turnips was 1.98 lbs. as compared with 1.83 lbs. on the ration without roots. The animals fed no roots were worth less money at the close of the feeding test and the profit per lot was $3.35 per head less than in the case of the steers fed roots.

The author concludes that well-bred yearling cattle may be fattened without roots as under the experimental conditions, but that such a ration is not to be recommended. "At least 28 lbs. of swedes should be fed daily, and 42 lbs. to 56 lbs. may be given with profit."

Feeding beet pulp to steers and sheep, R. W. CLARK (*Utah Sta. Bul. 82, pp. 3*).—Tests made with sheep and steers to ascertain the value of beet pulp are briefly reported. According to the author, both the steers and sheep fed alfalfa and beet pulp only made the smallest gains per day and required the largest amount of dry matter per pound of gain, though they gave the largest profits. The steers made a pound of gain from 11.5 lbs. of alfalfa hay and 31.4 lbs. of beet pulp at a cost of 2.8 cts. In the case of sheep the cost of a pound of gain was 3.8 cts., and 16.6 lbs. of alfalfa and 36.7 lbs. of beet pulp were required.

When beet pulp was fed ad libitum with alfalfa to steers it had a value of $1.85, and when similarly fed to sheep it had a value of $1.13 per ton. On a full ration of alfalfa and grain (bran and shorts 1:1) steers made a pound of gain at a cost of 4.93 cts. With another lot fed alfalfa, grain, and beet pulp a pound of gain cost 3.98 cts. When a full ration of alfalfa and pulp was fed with a half ration of grain a pound of gain was made from 9.2 lbs. of alfalfa, 2.03 lbs. of grain, and 19.1 lbs. of pulp, the

cost being 3.51 cts. When a full ration of grain and pulp was fed with a half ration of alfalfa a pound of gain was made from 4.28 lbs. of alfalfa, 3.65 lbs. of grain, and 21.3 lbs. of pulp at a cost of 3.84 cts.

In the author's opinion, molasses in small quantities (4 lbs. per head per day) fed with 8 lbs. of grain per head per day and beet pulp ad libitum had a value of $2.35 per ton.

The bulletin also contains a brief general discussion of methods of feeding beet pulp.

The feeding of undecorticated cotton cakes to cattle and sheep on pasture, D. A. Gilchrist (*County Council Northumberland, Education Com., Rpt. 1903, pp. 72–75*).—The comparative merits of Egyptian and Bombay cotton-seed cakes, which are both made from seed which has not been delinted or decorticated, were tested with cattle and with wethers, lambs, and ewes for 2 months, the cattle being fed 3 to 5 lbs. of cake per head daily during the first month and later 7 lbs. of the cake, and the sheep from 0.25 lb. to 0.5 lb. Considering the test as a whole greater gains were made on the Bombay cake than on the Egyptian cake. The Bombay cake was also considerably cheaper. "So far there is no reason to suppose that the harder and more woolly Bombay cake has had any injurious effects on the animals to which it was fed; but this can only be satisfactorily ascertained by a trial covering a considerably longer period."

Analyses of the 2 sorts of cotton-seed cake and of Indian cotton seed by S. H. Collins are reported. The differences observed were not great. "The physical character of the fiber of the 2 cakes is, however, very different; the fiber of the Bombay cotton cake having an objectionable woolly nature. . . . Indian cotton seed [is] a food greatly esteemed in India for feeding milch buffaloes and cows. Indian cattle do not appear to object to the woolly character of the fiber, and if British cattle are more fastidious it is probably due to the fact that they are accustomed to better feeding."

Manures for pasture in Tree Field, D. A. Gilchrist (*County Council Northumberland, Education Com., Rpt. 1903, pp. 2–18, dgms. 3*).—The effect of manures on pasturage as shown by gains in weight made by sheep was studied under practically the same conditions as in earlier work at Cockle Park (E. S. R., 13, p. 175). In the 20 weeks of the test the average weekly gain per sheep on all the plats was 2.2 lbs. The total gain in weight in excess of gains made by the sheep on the untreated plat ranged from 27 lbs. made by the 5 sheep on the plat which had been manured by 5 tons of common lime in 1897 to 144 lbs. made by 10 sheep on the plat which had been manured with 1,680 lbs. of basic slag in 1900. At the close of the test sheep were selected for slaughtering from the lots which contained suitably fattened animals. It appeared that sheep fattened best on the plat manured with 560 lbs. of basic slag in 1897 and the same amount in 1900.

The amount of forage remaining on the plats at the close of the season was measured by feeding it to cattle during the winter. A botanical analysis of the hay growing on the different plats is reported.

The effect of nitrogenous manures on the feeding value of hay, T. H. Middleton (*County Council Northumberland, Education Com., Rpt. 1903, pp. 56–68*).—Since it was found that nitrogenous manures exercise a pronounced effect on the character of the hay, feeding experiments with 5 lots of 10 sheep each were undertaken to determine whether its quality was as much affected as its appearance. The hay selected was mixed clover and rye grass grown on unmanured land; early-cut hay from a field top-dressed with 224 lbs. of nitrate of soda per acre; late-cut, but better cured, hay from a field manured as above; rowen, chiefly rye grass, from top-dressed land; and rowen, chiefly clover, from unmanured land.

The sheep fed rowen hay were given 0.5 lb. per head per day in addition to roots and concentrated feed. The others were given 2 lbs. of hay per head per day with roots, concentrated feed, and a little molasses. In the 105 days of the test the gain

ranged from 1.75 lbs. per sheep in the lot fed the early-cut hay from the top-dressed field to 2.06 lbs. in the case of the sheep fed clover rowen. Five animals in each lot were thought sufficiently fat for slaughtering.

According to the author "no difference in feeding value was found between hay (main crop) that had been dressed with nitrate of soda, and hay from unmanured land in the same field. Top-dressed hay cut 14 days before the usual time proved no better than similar hay cut at the usual time. Early cutting considerably reduced the crop." As regards the feeding value of the 2 sorts of rowen, in the author's opinion, additional experiments are needed before more definite conclusions can be drawn.

Experiments in feeding sheep under cover, T. H. MIDDLETON (*County Council Northumberland, Education Com., Rpt. 1903, pp. 69–71*).—Thirty-one sheep fed in an open shed made an average gain of 0.168 lb. per head per day and 30 sheep fed out of doors gained 0.189 lb. per head per day, both lots being fed similar rations of Swedish turnips, meadow hay, and mixed grains.

According to the author "though sheep do well under cover, when housed in the autumn it is better to finish half-fat shearlings in a grass field than in a shed, should bad weather at midwinter compel the farmer to take them off turnips. As might be anticipated, sheep that have spent half the winter in the open take a considerable time to get accustomed to a covered yard, and if an early sale be contemplated, the benefits of shelter are likely to be more than counterbalanced by the restlessness of the sheep in their new surroundings."

The feeding of sheep with gluten feed and other feeds, D. A. GILCHRIST (*County Council Northumberland, Education Com., Rpt. 1903, pp. 83–85*).—Using 3 lots each containing 10 grade wethers, the comparative value of gluten feed, split peas, and a mixture of equal parts of barley meal and undecorticated cotton-seed cake was studied, 0.75 to 1 lb. of the concentrated feeds being fed daily in addition to a basal ration of 10 lbs. of Swedish turnips and 0.75 lb. hay. The 3 rations had practically the same feeding value. At the beginning of the test the sheep averaged 114.4 lbs. each in weight. In 3 months the average daily gains per head were 1.36 lbs. on barley meal and cotton-seed cake, 1.47 lbs. on split peas, and 1.76 lbs. on gluten feed.

As regards the financial returns, in the author's opinion, all the 3 lots were satisfactory. The greatest profit, $1.26, was obtained with the lot receiving the gluten feed.

The feeding value of different varieties of swedes, D. A. GILCHRIST (*County Council Northumberland, Education Com., Rpt. 1903, pp. 86–91, dgm. 1*).—The comparative feeding value of Arctic (12.22 per cent dry matter), X L All (11.58 per cent dry matter), and Best of All Swedish turnips (11.55 per cent dry matter) was studied with 3 lots each containing 10 grade wethers averaging about 110 lbs. in weight. All the sheep were fed from 0.25 to 1 lb. of decorticated cotton-seed cake and maize meal 1:1, 0.5 lb. of hay, and 16 lbs. of Swedish turnips per head daily. The average gains per sheep per week in the 16 weeks of the trial were 1.387 lbs. on Best of All, 1.45 lbs. on X L All, and 1.731 lbs. on Arctic swedes.

"The financial results show satisfactory profits in each case, but the profit is nearly 40 per cent greater from Arctic swedes, which contain the largest amount of solid matter."

The investigation indicates "that a high percentage of solid matter in swedes is of great importance, and is likely to increase the feeding value of the swedes to a much greater extent than the proportionate increase of solid matter."

The improvement of permanent pastures, T. H. MIDDLETON (*Cambridge [England] Univ., Dept. Agr., Rpt. Expts. Crops and Stock 1903, pp. 3–18, fig. 1*).—In continuation of previous investigations (E. S. R., 14, p. 798), the improvement of pastures under various systems of manuring was tested by pasturing sheep on sample plats.

In the experiment in Cambridgeshire the largest gain, 174.4 lbs., was made by sheep on the pasture which had been manured with 1,120 lbs. of basic slag in the autumn of 1899. The smallest gain was 77.3 lbs. made by the sheep on the unmanured plats.

In the test carried on in Essex on stiff clay soil the greatest gain, 160.9 lbs., was also made on the plat which had been manured with 1,120 lbs. of basic slag per acre. The smallest gain, 46.5 lbs., was made on the unmanured plat.

The gains during the 4 months covered by the experiments in Norwich ranged from 198 lbs. with the sheep pastured on the plat manured with 1,568 lbs. of superphosphate to 369 lbs. with the sheep on the plat manured by feeding a mixture of linseed and undecorticated cotton-seed cake.

Some of the general conclusions which were reached follow: "When the pasture is situated on a clay soil, contains small clover plants, and is but scantily covered with grass, then the best results will usually be got from the application of heavy dressings of phosphatic manures (for example, dressings of from 8 to 10 cwt. of basic slag per acre). . . . When the pasture lies on a light and sandy soil, or when the sward is thick and close and the herbage is largely composed of strong grasses . . . [the most satisfactory manure] is a nitrogenous one, but nitrogenous manures must be used with great caution, for they are apt to stimulate the stronger and the coarser grasses, and in this way to secure quantity at the expense of quality. . . . To the grass and mixed herbage of light and medium soils no manure is likely to be so grateful as the droppings of animals fed upon the land, and the surest way to improve the condition of the pasture is to employ cotton cake or similar feeding stuffs to supply nitrogen, with light dressings of superphosphate and of kainit if it be proved that the land is in need of these mineral manures."

The formation of new pastures, experiment at Waresley, T. H. MIDDLETON (*Cambridge [England] Univ., Dept. Agr., Rpt. Expts. Crops and Stock 1903, pp. 19–26*).—The effect of different manures on pasturage was tested with sheep grazed on sample plats, the test being a continuation of earlier work (E. S. R., 14, p. 798). The greatest gain, 91.5 lbs., was made by the lot on a pasture which had been fertilized by feeding linseed cake. The smallest gain, 55 lbs., was made by the lot pastured on the unmanured land. In the author's opinion none of the sheep made satisfactory gains. The unmanured land was inferior to the other plats throughout the entire season.

Sheep-feeding experiment, T. H. MIDDLETON (*Cambridge [England] Univ., Dept. Agr., Rpt. Expts. Crops and Stock 1903, pp. 87–91*).—The relative value of gray peas, gluten feed, and gram or chick-peas (*Cicer arietinum*) was tested with 3 lots of 10 sheep each. The rations consisted of 1.25 lbs. of concentrated feed per head per day in addition to clover hay and roots. At the end of 32 days 5 animals from each lot were sold for slaughtering, the remainder being fed for 28 days longer. The average gain for the whole test was 14.1 lbs. per head on gray peas, 15.1 lbs. on gluten feed, and 15.8 lbs. on chick-peas. Under the experimental conditions none of the rations was considered profitable.

"The sheep did not much care for gluten feed, but they consumed the daily ration throughout the experiment. The other foods, especially the gram, were readily eaten." Gluten feed "is too dusty to be fed alone; it would do very well if mixed with a feeding cake. If used for feeding outside, the boxes containing it should have some cover, otherwise it will form a paste in wet weather and in this condition sheep will not eat it.

"Gram makes a useful feeding stuff for sheep. It may be fed whole or split. The animals are fond of it and there is no waste."

The author points out that chick-peas form the usual grain ration of horses in northern and western India and that chick-pea fed mutton is considered a delicacy in that country.

Lamb-feeding experiments, J. H. Stewart and H. Atwood (*West Virginia Sta. Bul. 90, pp. 217–222*).—In continuation of earlier work (E. S. R., 12, p. 73) 3 tests with lambs are reported comparing cowpea hay with mixed timothy and clover hay. In the first test 37 lambs weighing 2,340 lbs. gained 270 lbs. in 6 weeks on a ration of cowpea hay and shelled corn. A second lot of 37 lambs weighing at the start 2,352 lbs. gained 48 lbs. on a ration of mixed timothy and clover hay and corn, while a lot of 20 lambs weighing 1,052 lbs. at the start and badly affected with stomach worms lost 12 lbs. in the same period on a ration of cowpea hay and corn. The authors calculate that with the cowpea ration a pound of gain cost 6.79 cts., and with a mixed hay ration 51.77 cts.

In the second test, which covered 9 weeks, a lot of 26 lambs weighing 1,910 lbs. at the start gained 378 lbs. on a ration of cowpea hay and shelled corn, while a similar lot fed mixed timothy and clover hay and shelled corn gained only 223 lbs., the cost of a pound of gain in the 2 cases being 5.27 cts. and 9.52 cts.

The third test was made with 2 lots of 37 lambs each, the total weight of each lot being about 2,280 lbs. In 73 days lot 1 fed cowpea hay and corn gained 495 lbs. and lot 2 fed mixed timothy and clover hay and corn gained 200 lbs., the cost of a pound of gain in the 2 cases being 3.32 cts. and 16.84 cts. In this and the other cases the total amounts of feed consumed were recorded.

According to the authors—

"Valuing the cowpea hay at $5 per ton, the mixed hay at $10, and the corn at 1 ct. per pound, then the lambs which received cowpea hay were fed each year at a profit, while those receiving mixed hay were profitable in only one instance.

Practically none of the lambs gained in weight as rapidly as they should. This was due partially to the presence of internal parasites, which interfered with the process of digestion and assimilation, and partially to the inbred and debilitated flocks prevailing in this section from which the lambs were derived."

The hog industry, G. M. Rommel (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 47, pts. 1, pp. 96; 2, pp. 97–192; 3, pp. 193–298, maps 3*).—This bulletin constitutes an exhaustive summary of data relating to the pig-feeding industry in America, the topics discussed being selection, feeding, and management; recent American experimental work in pork production; and statistics of production and trade.

As regards suitable conditions, "the first place in hog raising in the United States is easily with the corn-growing sections, and here corn is the first grain thought of when the fattening of animals, especially hogs, is mentioned. It is, however, fallacious to argue that hog feeding will not give profitable returns outside of the corn belt. . . . Any locality that will grow clover of any species, that is favorable to the production of alfalfa, peas, or beans, where grains are readily grown—not only corn, but barley, wheat, oats, or rye—will be a favorable situation for the successful production of pork. If it is a locality where dairying is common, no better advantages are required; for, given leguminous pasture—clover, alfalfa, peas, beans, etc.—as a basis, with a grain feed that can be readily grown and also dairy by-products, the very highest grade of pork can be produced at a minimum cost."

In the selection of breeding stock, available data show that in actual practice "the man who feeds for the market recognizes, not breed, but type. . . . [Color and other characteristics vary] but on the points that represent the real meat-yielding parts of the animals the standards are almost identical. Breeders look for quality, depth, length, and width of form and depth and condition of flesh, regardless of whether their hogs are black, red, or white. At first sight breeds of the bacon type seem to be exceptions to this rule, but as yet there is not in the United States what can be called a general market class for hogs of this type. . . . At present (1902) the hog that sells for the highest price on the markets of the central West is the hog of the lard type." The conformity of breeds to common standards is shown by data compiled from score cards of the National Association of Expert Judges on Swine.

Among other points regarding the feeding and management of pigs, the author discusses the proper time for weaning on the basis of information secured from a large number of pig raisers. Although breeders differed widely, the majority favored weaning at 6 to 10 weeks of age.

In the section dealing with experimental pork production, the investigations carried on at the experimental stations in Canada and the United States are summarized and discussed. Comparing ground and unground corn the average results, judged purely on the basis of feed required per pound of gain, are in favor of corn meal, 4.79 lbs. of the meal being required as compared with 5.24 lbs. of the whole grain. When the cost of grinding is taken into account the advantage is not so obvious, and the conclusion was reached that "it is beyond anyone to say that an advantage may be expected to follow the feeding of corn meal sufficient to pay the cost of grinding." When other small grains were considered the results summarized showed a wider variation between the value of the ground and unground grains than in the case of corn, and the results were more uniformly favorable to grinding. In the case of wet and dry feed the average results showed an advantage of a little over 2 per cent in favor of soaking.

A summary of the experiments with cotton-seed meal shows that the cause of the poisonous symptoms, which often follow its use, is not definitely known. "Points that may in time lead to the discovery of the trouble are that old meal seems to be more fatal than fresh, that cotton-seed meal is more fatal than cotton seed in any condition, and that the poisonous agent is not in the oil, but seems to be entirely left in the cake when the oil is expressed. It is also well known throughout the South that decomposed cotton seed has little, if any, dangerous character, and it has been pretty clearly established . . . that the meal is so changed by the processes of digestion that hogs following steers which are being fed a heavy cotton-seed meal ration are not injured by the droppings." As regards the feeding value of cotton-seed meal, the results of different investigators have not been uniform.

The value of commercial by-products, dairy by-products, pasture and pasture substitutes, and similar topics are also discussed, as well as tests which have to do with feeding for bacon production.

In addition to census returns the section devoted to statistics of pork production and trade includes statistics of domestic, foreign, and miscellaneous trade in pork and pork products. A large amount of the statistical material is based on data gathered by the Bureau of Animal Industry. The bulletin contains a complete index.

Skim milk for pigs, G. H. True (*Arizona Sta. Bul. 47, pp. 300–302*).—According to the author 2 pigs weighing 81 lbs. following steers and fed 6,000 lbs. of skim milk in addition in 113 days gained 248 lbs. and increased $16.12 in value. In the form of pork the skim milk was worth 26.8 cts. per 100 lbs.

In another test, which is briefly reported, pigs fed skim milk in addition to alfalfa and barley gained 1.48 lbs. per head per day. Those fed skim milk and alfalfa 1.32 lbs., and those fed skim milk and barley 1.32 lbs., while those fed skim milk only gained 1.05 lbs. The feeding period covered from 19 to 49 days. The estimated value of the skim milk, judged from the returns in pork, ranged from 18.2 cts. in the case of the pigs fed skim milk only to 28.4 cts. in the case of those fed skim milk and alfalfa.

Alfalfa and skim milk v. alfalfa, skim milk, and barley as rations for growing pigs, T. F. McConnell (*Arizona Sta. Rpt. 1903, pp. 337–341*).—A lot of 5 pigs hurdled on alfalfa and fed skim milk with barley in addition made a total gain of 58.8 lbs. each in 10 weeks. Four pigs fed in a similar way without barley gained 43.5 lbs., the weight of the pigs in each case at the beginning of the trial being about 105 lbs. per head. Lot 1 (fed grain) required 9.23 lbs. of skim milk, 4.73 lbs. of rolled barley, and the alfalfa grown during the experimental period on 105.11 sq. ft. to produce a pound of gain. In the case of the lot fed no grain 16.45 lbs. of skim

milk and the alfalfa grown on 162.5 sq. ft. of land were required per pound of gain. According to the author, the pigs fed only alfalfa and skim milk did not have as firm flesh as the others; furthermore, the digestive organs were more distended and "in every way their condition indicated a larger percentage of offal with a smaller percentage of marketable flesh."

In this test one of the so-called "hog tamers" was employed to prevent the pigs from rooting. This device the author considers "entirely successful and much to be preferred to the hog-ring."

Feeding farm horses and mules, C. W. BURKETT (*North Carolina Sta. Bul. 189, pp. 99–127*).—Using horses and mules belonging to the college, feeding tests were undertaken to compare local grown feeding stuffs with each other and with purchased feeds. In general the tests were so arranged that the rations compared were fed at the same time to each of a pair of animals performing like work under uniform conditions. The principal feeding stuffs studied were bran, cowpea hay, gluten meal, corn-and-cob meal, shelled corn, corn silage and stover, cowpeas, cotton-seed meal, animal meal, and blood meal, 59 rations being tested.

According to the author the test as a whole showed that the forage crops grown in North Carolina are adapted to horse feeding, being efficient, easily grown, and available for every farmer, and that it is not necessary to purchase feeding stuffs outside the State.

"Cowpea hay is a valuable horse feed. Combined with corn-and-cob meal it makes a practical working ration. It can also be substituted for bran and oats, providing a reasonable quantity of corn is added to the daily ration."

As an example of the successful use of cowpea hay it was found that 2 mules weighing about 1,000 lbs. each maintained their weight for a period covering about 2 months on a ration of 10 lbs. of cowpea hay, 1.5 lbs. of cotton-seed meal, and 15 lbs. of corn-and-cob meal, the average cost per day being 19.5 cts.

"Corn ensilage is a superior feed for horses and mules. One of the most satisfactory rations fed in this series of experiments was composed of 21 lbs. of ensilage, 15 lbs. of corn, 2 lbs. of bran, and 1 lb. of cotton-seed meal. The ration was cheap, efficient, and wholesome to the animals. Corn stover is a roughage material that is exceedingly valuable for feeding farm horses and mules. It is a good substitute for hay for the winter feeding of horses and mules because of its feeding value, the yield per acre, and commercial value.

"Oat hay when cut while in the milk state is a satisfactory horse feed. When thus harvested it compares favorably with clover hay and cowpea hay."

Rations containing 10 lbs. of oat hay with 1 pound of cotton-seed meal, 10 lbs. of corn-and-cob meal, and 5 lbs. of bran or oats were found to be satisfactory in a test covering about a month made with 2 mules weighing nearly 1,000 lbs. each. The bran ration was regarded as somewhat superior to the oat ration and was also the cheaper.

"Cotton-seed meal can be used to replace a part of the corn or oats in a horse or mule ration. Two pounds of cotton-seed meal as a part of the daily rations were fed to horses and mules with satisfaction. This quantity can be fed in a mixture with either grain or sprinkled on ensilage or on hay or stover that has been moistened previously to feeding. In comparison with other feeding stuffs cotton-seed meal, because of its high feeding value, is a relatively cheap feed. Corn stover, corn, and cotton-seed meal, because of feeding and commercial values, make satisfactory rations for winter feeding of horses and mules, or at other times when on light or moderate work. Some of the animals in these experiments did not at first relish cotton-seed meal. Where animals can be made to acquire the taste it should be made a part of the daily ration.

"Tankage and dried blood were used in these tests satisfactorily. The latter is especially valuable when horses are 'run down' and thin in flesh."

As an example of the use of tankage a test covering 3 weeks, and made with 2 horses weighing not far from 1,300 lbs. each, may be mentioned, in which 2 lbs. of this material with 4 lbs. of bran, 10 lbs. of corn-and-cob meal, and 30 lbs. of corn silage was compared with a similar ration in which 15 lbs. of clover hay replaced the corn silage, the relative cost of the 2 rations being 18.5 cts. and 23 cts. Both rations were considered satisfactory. The same may be said of 2 rations containing dried blood which were tested for about a month with 2 mules weighing somewhat under 1,000 lbs. each. The first ration was made up of 1 lb. of dried blood, 25 lbs. of corn silage, 10 lbs. of corn-and-cob meal, and 4 lbs. of bran, the cost being 16.5 cts. The other ration was made up of the same constituents except that 10 lbs. of clover hay replaced the corn silage. The cost in this case was 19 cts.

The author considers that further tests are necessary to demonstrate the extent to which dried blood and tankage may be most efficiently fed.

"Bran was used as a substitute for oats and for corn acceptably and successfully. When it can be obtained at a moderate cost it should always find a place in feeding work animals. When corn and oats, though home-grown, are high commercially, it is often economy to sell part of the corn and oats in exchange for bran, providing the latter is not likewise temporarily high in market value.

"When the whole ear is ground, making what is termed here corn-and-cob meal, the same efficiency in work and maintenance of weight in horses and mules follows as where an equal quantity of shelled corn is fed. When corn on the ear was compared with an equal quantity of corn ground, the cob included in the latter, the difference was in the favor of the corn-and-cob meal, when corn stover was used as a roughage. When clover hay was used as a roughage the difference is not sufficient to note. Whether corn shall be ground or not will depend on the cost in labor and trouble in performing the operation.

"When wheat and cowpeas were compared as a part of the grain ration, cowpeas were equal to wheat, or slightly better. The cost of production and commercial value must always be considered when either is to be fed in connection with or as a substitute for other concentrates. Cowpeas are a satisfactory substitute for oats in feeding farm horses and mules."

In one of the tests cowpeas were compared with oats, 4 lbs. of each of these feeds being added to a basal ration of 4 lbs. ground wheat, 4 lbs. corn-and-cob meal, and 14 lbs. meadow hay, the cost of the oat ration being 24.4 cts. and of the cowpea ration, 20.4 cts. In the 2 weeks of the test the 2 horses, which weighed at the beginning not far from 1,100 lbs. each, gained a little in weight.

"Various kinds of feeding stuffs can be used to advantage and with economy in feeding farm horses and mules. There is no so-called 'one ration for horses.' A mixture of corn and bran, or of corn and cowpeas, or of corn, bran, and cotton-seed meal, is a good substitute for corn and oats in feeding work animals. Any feeding stuff or combination of feeding stuffs that furnishes the necessary and desirable nutrients at least cost should be the important consideration in the preparation of rations for farm horses and mules."

Poultry experiments, J. H. STEWART and H. ATWOOD (*West Virginia Sta. Bul. 88, pp. 147–162, pl. 1*).—The effect of feeding ground and moistened grain and also of light and heavy rations on egg production and egg fertility was studied. The first test was begun December 1, 1902, with 3 lots each containing 20 single-comb White Leghorn pullets and 2 cockerels and covered 240 days. All the lots were fed practically the same amount of grain (corn, wheat, and oats) and beef scrap, lot 1 being given ground grain and lot 3 whole grain only, while in the case of lot 2 one-third of the grain ration was ground and two-thirds fed whole. The total grain eaten per lot was approximately 1,000 lbs., and the total beef scrap 64 lbs., all the birds gaining somewhat in weight.

The total egg production in the case of lot 1 (ground grain) was 1,817 eggs, with lot 2 (ground and unground grain) 1,804 eggs, and with lot 3 (whole grain), 1,657

eggs. As shown by tests with different sorts of incubators, the eggs laid by lot 1 (ground grain) hatched slightly better than those from either of the other lots, but in the author's opinion this was due to the fact that the pullets were fed grain in the form of a mash. The eggs laid by lot 2, fed some ground grain, should have hatched better than those laid by lot 3, feed all whole grain, but such was not the case. The observed facts are explained on the ground that the pullets in lot 1 were relatively heavier than those in the other lots.

The relative merits of heavy and light rations were tested with 2 lots each containing 12 Rhode Island Red pullets, 8 2-year-old hens, and 2 cockerels. During the test, which began in December and covered some 7 months, lot 1, fed a heavy ration of grain and beef scraps, laid a total of 1,139 eggs and lot 2, fed a light ration of similar character, laid 930 eggs, the total amount of feed consumed in the 2 cases being 1,056.5 lbs. and 857.4 lbs. Data are also recorded regarding the weight of the poultry during the test proper and a month's preliminary feeding. As shown by the average of a number of tests with incubators, 66.8 per cent of the eggs from lot 1 (heavy ration) which were tested hatched as compared with 55.9 per cent of those from lot 2 (limited ration).

In another test made under practically the same conditions with 2 lots, each containing 20 White Leghorn pullets and 2 cockerels, and covering 166 days, lot 1 laid 1,358 eggs, consuming a total of 954 lbs. of grain with some beef scrap, while lot 2 laid 1,028 eggs, consuming 709 lbs. of the same feed as lot 1. In this case also incubator tests showed that the eggs from liberally fed fowls hatched better than those from fowls fed a limited ration.

"The results of these two tests should be construed as indicating that when the conditions are favorable for normal egg production, then the eggs will hatch better than when the conditions are unfavorable. On the other hand, it is quite probable and substantiated by experience, that breeds that are less active than the Leghorn, when supplied too liberally with food, become so fat that neither do the eggs hatch well nor are the chicks strong and vigorous."

The comparative fertility of eggs laid by hens, included in a previously reported test (E. S. R., 14, p. 902) on the comparative value of beef scrap, ground meat and bone, and milk albumen as sources of protein, were also studied. No material differences were observed which could be attributed to the feeding stuffs tested.

The effect of different feeding stuffs on the color of egg yolks and the flavor of eggs was studied, the grains included being corn, wheat, oats, Canada field peas, cowpeas, soy beans, peanuts, and sunflower seed. The flavoring materials used were trimethylamin, celery oil, and sassafras oil. Beef scrap constituted part of all the rations except in one case, where it was replaced by smoked herring. The green feed consisted of sugar beets, which it is said were readily eaten.

"Quite contrary to expectations the flavor of the eggs was not noticeably altered by any of the rations or flavoring materials employed. . . .

"The different rations, however, very clearly affected the color of the yolks. When the grain ration consisted of wheat, oats, or white corn, fed either alone or in combination with each other, the yolks were so light colored that the eggs would be quite unsuitable for fancy trade. When the grain supply consisted entirely of white corn, the yolks were very light colored, while on the other hand, the feeding of yellow corn imparted to the yolks that rich yellow color which is so desirable."

The importance of mineral matter and the value of grit for chicks, W. P. Wheeler (*New York State Sta. Bul. 242, pp. 293–314*).—With a view to learning the value of different inorganic substances as part of a ration for young chickens with reference to the nutritive material which they supply and their value from a mechanical standpoint, 7 series of feeding experiments were undertaken. Usually the trials extended over 10 or 12 weeks and were begun with chickens 1 to 3 weeks old. In every case the groups studied were fed alike except for the mineral portion of the ration.

Two lots of chickens were fed whole and ground grains, green alfalfa, gluten meal, and blood meal. In addition 1 lot was fed 2 oz. of Florida rock phosphate and 1 oz. of fine white glass sand per 24 oz. of dry feed, the mineral substances being well mixed with the ground grain. Lot 2 was fed the same mineral matter except for the first 2 weeks of the test the amount of sand was doubled. About 30 per cent of the protein in the ration was supplied by animal food. In 10 weeks chicks in lot 1 gained a pound in weight for every 2.7 lbs. of dry matter in the food, exclusive of the Florida rock. The chicks in lot 2 required 3 lbs. of dry matter per pound of gain, the total cost of food per pound of gain in the two cases being 3.7 cts. and 4.1 cts.

Of the 2 lots included in the second group one was fed the same grain ration and mineral matter as mentioned above, while the other lot was fed the same grain, etc., the mineral portion of the ration consisting of 0.5 oz. of ground oyster shells per 24 oz. of food. Exclusive of added mineral matter a pound of gain in the 2 lots required respectively 3.6 lbs. and 3.8 lbs. of feed, the cost, including rock and shell, being respectively 5.2 cts. and 5.1 cts. It was noted that the lot fed oyster shells ate more feed and made greater and more rapid gains than the lot fed the ground Florida rock.

Two lots were fed a ration made up of grains, milling products, linseed meal, gluten meal, and green alfalfa. One of the lots was given an ounce of sand per 15 oz. of food and the other an ounce of ground Florida rock. The 2 lots required respectively 4.7 lbs. and 5.5 lbs. total dry matter per pound of gain, the cost of a pound of gain being 5.8 cts. and 7.1 cts. The lot fed the ground Florida rock consumed somewhat less food and made the larger growth.

In the fourth test 4 lots were fed a ration of grains, milling products, etc., similar to that just mentioned, the ash constituents of this basal ration constituting from 3.1 to 3.3 per cent of the total dry matter. One of the lots was fed sand; another ground Florida rock; and a third bone ash and oyster shells 2 : 1 in the proportion of 1 oz. to 10 oz. of grain in every case. The fourth lot received no extra mineral matter. The chicks in this lot required 5 lbs. of dry matter per pound of gain; those in the lot fed sand, 4.5 lbs.; the lot fed Florida rock phosphate, 4 lbs.; and the lot fed bone ash and oyster shells, 4.6 lbs. exclusive of added mineral matter in each case. The cost of a pound of gain ranged from 4.9 cts. with the lot fed the Florida rock to 7.4 cts. with the lot fed bone ash and shell.

The fifth trial was made with 3 lots fed a basal ration of grain and animal meal carrying a large proportion of ground bone. The ration was high in mineral matter, about 85 per cent of which was supplied from the animal meal and bone. The animal food also supplied about 44 per cent of the protein in the ration. One of the lots was fed 3 oz. of ground oyster shell and the second 3 oz. of sand per 28 oz. of dry feed, while the third received no additional mineral matter. With ground oyster shells 3.8 lbs. of food and with sand 3.4 lbs. of food were required per pound of gain, the cost in each case being 5.7 cts. and 4.1 cts. per pound. Similar values for the lot receiving no additional mineral matter were 3.7 lbs. and 4.9 cts.

The sixth test was made with 2 lots and the seventh with 4 lots. The basal ration contained no animal food but was made up of grain, green alfalfa, etc. Two lots were fed ground oyster shells, 2 lots Florida rock, one sand and one bone ash and ground oyster shell 1:1, the proportion of added mineral matter in each case being 1 oz. per 11 oz. grain feed. In the majority of cases the mineral matter constituted about 12 per cent of the total ration. Considering the 2 tests as a whole, the feed required per pound of gain ranged from 3.9 lbs. with one of the lots fed ground oyster shells and one fed Florida rock to 5.3 lbs. with one of the lots fed ground oyster shells. The cost of a pound of gain ranged from 4.8 cts. with one of the lots fed Florida rock to 6.8 cts. with one of the lots fed oyster shells.

The author's conclusions follow:

"The mixing of sand in the food—both in a ration containing animal food and one without—resulted in better health for the chicks and more efficient use of the food.

"The addition of raw, ground Florida rock phosphate and sand to rations both with and without animal food resulted in better growth and more efficient use of food than when sand alone was added.

"The addition of the ground rock to rations without animal food resulted in more rapid growth and more efficient use of food than the addition of sand alone.

"The addition of ground rock phosphate to rations both with and without animal food was followed by better growth, and on the whole from less food, than the addition of finely ground oyster shell.

"Food mixed with finely ground oyster shell was less healthful and less efficient than the same food mixed with fine sand.

"Mixing bone ash and ground oyster shell in the food resulted in more rapid growth than the mixing of sand alone. But injury attributed to ground oyster shell made the feeding less profitable."

Ash and grit for growing chicks, F. H. HALL and W. P. WHEELER (*New York State Sta. Bul. 242, popular ed., pp. 7*).—A popular summary of the above bulletin.

DAIRY FARMING—DAIRYING.

The dairy herd, G. H. TRUE (*Arizona Sta. Rpt. 1903, pp. 335–337*).—This is a yearly record of 6 or 7 cows for 3 years.

The Waldeck cattle, W. RITGEN (*Inaug. Diss., Univ. Jena, 1903, pp. 75*).—A descriptive account of the native breed of cattle in Waldeck and the surrounding region, with considerable statistical data.

Dehorning cattle, C. L. BEACH (*Connecticut Storrs Sta. Rpt. 1903, pp. 176–182, fig. 1*).—Observations were made on the influence of dehorning cows upon the yield and composition of milk. In 1898 11 out of 24 cows in the herd were dehorned in May and the entire herd turned out to pasture on the following day. As compared with the cows not dehorned, the total loss of milk for the dehorned cows amounted to 127.08 lbs. during the first 10 days following dehorning, 66.47 lbs. during the second period of 10 days, and 11.73 lbs. during the third period of 10 days. In May, 1903, 9 cows were dehorned, records being obtained for the week preceding dehorning and for the 6 weeks following. The cows were pastured after the first 2 weeks. As compared with the yield of milk from the same number of cows not dehorned, the total loss of milk for the dehorned cows was 173.2 lbs. for the first week, 156.1 for the second week, 79.8 for the third week, 85.5 for the fourth week, 93.4 for the fifth week, and 51.3 for the sixth week. In 1898 the average loss of milk was 20 lbs. per cow, and in 1903, 70 lbs. The corresponding losses in butter fat were, respectively, ⅓ lb. and about 2 lbs.

"The pain of the operation of dehorning has been overestimated, and the mortality is practically nothing. The shrinkage in the milk and butter-fat yields of dairy cows is small and temporary. The worry, pain, and cruelty of animals to their mates is eliminated when these instruments of torture are removed, and the lack of fear and the quiet contentment of the individuals of the herd are at once noticeable. The benefits from dehorning dairy cattle can not be accurately measured, but there is an almost unanimous opinion in its favor among those who have practiced it in their herds."

Milking records, C. L. BEACH (*Connecticut Storrs Sta. Rpt. 1903, pp. 183–186*).—Data are given which show the amount of milk obtained by a second milking immediately following careless or unskillful milking. The additional milk from 6 cows amounted to 22.35 lbs. and tested 10.6 per cent of fat. A score card used in judging the efficiency of students in milking is also given.

Contribution to the study of the influence of milking on the composition of milk, L. Lepoutre (*Bul. Agr.* [*Brussels*], *20* (*1904*), *No. 1, pp. 91–117*).—The influence of different methods of milking upon the fat content of the milk was studied in experiments with 4 cows. When each quarter of the udder was milked separately the fat content of the milk from the quarter milked first was almost invariably higher than that of the milk from the quarter milked last. For instance, the percentage of fat in the milk from the posterior right, anterior right, posterior left, and anterior left quarters milked in the order mentioned were, respectively, 4.4, 2.5, 2.4, and 2 per cent.

When this order was changed and the posterior left, anterior left, posterior right, and anterior right quarters were milked in the order named, the figures were, respectively, 4.8, 2.6, 2.5, and 2.2 per cent. Likewise the milk from 2 quarters, a posterior and an anterior, milked first and at the same time showed a higher fat content than the milk from the 2 remaining quarters milked last. This difference was less marked when diagonally opposite quarters were milked at the same time than when the 2 right or the 2 left were milked together. The data for the experiments are reported in detail. The physiology of milk secretion is discussed briefly, but no definite explanation of the results obtained is offered.

In the milk from one quarter obtained in 6 portions during the entire milking the fat content increased from 3.1 to 6.8 per cent, the total solids increased from 12.59 to 15.23 per cent, and the ash decreased from 0.78 to 0.73 per cent.

Comparative tests of four methods of milking made at the dairy station in Belgium, A. de Mestral (*Bul. Agr.* [*Brussels*], *20* (*1904*), *No. 1, pp. 118–124*).—The method of milking in ordinary use, the Swiss method, the ordinary method or the Swiss method followed by a supplementary milking within 15 to 30 minutes after the first, and the Hegelund method were compared. The experiments were made with 3 cows and covered a period of 2 months. While the results were not sufficiently conclusive to show the relative value of the different methods, they indicated, however, that the ordinary method was much inferior to the other three.

Variations in the composition of milk and their probable causes, D. A. Gilchrist (*Newcastle-upon-Tyne: Northumberland and Durham Dairy Farmers' Assoc.*, *1903, pp. 16*).—This is a brief report upon the examination of a large number of samples of milk of individual cows, and also of mixed milk, 6 herds being represented and the tests extending over periods of 1 to 12 months. In collecting the samples data were obtained on the breed of cows, times of milking, weather conditions, and rations. It was found that morning's milk was frequently below the standard of 3 per cent of fat when the previous milking was early in the afternoon.

As a remedy for this it is suggested that the cows be milked 3 times a day, the last milking being late in the evening and the milk kept in the best condition possible over night. Even with equal intervals between milkings the fat content of the milk of individual cows frequently fell below the standard. With one or two exceptions, the marked changes in the feeding of the different herds while the tests were in progress did not materially affect the quantity or the quality of the milk. Weather conditions, on the contrary, apparently exerted a very important influence on milk production. The influence of other causes, such as the temperament of the cow and regularity in time and manner of feeding, are also considered.

Variation in the milk of a dairy herd during the summer months, T. S. Dymond and B. W. Bull (*Essex Education Com., County Tech. Labs., 1904, Mar., pp. 15, dgms. 2*).—A record is given of 5 shorthorn cows for 2 weeks each month from May to September, inclusive. Notes are also given on weather conditions. The results are compared with those of a similar study made during the winter months and previously reported (E. S. R., 15, p. 74). The conclusions were drawn in the earlier paper that variations in the composition of milk are due mainly to idiosyncrasies of cows over which no control can be exercised, and that there is little danger of the mixed milk of a herd falling below the legal standard in England.

Other causes of minor importance, such as food, temperature, unequal intervals between milkings, etc., were mentioned. In the present paper data are also given showing variations occurring during the period of heat. In the winter the decrease in yield per month was about 5 per cent; in the summer it was nearly 10 per cent. In general the fat content of the milk increased as the yield decreased. In July there was a decrease in the solids-not-fat in the milk of every cow. While the fat and solids-not-fat were frequently below the standard in the case of individual cows, this was not true of the mixed milk of the 5 cows in any instance.

The mineral constituents of cows' milk and their variations during the period of lactation, A. TRUNZ (*Ztschr. Physiol. Chem., 40 (1903), No. 3–4, pp. 263–310*).—The author reviews the literature concerning the mineral constituents of milk, and reports determinations of the total ash and the different ash constituents in the milk of 2 cows at frequent intervals during the entire lactation period. Determinations were also made of the specific gravity, fat, total proteids, casein, albumin and globulin, and milk sugar.

Cow No. 655 was 3½ years of age at the beginning of the lactation period, which lasted from December 25, 1901, to November 8, 1902. Cow No. 674 was 7½ years old at the beginning of the period, which lasted from January 14 to December 6, 1902. The course of lactation in both instances was considered normal. The accompanying table shows the total ash and the different constituents by months for each cow. In the percentages for pure ash as given in the table, deductions were made for the sulphuric acid and the phosphoric acid derived from the phosphorus of the casein.

The influence of feeding stuffs on milk secretion and on the composition of milk, O. LEMMERMANN and G. LINKH (*Landw. Jahrb., 32 (1903), No. 4, pp. 559–625*).—In a review of the literature of this subject the authors found very little of a positive nature as to the existence of a feeding stuff having a specific influence on milk secretion. All the experiments which have indicated such an influence can not be looked upon as conclusive, according to the authors, on account of the manner in which the experiments were made.

Experiments with 4 cows were conducted for the purpose of determining if such an influence could be ascribed to palm-nut cake, cocoanut cake, brewers' grains, and a mixture of equal parts of anise, fennel, juniper, and caraway. The basal ration consisted of feeding stuffs not believed to have any specific influence on the yield and composition of milk. In all cases the rations contained the same amount of digestible matter.

The results, which are reported in detail, indicated that each of the feeding stuffs under examination exerted a specific influence outside of its food value, although this influence was not constant with the different animals. A feeding stuff which apparently exerted a specific influence with one animal was entirely without effect with another animal. On the other hand, the different feeding stuffs acted differently on the same animal. This specific influence consisted in increasing slightly the yield of milk, or in retarding the decrease in yield due to the advance of lactation. In all cases this influence was so small that it is considered of no practical importance. No dairy feeding stuff is therefore believed to justify a price in excess of its food value.

The influence of feeding stuffs on the character of the butter fat, O. Lemmermann and F. Moszeik (*Landw. Jahrb., 32 (1903), No. 4, pp. 626–634*).—In experiments with 7 cows a study was made of the influence upon the butter fat of sesame cake fed alone and of sesame cake, peanut cake, and palm-nut cake fed in different mixtures. In no instance was sesame oil detected in the butter by means of the Badouin reaction. The Reichert-Meissl number showed no variations which could be attributed to the influence of the different oil cakes. On the contrary, the refractometer and iodin numbers of the butter fat varied unmistakably with the corresponding numbers of the fats in the feeding stuffs. A direct influence on the character of the butter fat was, therefore, apparently exerted by the fat in the food. It is considered as the most obvious explanation that a portion of the fat in the food passed through the organism without undergoing much change.

The constituents of milk—their properties and changes, R. W. Raudnitz (*Separate from Ergebnisse Physiol., 2 (1903), pp. 136*).—This is a general review of the literature of this subject, the bibliography including about 670 references.

Contribution to the knowledge of goats' milk, P. Buttenberg and F. Tetzner (*Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, pp. 270–272*).—The milk of 5 goats was analyzed morning and evening for 6 days. The fat content was frequently below 3 per cent and the solids-not-fat frequently below 8 per cent. The average composition of the mixed milk of the 5 goats for the 6 days was 3.04 per cent of fat and 8.15 per cent of solids-not-fat for morning's milk, and 3.67 per cent of fat and 8.19 per cent of solids-not-fat for evening's milk.

Preventing contamination of milk, W. J. Fraser (*Illinois Sta. Bul. 91, pp. 219–249, figs. 13*).—Brief notes are given on the sources of bacteria in milk and on the changes produced by bacteria in milk, and investigations conducted for the purpose of determining the effect of the different operations commonly performed in dairies and dairy barns upon the bacterial content of milk are reported.

Petri dishes having an area of about 63 sq. cm., and filled with an agar culture medium were exposed for different lengths of time, usually a half minute, under various conditions. In all 1,185 exposures were made. Only the average results are given in the bulletin. Some of these are summarized in the following table:

Average number of colonies developed from exposures made in different places.

Place of exposure.	Number of exposures.	Number of colonies.
Open field	43	0.9
Barnyard	51	13.0
Well-kept barn during milking	10	32.0
University barn during milking	46	38.0
Poorly-kept barn during milking	21	168.0
Barn empty, closed 3 hours	12	.6
Before feeding	9	46.0
After feeding	31	109.0
After brushing cows	38	307.0
Under apparently clean unwashed udder	158	578.0
Under washed udder	262	192.0
Bottling room	60	.3
Dairy room	3	15.0

The effect of feeding roughage and brushing cows was to increase the number of colonies from 46 to 109 and 307. The greatest source of contamination in milk was found to be the cow herself, and the greater part of this contamination was found to come from the udder. Washing the udder reduced the number of colonies on an average from 578 to 192. Determinations were also made of the amount of dirt falling from udders apparently clean, slightly soiled, and muddy during the time usually required for milking and with manipulations corresponding to those used in milking. With udders apparently clean the amount of dirt falling before washing was 3.5 times as great as that falling after washing; with udders slightly soiled the amount before washing was 18 times as great as that after washing; and with muddy udders the amount before washing was 90 times as great as that after washing, showing the decided advantage of washing udders before milking in the production of clean milk.

City milk supply, W. J. Fraser (*Illinois Sta. Bul. 92, pp. 251–272, figs. 9*).—The statements made in this bulletin are based upon the results of 7 years' experience in conducting a sanitary dairy at the University of Illinois and upon the results of investigations. Suggestions are made concerning the care of yards, construction and care of barns and stables, cleanliness in milking, care of milk and dairy utensils, standardizing milk and cream, and other matters requiring attention in the production of good milk.

Milk production at the University of Illinois (*Illinois Sta. Circ. 73, pp. 16, figs. 8*).—This is a description of the methods employed in the production of sanitary milk at the University of Illinois, and is distributed with the bulletin noted above as an illustration of the means that may be taken of informing the public of the methods employed in the production of good milk.

Comparison of bacteria in strained and unstrained samples of milk, H. W. Conn and W. A. Stocking, Jr. (*Connecticut Storrs Sta. Rpt. 1903, pp. 33–37*).—This series of experiments was designed to test the effect of straining upon the bacterial content and keeping quality of milk. The milk was drawn into an ordinary open pail, sampled, strained through 2 layers of sterilized cheese cloth and again sampled, plate cultures being made from the samples soon after taking, after being kept at a temperature of 70° F. for 50 hours, and at the time of curdling. Determinations of acidity were made at the end of 50 hours and at the time of curdling.

The results, which are tabulated, show on an average very little difference in the bacterial content of the strained and unstrained samples, and also very little difference in the time of curdling. The time required for curdling varied from 42 to 104 hours, the samples all being kept at the same temperature. This difference was apparently not due to the number of bacteria originally in the milk, as the sample curdling in the shortest time had at the outset the smallest number of bacteria. A slightly larger percentage of acid bacteria were present in the unstrained than in the strained samples, the difference, however, not being considered large enough to have any significance.

In general, samples showing the greatest number of bacteria at the end of 50 hours showed also the highest percentage of acidity. The number of bacteria present at the end of 50 hours seemed wholly independent of the number present at the outset. While the lactic-acid bacteria in fresh milk ranged from 9 to 53 per cent of the total number present, they constituted usually from 99 to 100 per cent at the time of curdling. The number of bacteria at the time of curdling varied from 211,000,000 to 2,700,000,000 and had apparently no relation to the time of curdling. The acidity of the milk at the time of curdling also varied greatly, and while usually it was from 0.6 to 0.8 per cent, in 2 cases it reached 1.15 and 1.23 per cent.

Strained and unstrained milk preserved at 70 and 50° F., H. W. Conn and W. A. Stocking, Jr. (*Connecticut Storrs Sta. Rpt. 1903, pp. 38–51*).—In continuation of the above experiments tests were made to compare the number and kind of

bacteria in milk when fresh and at a later period, to determine whether straining through cheese cloth exerts an influence upon the bacterial content of the milk, to study the relation between the number of bacteria and the development of acid, and to study the effect of a change in temperature upon the total number of bacteria and the relative number of the different types. The milk was obtained from one cow in the ordinary manner, and strained and unstrained samples were kept at temperatures of 50 and 70°.

Some of the general conclusions drawn from the tabulated data are summarized below:

The examination of the fresh milk showed that straining through cheese cloth had only a slight effect in removing bacteria, which was considered somewhat surprising, inasmuch as previous experiments had shown that straining in this manner removed about 40 per cent of the dirt present. Of the bacteria removed by straining the larger percentage consisted of nonacid species, although the results as a whole showed very little difference. The relative proportion of the acid and nonacid bacteria in fresh milk was, however, considered of little importance as regards the rapidity of curdling, inasmuch as the type of lactic-acid bacteria originally present was replaced in most cases by the end of 50 hours by *Bacterium lactis acidi*.

The examination of the milk kept for 50 hours at 70° showed that the strained samples contained on the whole a slightly larger number of bacteria than the unstrained samples. Neither the total number of bacteria nor the percentage of lactic-acid bacteria was believed to be influenced to any appreciable extent by straining. In cases where the acid bacteria had reached 99 per cent of the total number of bacteria present the acidity of the milk was not very greatly increased, indicating that the production of acid takes place rapidly only after the acid bacteria have gained full control. The development of acid bacteria was unaffected by straining. In general, samples containing the larger number of acid bacteria also contained the highest percentage of acid.

The examination of milk kept for 50 hours at 50° showed a striking reduction in the number of bacteria as compared with the milk kept at 70°, the average number in the samples kept at 70° being nearly 500,000,000 and at 50°, 6,000,000. The acid bacteria were reduced in greater proportion than the total bacteria. The strained samples contained slightly larger numbers of acid bacteria than the unstrained samples, although the difference was considered too slight to have any meaning. There was practically no increase in the acidity of the milk, the average acidity being about 0.20 per cent, while that of the original samples averaged 0.18 per cent.

At 70° the time required for curdling was 87 and 97 hours, while at 50° the average was about 300 hours, the unstrained samples keeping on an average about 10 hours longer than the strained samples. The time of curdling at 50° appeared to be unrelated to the total number of bacteria present at the outset. The conclusion is drawn that for practical purposes the temperature is of more importance in the keeping of milk than the original bacterial contamination. The number of bacteria present at the time of curdling varied from 282,000,000 to 1,659,000,000. The acidity also showed considerable variations.

Aseptic milk, H. W. CONN and W. A. STOCKING, Jr. (*Connecticut Storrs Sta. Rpt. 1903, pp. 52–62*).—This series of experiments, which is in continuation of the two series noted above, was designed to compare ordinary milk with milk obtained under exceptional precautions and here called aseptic milk. The precautions taken included the washing of the udder and flanks of the cow with a 3 per cent solution of boric acid and wiping with a sterilized cloth, the milker also washing his hands with the same solution and wiping them on a sterilized cloth. After the milking was half done these precautions were repeated, and milk was drawn into a sterilized covered pail through 4 thicknesses of sterilized cheese cloth and a layer of absorbent cotton and sampled for bacteriological examination. All the experiments were made with the

milk of one cow, which was obtained by the method outlined and by the ordinary method on alternate days. Samples were kept at 70° and at 50° F.

The extra precautions mentioned reduced the bacterial content of the fresh milk in two series of experiments from averages of 3,888 and 3,116 bacteria per cubic centimeter to 267 and 242, but apparently increased the percentage of lactic-acid bacteria. In no instance was the typical *Bacterium lactis acidi* found.

In the samples kept at 70° the bacteria multiplied more rapidly in ordinary milk than in the aseptic milk. The aseptic milk showed in practically every instance a smaller number of bacteria at the end of 12, 24, and 36 hours than milk drawn in the ordinary way. The development of acid was correspondingly much slower in the aseptic samples. Ordinary milk curdled, on an average, in 79 hours and aseptic milk in 113 hours.

In the samples kept at 50° the differences were even greater than in the samples kept at 70°. The average increase of bacteria at this temperature in 36 hours was 10-fold in the aseptic milk and 30-fold in the ordinary milk. The time of curdling was, respectively, 226 and 400 hours. It is considered that the most striking results of the experiments were the effect of a temperature of 50° in checking bacterial growth and in improving the keeping quality of the milk. The lower temperature checked the development of lactic-acid bacteria and favored the development of miscellaneous species.

Qualitative analysis of bacteria in market milk, H. W. Conn and W. M. Esten (*Connecticut Storrs Sta. Rpt. 1903, pp. 63–91*).—In continuation of investigations previously reported (E. S. R., 13, pp. 688, 987), bacteriological examinations were made of the market milk of Middletown, Conn. The milk was obtained from about 20 milkmen, and was supposed to be from 2 to 12 hours old. The methods of examination employed were the same as those previously described. The bacteria ordinarily found in normal milk are divided into 12 groups, each of which is described. Data for selected experiments are reported in this article, and a number of conclusions are drawn.

The number of bacteria varied from 8,000 to 2,900,000 per cubic centimeter. In a general way the percentage of lactic-acid bacteria increased with the total number. An increase in the total number of bacteria was associated with a decrease in the number of varieties. On the other hand, a small number of bacteria was associated, as a rule, with a large number of varieties. The liquefying bacteria in general varied inversely as the total number of bacteria, and also inversely as the percentage of lactic-acid bacteria. The liquefying bacteria also varied with the season, the number being greater during May and June than during the several months preceding. The number of varieties of bacteria varied greatly in the different samples, in some cases being only 4 or 5, while in others no less than 17 species were recognized.

Comparative tests were made of several modifications of the methods of study previously described and used in the above investigations. It has been found preferable to sterilize the litmus solution separately and add it to the gelatin at the time of using, thus securing a greater uniformity in the color of the medium. Three culture media—whey gelatin, peptone gelatin, and milk custard—were tried alone and in different mixtures. Part of the data for these tests are included in the report. The most satisfactory medium for all purposes, including both quantitative and qualitative analysis, has been found to be a mixture of the common beef peptone gelatin and the whey gelatin, litmus being added in a manner to secure uniformity of color in the different plates.

Bacteria in freshly drawn milk, H. W. Conn (*Connecticut Storrs Sta. Rpt. 1903, pp. 92–98*).—This is a comparison of the results obtained by Harrison and Cumming (E. S. R., 14, p. 907) with those obtained in Connecticut. In the work at Middletown and Storrs, Conn., the number of bacteria found in the fore milk has been much lower, the average of 70 experiments being 6,900 bacteria per cubic centimeter,

as compared with an average of 25,000 to 50,000 reported by Harrison and Cumming. The most striking difference, however, related to the species of bacteria present. In the work of Harrison and Cumming over 95 per cent of the bacteria were reported as belonging to the lactic-acid group and including *Bacterium lactis acidi*. In the work in Connecticut, involving hundreds of experiments carried on in the two localities mentioned, the lactic-acid bacteria were commonly less than 50 per cent and often below 30 per cent; and in practically no instance was the *Bacterium lactis acidi* present. The differences are attributed in part to local conditions, but mainly to the different methods of analysis used. The author attributes the discrepancies in results to the use by Harrison and Cumming of ordinary gelatin in the preparation of plate cultures and the subsequent isolation and study of only a limited number of colonies.

Dairy bacteriology laboratory, W. A. STOCKING, Jr. (*Connecticut Storrs Sta. Rpt. 1903, pp. 22–27, figs. 5*).—This is an illustrated description of the new dairy bacteriological laboratory at the Connecticut Storrs Station.

Milk bacteria, C. HAPPICH (*Fortschr. Vet. Hyg., 1 (1903), No. 4, pp. 149–151*).—The bacteria found in milk are classified as indifferent, useful, harmful, and pathogenic, and each class is described.

Milk fermentations, M. A. O'CALLAGHAN (*Agr. Gaz. New South Wales, 15 (1904), No. 2, pp. 111, 112, pls. 3*).—Notes are given on the use of boric acid in the preservation of normal milk, condensed milk, and concentrated milk. In experiments which are briefly reported the development of lactic-acid bacteria was very materially checked in fresh milk by the addition of 0.25 and 0.50 per cent of boric acid, while this quantity of preservative did not appear to retard butyric-acid fermentation in the slightest. In concentrated milk the use of 0.25 to 0.50 per cent of boric acid appeared to check the growth of nearly all species of bacteria.

The soluble ferments of cows' milk, J. LESPERANCE (*Med. Rec. [New York], 65 (1904), No. 12, pp. 447–450*).—This is a general discussion of the subject. In summarizing the discussion the author states that the presence of peptic, tryptic, lipasic, oxidizing, and glycolytic ferments in milk have been definitely determined. A bibliography is appended.

On the coagulation of milk, A. S. LOEVENHART (*Ztschr. Physiol. Chem., 41 (1904), No. 3, pp. 177–205*).—Some of the results of the investigations here reported may be summarized as follows: In regard to the action of their salts on casein and paracasein, metals may be divided into 3 groups—group 1 including sodium, potassium, ammonium, and possibly also rubidium and cesium, the salts of which precipitate neither casein nor paracasein; group 2 including the salts of lithium, beryllium, magnesium, calcium, strontium, barium, manganese, iron, cobalt, and nickel, which precipitate paracasein readily at room temperatures, but casein only after a long time at 40° C. or above; and group 3 including all the other heavy metals and ferric iron, the salts of which precipitate both casein and paracasein promptly at room temperatures. The precipitating action of the salts increased in proceeding from the stronger to the weaker metals.

Paracasein was precipitated more readily than casein by all the reagents. Paracasein and casein are believed to differ only in their physical nature, and are, therefore, modifications of one and the same substances. The coagulation of milk is believed for the most part to depend upon a change in the arrangement of the mineral constituents of milk. The calcium salts present in milk do not exist originally in a form capable of precipitating the casein or paracasein, but are made available for this purpose during the action of the rennet.

A study was made of the metacasein reaction of Roberts, which consists in the addition of pancreatic extract to milk by which the milk, while not apparently changed, is nevertheless rendered capable of being coagulated by heat. This was found to be directly dependent upon the presence of calcium salts, and could

also be obtained in other ways. It was believed to represent merely a stage in the process of coagulation. The transformation of the casein into paracasein was found to take place more rapidly than the liberation of the calcium salts, and was completed at the time of the appearance of the metacasein reaction. The calcium salts are made available during the period from the beginning of the metacasein reaction to the appearance of coagulation.

Supplying large cities with milk for infants. I, The necessity of a transformation in the production of milk for infants, M. SEIFFERT (*Die Versorgung der grossen Städte mit Kindermilch. I, Die Notwendigkeit einer Umgestaltung der Kindermilcherzeugung. Leipzig: Weigel, 1904, pp. 278, pls. 4*).

Progress in the field of the chemistry, hygiene, and bacteriology of milk and its products, WEIGMANN, HÖFT and GRUBER (*Chem. Ztg., 28 (1904), No. 19, pp. 229–232*).—A summary of the literature during 1903, 128 references being given in footnotes.

The technique of butter making in Denmark, M. BEAU (*Jour. Agr. Prat., n. ser., 7 (1904), No. 6, pp. 183–185*).—A brief description of the methods employed in making butter in Denmark.

Notes on the biology of anaerobic bacteria in cheese, A. RODELLA (*Centbl. Bakt. u. Par., 2. Abt., 11 (1904), No. 14–15, pp. 452–456*).—Brief notes are given on recent investigations relating to the growth of anaerobic bacteria. According to the author, anaerobic forms isolated from Emmenthaler cheese not only grow in a medium containing 0.5 per cent lactic acid, but even exert a liquefying action on the casein. This action, however, is much greater in an alkaline medium.

The utilization of skim milk in dairying, C. KNOCH (*Die Magermilch-Verwertung in den Molkereien. Leipzig: M. Heinsius Nachfolger, 1903, pp. 217, figs. 41*).—The composition of skim milk is discussed, and the different methods of utilization are described.

Dairying, C. MARTIN (*Laiterie. Paris: J. B. Baillière & Sons, 1904, pp. 380, figs. 114*).—This treatise constitutes one of the volumes of the *Encyclopédie agricole*. The different subjects included in dairying, such as the composition and properties of milk, bacteria in milk, care and handling of milk, milk inspection and sale, butter making, cheese making, cooperative societies, condensed milk, utilization of by-products, etc., are quite fully treated.

Dairying division, J. A. KINSELLA (*New Zealand Dept. Agr. Rpt. 1903, App. II, pp. 30–80, pls. 3*).—This report of the dairy commissioner comprises a summary of the work of the division during the year, statistical data relating to dairying in New Zealand, and suggestions for the improvement of the industry.

VETERINARY SCIENCE AND PRACTICE.

The present status of the doctrine of immunity, C. O. JENSEN (*Maanedsskr. Dyrlæger, 15 (1903), No. 7–8, pp. 253–269, figs. 17*).—In this article the author discusses the subject of immunity from a historical standpoint and reviews in a critical manner the contributions made to the subject by Pasteur, Metchnikoff, Buchner, Virchow, and Ehrlich.

Vitality and immunity, C. SCHULIN (*Jour. Comp. Med. and Vet. Arch., 24 (1903), Nos. 1, pp. 1–6; 2, pp. 77–88; 3, pp. 147–156; 4, pp. 233–240*).—A general discussion of the phenomenon of immunity with special reference to the physiological basis of vitality in animals. The literature relating to immunity is discussed from this point of view. The author believes as a result of his studies that pathogenic organisms are developed from saprophytic bacteria and that there is little stability of type in bacteria. These organisms are believed to be capable of adapting themselves readily to changed conditions.

Agglutinins and precipitants, A. WASSERMANN (*Ztschr. Hyg. u. Infectionskrank., 42 (1903), No. 2, pp. 267–292, fig. 1*). The author described the nature and properties

of agglutinins and precipitants in accordance with the recent theories regarding vaccination and immunity. Experiments were made on rabbits for the purpose of testing the relationship of agglutinins to other substances which are found in the blood serum.

The influence of high pressure on micro-organisms, G. W. Chlopin and G. Tammann (*Ztschr. Hyg. u. Infectionskrank., 45 (1903), No. 2, pp. 171-204*).—The author tested the influence of pressures varying from 500 kg. to 3,000 kg. per square centimeter upon the growth and virulence of various micro-organisms, including the bacillus of mouse typhus and the anthrax bacillus. The high pressure was brought about gradually and the normal pressure was then gradually restored. In experiments with the bacillus of mouse typhus it was found that the virulence of the organism was considerably reduced by subjection to a pressure of 2,000 kg. per square centimeter at a temperature of 36° C. In general the experiments showed that a considerable increase of pressure lowered the vital functions of micro-organisms and that these functions did not regain their normal state until after some time. A pressure of 3,000 kg. per square centimeter, however, was not sufficient to kill bacteria, mold fungi, or yeasts, and exercised only a slight immediate effect upon the micro-organisms. The effect was proportional to the length of period and to the pressure, and was manifested in weaker movements, less rapid multiplication, less active production of fermentation and pigments, and an attenuation of the virulence.

The death of bacteria when boiled under diminished pressure, J. Schut, Jr. (*Ztschr. Hyg. u. Infectionskrank., 44 (1903), No. 2, pp. 323–358, pl. 1, figs. 6*).—In these experiments a considerable variety of saprophytic and pathogenic bacteria, including anthrax bacilli, were used. The purpose of the experiments was to determine whether the lowering of the pressure influenced the effectiveness of a given temperature in the destruction of micro-organisms. It was found that bacteria and other spores are killed less quickly by subjection to a given temperature without boiling than by being boiled at the same time. Live steam was found to be more effective in the destruction of micro-organisms than boiling water at the same temperature. The experiments also showed that the resistance of micro-organisms to high temperature depends in part on the temperature at which they had been cultivated, and the medium in which they are suspended. Live steam was found to be practically as effective at a temperature of 90 as at 100° C.

Fourteenth annual report of the veterinary service in Hungary, F. Hutyra (*Jahresber. Vet. Ungarn, 14 (1902), pp. 135*).—As usual in his annual report, the author presents an account of the official veterinary service of Hungary, together with detailed notes on the prevalence and means of combating rinderpest, anthrax, rabies, glanders, epizootic swine diseases, tuberculosis, etc.

Report of the veterinary service in the Kingdom of Saxony for 1902 (*Ber. Veterinärw. Königr. Sachsen, 47 (1902), pp. 324*).—This report contains an account of the veterinary commission, the official veterinarians of Saxony, and notes on the work of the veterinary service on a great variety of animal diseases in different parts of the kingdom.

Annual report of the Bacteriological Institute for the Province of Saxony, H. Raebiger (*Berlin. Tierärztl. Wchnschr., 1903, No. 41, pp. 639–641*).—Notes are given on contagious vaginal catarrh of cattle and its treatment, infectious dysentery in calves, Borna horse disease, pleuro-pneumonia of cattle, swine erysipelas, swine plague, fowl cholera, and the destruction of rats by means of bacterial cultures.

Bloemfontein veterinary conference, S. B. Woollatt (*Agr. Jour. and Min. Rec. [Natal], 6 (1903), No. 23, pp. 841–843*).—At this conference a lengthy discussion on rinderpest was had and a resolution was adopted declaring that one of the most important points in preventing this disease is the making of an immediate and correct diagnosis, and that all of the governments represented at the conference should at once give notification of the presence of rinderpest in their country.

Attention was also given to a consideration of African coast fever in cattle, glanders, foot-and-mouth disease, rabies, sheep scab, etc.

Infectious diseases of our farm animals, W. H. Dalrymple (*Jour. Comp. Med. and Vet. Arch., 24 (1903), No. 4, pp. 201–212*).—Brief notes on the nature and means of combating tuberculosis, foot-and-mouth disease, Texas fever, and other contagious diseases of domestic animals.

On certain septicemias and some other infections of young animals, A. E. Mettam (*Jour. Comp. Path. and Ther., 16 (1903), No. 3, pp. 229–244*).—Brief notes are given on some of the more common forms of septic infections and intoxications. Particular attention is given to a discussion of white scour in calves and the connection of this trouble with lung disease in calves. The 2 diseases are believed to be of the same origin. For the prevention of these diseases the author recommends careful antisepsis of the umbilicus.

Researches on tetanus, H. Meyer and F. Ransom (*Proc. Roy. Soc. [London], 72 (1903), No. 477, pp. 26–30*).—The authors believe that they have demonstrated that the transportation of the toxin to the central nervous system takes place only by way of the motor nerves. Experiments were carried out, during which it was shown that the progress of the toxin along the motor nerves could be checked by an application of antitoxin to the nerve cords. That the course of the toxin is centripetal along the motor nerve was shown by experiments to determine the period of incubation of tetanus from infection by different methods. The characteristic tetanic rigidity of the muscles is believed to be due to the action of the toxin on the nervous centers. It was found that the tetanus toxin does not reach the spinal centers by way of the sensory nerves nor in the lymphatics of the motor nerves, but in the protoplasm of these nerves.

The relation of various tissues of the animal organism to tetanus toxin, A. Ignatowsky (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1903), Nos. 1, pp. 4–14; 2, pp. 158–168*).—The author briefly reviews the literature relating to this problem. The chief purpose of the experiments reported in this paper was to determine whether all of the organs of the body are capable of fixing tetanus toxin. The organs studied included the brain, spleen, spinal cord, musculature, liver, kidneys, and pancreas, as well as the blood. During the author's investigations it was not found that any special substance was produced in different organs which might account for a reaction toward tetanus toxin. The brain, spinal cord, liver, kidney, spleen, lung, and muscle tissue of rabbits and guinea pigs dead of tetanus, when inoculated into mice were found to be capable of transmitting tetanus without regard to their blood content. The symptoms of the form of tetanus thus produced were quite different from those observed in typical cases, however. It was found that the bile and urine of animals affected with tetanus does not contain any tetanus toxin under normal conditions. The various organs of the body were found to be capable of fixing or neutralizing the tetanus toxin to some extent.

The absorption of tetanus toxin in mammals, A. Marie (*Bul. Inst. Pasteur, 1 (1903), No. 17, pp. 633–640*).—A general discussion of the course taken by the tetanus virus in passing from the periphery to the central nervous structures. It has been shown that the tetanus toxin is absorbed by the terminal portions of the motor nerves, and that a small quantity of toxin placed in contact with these nerves is sufficient to produce tetanus, even in animals which have received a sufficient quantity of antitoxin to render them immune to inoculations with toxin by the hypodermic or intravenous methods. Tetanus toxin is always found in the nerves in inoculated animals. Arguments are presented to prove that the toxin does not penetrate from the periphery to the central nervous system in the lympathic spaces around the nerves, but rather in the nerve substance itself. It is believed that the larger part of the period of incubation is occupied by the transportation of the poison from the periphery to the nervous center in the axis cylinder of the nerves.

Experiments concerning tuberculosis, I, M. DORSET (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 52, pp. 30, pls. 5*).—The present part of this bulletin is concerned with a discussion of the virulence of human and bovine tubercle bacilli for guinea pigs and rabbits. Tubercle bacilli were obtained from cattle as well as from children and adult human beings, and this material was used in the inoculation of guinea pigs and rabbits for the purpose of testing its virulence. In the isolation and propagation of all cultures a medium was used consisting of mixed white and yolk of hens' eggs, and pure cultures were obtained from guinea pigs inoculated subcutaneously with bits of tissue from the various cases of tuberculosis. It was found during the author's numerous experiments that the gross characters of cultures on the egg medium permitted the separation of the cultures into 2 groups, the first of which consisted of 2 bovine and 2 human cultures, while the second included only human tubercle bacilli. The microscopic characters of various cultures on egg media were not such as to allow the differentiation between human and bovine bacilli. Likewise no differentiation could be made in cultures on dog serum. The guinea pigs used in these experiments were healthy and of an average weight of 532 gm. Detailed notes are given on the behavior of various inoculated guinea pigs and the periods during which they lived after inoculation. It was found during these experiments that certain tubercle bacilli of human origin can not be distinguished from the standpoint of their culture, morphology, or virulence for rabbits and guinea pigs from tubercle bacilli of bovine origin. Considerable variation in the virulence of human tubercle bacilli for rabbits and guinea pigs was observed. The general conclusions which are stated as being based on this and other parts of the bulletin still to be published may be stated as follows: From cases of human tuberculosis bacilli may be obtained which will produce the disease in pigs, cattle, and monkeys when inoculated subcutaneously. The genetic relation of tubercle bacilli of various origins appears to be well established. As a rule, bovine bacilli are more virulent than human bacilli for all animals upon which experiments have been made.

Reports on bovine tuberculosis and public health, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 53, pp. 63*).—This bulletin contains 3 reports made before the American Public Health Association in 1901, 1902, and 1903, respectively. The reports have all been noted (E. S. R., 13, p. 786; 15, pp. 313, 512).

Homogeneous cultures of the human tubercle bacillus in peptonized water and the serum reaction obtained with such cultures, E. HAWTHORN (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 22, pp. 816, 817*).—The author describes the behavior of the human tubercle bacillus when grown in peptonized water, and notes briefly certain agglutination experiments made with organisms thus treated. In the agglutination experiments the method of Arloing was closely followed. The results indicate that considerable dependence may be placed upon the agglutination method in diagnosing tuberculosis. The serum reaction was positive only in the case of animals which were affected with tuberculosis.

Experiments on tuberculosis, G. DEAN and C. TODD (*Jour. Path. and Bact., 8 (1903), No. 4, pp. 458–489*).—The object of the experiments recorded in this paper was to determine whether the human tubercle bacillus undergoes any change in virulence for cattle by a preliminary passage through other animals. The experimental animals employed were pigs, cats, rabbits, rats, and mice. A considerable number of each species was used and the material employed for the inoculation of calves was taken from the experimental animals which first succumbed to infection. The calves were killed and carefully examined after a period of 4 months. The experiments which are described in detail indicate that the human tubercle bacillus is not greatly increased in virulence for calves by a single passage through the pig, cat, rabbit, or rat. The human tubercle bacillus, however, proved to be virulent for calves and capable of producing extensive granular tuberculosis in these animals.

The experiments showed, furthermore, the great importance of other bacterial organisms associated with the tubercle bacillus during the process of infection. The author fed human tuberculous sputum to 3 pigs, each pig receiving about 15 cc. at a time. All these animals became infected with generalized tuberculosis and died. The results thus obtained are compared with the work of Koch and his pupils.

Recent work on the question of the identity of human and bovine tuberculosis, A. von Székely (*Centbl. Bakt. u. Par., 1. Abt., Ref., 34 (1903), No. 6–7, pp. 161–181*).—The author reviews in a critical manner the recent literature dealing with the determination of the relationship between human and bovine tuberculosis in connection with a bibliography of this subject. As a result of this review it is concluded that the problem is not definitely solved, but that the possibility of intertransmission of tuberculosis between man and animals must be admitted.

Protective vaccination against tuberculosis, C. O. Jensen (*Maanedsskr. Dyrlæger, 15 (1903), No. 1, pp. 17–23*).—The work of Koch, Maragliano, von Behring, and others is critically reviewed and the hope is expressed that a thoroughly practical method of protective vaccination will soon be developed.

Cultivation of tubercle bacilli in bacterial mixtures and disinfection by formaldehyde, C. Spengler (*Ztschr. Hyg. u. Infectionskrank., 42 (1903), No. 1, pp. 90–114*).—During the experiments reported in this paper a large number of cultures of tubercle bacilli, chiefly from the sputum of tuberculous patients, were made on the various nutrient media, and the effect of formaldehyde fumes upon such cultures was tested. It was found that in mixed cultures other organisms were destroyed by the formaldehyde gas, while the tubercle bacilli remained apparently unaffected or even developed more vigorously.

The method of applying disinfection with formaldehyde gas was that recommended by Flügge. The author concludes that this method may be used to assist in the identification of the tubercle bacillus, but is not reliable as a disinfecting method. In a reply to this paper by C. Flügge the latter argues that the formaldehyde gas was not applied in sufficient concentration and that the tubercle bacilli were inclosed in too large masses of material to allow the development of the full effects of the treatment.

The lesions produced in the kidneys by chloroform extract of tubercle bacilli, L. Bernard and M. Salomon (*Compt. Rend. Soc. Biol. Paris, 55 (1903), Nos. 30, pp. 1233–1235; 31, pp. 1306–1308*).—A chloroform extract of tubercle bacilli was injected into the substance of the kidneys of rabbits and guinea pigs and the progress of the intoxication was studied. Three days after injection the kidney capsule became hemorrhagic and masses of fibrin were observed holding red blood corpuscles. The center of the intoxication is invaded by leucocytes and a considerable extravasation develops. With small doses of tubercle toxin this produces merely an interstitial nephritis, while with large doses a leucocytic infiltration is caused, with or without necrosis of the parenchyma of the kidneys.

The acclimation of rabbits to fatal doses of dead tubercle bacilli, Dembinski (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 33, pp 1409–1411*).—The experiments which were carried on by the author indicate that it is possible by means of gradually increasing intravenous doses of dead tubercle bacilli to bring about a great resisting power in rabbits to the toxins contained in this substance. The resistance of rabbits thus treated, however, is limited. When treated rabbits were inoculated in the brain with quantities two or more times the size of fatal doses, they died as rapidly as the control rabbits.

Rendering judgment on intestinal tuberculosis, K. Müller (*Ztschr. Fleisch u. Milchhyg., 13 (1903), No. 10, p. 317*).—According to the German meat-inspection laws it is necessary to condemn or destroy all organs of which the corresponding lymph glands are tuberculous. Attention is called to the necessity of applying these measures strictly in dealing with intestinal tuberculosis in cattle.

The frequency of tuberculosis of the mesenteric glands in hogs, K. MÜLLER (*Ztschr. Fleisch u. Milchhyg., 13 (1903), No. 8, pp. 242, 243*).—In an examination of 1,328 hogs tuberculosis was found in the intestines or mesenteric glands in 119 cases, in the liver in 19 cases, and in the lungs in 15 cases. In 50 per cent of the cases in which the small intestines were affected, the disease could be recognized without making an incision. According to statistics collected by the author tuberculosis exists in about 9 per cent of all hogs examined.

Pasture and tuberculosis, SCHRÖDER (*Berlin. Tierärztl. Wchnschr., 1903, No. 41, p. 639*).—According to the author's observations the percentage of tuberculosis in hogs falls very decidedly during the late summer months. It is recommended, therefore, that where it is possible animals be turned out to pasture early in the spring.

The treatment of experimental tuberculosis by means of emulsions of tuberculous ganglia, A. RODET (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 27, pp. 1109–1114*).—The purpose of the author's experiments was to determine whether lymphatic ganglia of tuberculous animals contain any curative principles which could be used in the treatment of tuberculosis. The experiments were made with laboratory animals, chiefly guinea pigs, and the results obtained were for the most part negative. It was found that the treatment of inoculated animals with an extract from the lymphatic ganglia alone or associated with goat serum had little effect in checking the development of tuberculosis.

Tuberculins, BÉRANECK (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 21, pp. 889–891*).—Attention is called to the fact that there are several kinds of tubercle toxins, some of which are diffusible and affect the nervous system, while others remain in conjunction with the bacterial bodies and exercise their action by contact with the surrounding tissues. In studying the course of tuberculosis in guinea pigs it was ascertained that the toxins cause a slow wasting process in the organism, while the tubercle bacilli exercise a positive chemotactic influence upon the phagocytes. The phagocytes surround the bacilli but are unable to digest them. In order, therefore, to check the process of tuberculosis it is necessary to neutralize the toxins by means of antitoxins, or to increase the bacteriolytic power of the phagocytes.

The author made a number of experiments for the purpose of testing a method of vaccination. Objection is made to certain methods of obtaining tuberculin on the ground that these methods do not permit a differentiation of the toxins contained in the nutrient medium and those which are fixed in the bacterial bodies. It was observed during the author's experiments that certain cultures were acid while others were alkaline, and an attempt was made to increase the production of acidity. It was found that by artificially rendering cultures decidedly alkaline a tendency was developed toward a production of acid, which was conspicuously shown when the acidity was determined by titration 2 months afterwards. As a result of his experiments the author distinguishes between basitoxins and acidotoxins. For therapeutic purposes the author used a mixture of these 2 toxins in experiments on guinea pigs and man. No undoubted case of cure or immunity against tuberculosis has thus far been produced, but the resistance to the disease has been somewhat increased.

The normal temperature of cattle, J. HAJNAL (*Berlin. Tierärztl. Wchnschr., 1903, Nos. 39, pp. 601–605; 40, pp. 617–619*).—The author made an elaborate study of the normal temperature of cattle with special reference to the bearing of this question upon the results obtained from tuberculin injections. Tables are presented showing the relation of age to normal temperature and also showing the temperatures obtained after tuberculin injections and during the progress of various infectious and other diseases. The author concludes that the normal temperature for the first few days of life is about 40° C., while at ½ year of age it varies from 39 to 40°, at 9 months, between 38.8 and 39.5°, and in cattle over 1 year of age the normal temperature varies between 38 and 39° C.

Biology of the anthrax bacillus and its demonstration in the carcasses of the larger domesticated animals, J. BONGERT (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), Nos. 6, pp. 497–507; 7, pp. 623–630; 8, pp. 772–792, pls. 3; 35 (1903), Nos. 1, pp. 14–24; 2, pp. 108–201*).—In the long series of experiments reported in this article the author attempted to determine how long the anthrax bacillus could be demonstrated successfully in the carcasses of animals dead of this disease, and also to determine the most convenient and most reliable methods for identifying the organism. The literature of the subject is discussed in connection with a bibliography. The experiments carried on by the author included the direct identification of the anthrax bacillus by microscopic means, its demonstration by inoculation and by blood cultures. A study was made of the most suitable methods for preserving anthrax material and for determining the conditions under which spore formation takes place. The results of the examination of anthrax carcasses and streak blood cultures and inoculation experiments made from such material are presented in a tabular form. As a result of his studies the author concludes that the morphological demonstration of anthrax by means of streak cultures is not a thoroughly reliable method. The diagnosis of anthrax by inoculation of experimental animals sometimes fails on account of the interference of other micro-organisms. Blood cultures are considered as furnishing the best means for determining anthrax bacillus. This organism remains in a living condition for from 36 to 50 days, but only 8 to 20 days in decomposing dried blood or the fluids of different tissues. If animal material containing anthrax bacilli is kept upon impervious substrata, the bacilli are destroyed under the action of putrefying bacteria without forming spores. It was found that the anthrax bacillus can multiply and form spores in a very dilute solution of blood in distilled water.

Morphology and chemo-biology of the anthrax bacillus and the bacillus of malignant edema, R. GRASSBERGER and A. SCHATTENFROH (*Arch. Hyg., 48 (1903), No. 1, pp. 1–105, pls. 11*).—The work reported in this study included a comparison of the morphological and biological characters of the bacilli of blackleg and malignant edema. It was found that these organisms are not always easily differentiated. There are intermediate forms which are pathogenic for mice and rabbits, like the bacillus of malignant edema, while at the same time they show characters which belong to the bacillus of blackleg. Two distinct forms of blackleg bacillus were isolated, one motile without flagella and without spores, and the other with spores and flagella.

Cases of anthrax without marked elevation of temperature, G. H. GIBBINGS (*Jour. Comp. Path. and Ther., 16 (1903), No. 2, pp. 169, 170*).—Notes are given on 2 cases of anthrax in which the temperature rose only to 102 and 103° F., respectively. One case ran a fatal course and in the other recovery took place after about a week. These cases are described for the purpose of calling attention to the necessity of precaution in diagnosing anthrax.

A peculiar staining reaction of the blood of animals dead of anthrax, J. M'FADYEAN (*Jour. Comp. Path. and Ther., 16 (1903), No. 1, pp. 35–40, pl. 1*).—In examining the blood from animals dead of anthrax under a magnification of 800 to 1,000 diameters it is observed that the nuclei of the leucocytes exhibit a greenish-blue tint, while the anthrax rods are blue. The segmented character of the rods is quite apparent.

The characteristic feature of the staining reaction is found in the color of the amorphous material around the bacilli. This material exists in the form of granules of a violet or reddish-purple color. The material which thus stains violet with an aqueous solution of methylene blue is believed to be derived from the bacterial envelop. According to the author's experience this reaction is always obtained from anthrax blood, but it is not recommended that the reaction be depended upon exclusively in the diagnosis of anthrax.

Serum therapy for anthrax, A. Jürgelunas (*Ztschr. Hyg. u. Infectionskrank.*, 44 (1903), No. 2, pp. 273–280).—For the production of an immunizing serum a goat and a sheep were inoculated subcutaneously with the first anthrax vaccine and 2 weeks later with the second vaccine. The serum thus obtained was tested in experiments on guinea pigs.

The author concludes from his experiments that the serum of animals which have been rendered unsusceptible to anthrax possesses preventive properties toward this disease. The same serum was used in a series of experiments in the cure of anthrax in guinea pigs. It was found in these experiments that when guinea pigs were inoculated simultaneously with the serum and anthrax cultures, or with the cultures first, followed by the serum after 2 to 4 hours, a portion of the animals lived, while the remainder became infected and died.

The control of anthrax according to the method of Sobernheim, Burow (*Berlin. Tierärztl. Wchnschr.*, 1903, No. 35, pp. 541–545).—In 1897 Sobernheim announced that he had succeeded in immunizing sheep against experimental anthrax. This method was used by the author in vaccinating 8,000 animals, of which only 8 died from anthrax. In the author's opinion further attention must be given to determining the proper degree of attenuation for the vaccine material. The author believes that cattle are more susceptible to anthrax than other domesticated animals. The method of Sobernheim consists in the use of an anthrax serum, followed by an attenuated culture, the doses of the serum being 10 cc. for all animals, and that of the culture being from 0.3 to 0.5 cc. for calves, and 0.5 to 1 cc. for adult cattle.

The natural immunity of fowls to anthrax, O. Bail and A. Pettersson (*Centbl. Bakt. u. Par.*, 1. Abt., *Orig.*, 34 (1903), Nos. 1, pp. 102–108; 2, pp 247–259).—As a final result of the investigations of these authors for the purpose of determining the resisting power of chickens to anthrax, it is concluded that the anthrax bacilli in chickens are destroyed by means of a complement which takes its origin from the bone marrow. This substance, however, is given off quite slowly, so that a portion of the bacilli injected into fowls remains alive for considerable time. The active complement in these processes is not a new product sustaining a relation to the anthrax bacillus alone, but is associated with the corresponding immune body of fowls.

The behavior of anthrax and fowl cholera bacilli in mice during mixed infection, H. M. Gram (*Ztschr. Hyg. u. Infectionskrank.*, 42 (1903), No. 2, pp. 255–266).—The literature of this subject is critically reviewed in connection with a brief bibliography. The author made a number of experiments, during which mice were inoculated simultaneously with anthrax bacilli and fowl cholera bacilli. It was found during these experiments that the association of these bacilli in cultures or in the bodies of mice had no effect upon either pathogenic organism in the way of attenuating or otherwise modifying its action. All the mice which were inoculated with both kinds of organisms died at the same time with the control mice, which were inoculated with one organism. Likewise the association of these 2 organisms had no tendency to increase the virulence of either anthrax bacillus or the fowl cholera bacillus.

Foot-and-mouth disease in Massachusetts, A. Peters (*Jour. Comp. Med. and Vet. Arch.*, 24 (1903), Nos. 3, pp. 133–143; 4, pp. 222–233).—An outline is given of the symptoms and pathological anatomy of this disease, with notes on outbreaks which have occurred in Europe and a detailed description of the recent outbreak in New England. The measures which were adopted by the Cattle Bureau of Massachusetts and the Bureau of Animal Industry of this Department in controlling the disease are described, and notes are given on the effectiveness of quarantine measures and the various methods of eradication which were adopted.

Analogous foot-and-mouth disease, C. C. Mills (*Jour. Comp. Med. and Vet. Arch.*, 24 (1903), No. 5, pp. 292–296).—The author observed 3 or 4 outbreaks of this

disease during the past 10 years. Each outbreak extended over a considerable area and affected a number of animals. The temperature of affected cattle ranged from 103 to 105½° F. Vesicles were formed in the mouth and the animals became stiff as the result of lameness in the joints and sore feet. Nearly all cases observed by the author were among animals which fed almost exclusively upon blue-grass pastures. Recovery usually took place after a change of feed. The symptoms are remarkably similar to those of true contagious foot-and-mouth disease.

The treatment of foot-and-mouth disease by the method of Baccelli, E. Humbert (*Clin. Vet., 26 (1903), No. 28, pp. 168–170*).—The use of corrosive sublimate in the treatment of foot-and-mouth disease was tested by the author and the method employed by Baccelli was critically examined. It is believed that the method is really valuable in checking the course of the disease.

Experiments in the treatment of foot-and-mouth disease by the method of Baccelli, N. L. Buonsanti (*Clin. Vet., 26 (1903), No. 35, Sup., pp. 93*).—An elaborate study was made of the use of corrosive sublimate in the treatment of this disease and the author's final report is contained in the present article. Notes are given on the prevalence of foot-and-mouth disease, the symptoms and anatomical lesions which appear during the progress of the disease, together with a record of experiments undertaken for the purpose of showing the tolerance of cattle toward intravenous injections of corrosive sublimate and the effect of this treatment upon the course of foot-and-mouth disease. In the author's experiments it was found that cattle endured without bad effects therapeutic doses of corrosive sublimate at the rate of 0.04 to 0.05 gm. per 100 kg. live weight. In the author's opinion the efficacy of this treatment in cases of foot-and-mouth disease was demonstrated. The temperature was lowered, the course of the disease was shortened, and the development of dangerous complications was prevented in a large percentage of cases. The method is recommended as safe when applied under antiseptic precautions and as worthy of a more general application.

Texas cattle fever (*Jour. Jamaica Agr. Soc., 7 (1903), No. 12, pp. 485–490*).—The course, symptoms, and pathological lesions of this disease are described in some detail and notes are presented on the method of immunization by means of the blood of recovered animals.

The treatment of malaria in cattle, Jackschath (*Berlin. Tierärztl. Wchnschr., 1903, No. 34, pp. 530–532*).—Malaria in cattle appears to be associated with certain soil and climatic conditions which resemble the conditions of malarial districts for man. Animals which come to such regions from localities where the disease does not prevail regularly become affected. Detailed notes are given on the symptoms and course of the disease. The author recommends blood letting in the early stages, followed by injections of spirits of camphor and the administration of doses of iron sulphate in sweet milk. After pronounced symptoms of constipation have appeared, however, the author believes that prognosis is unfavorable in the majority of cases. As a preventive treatment it is recommended that in the spring cattle be given sugar of lead in doses of 0.5 gm. for a period of 8 days.

Milk fever: A new treatment, E. H. Lehnert (*Jour. Comp. Med. and Vet. Arch., 24 (1903), No. 5, pp. 307–310, fig. 1*).—The oxygen treatment was used by the author with good results. In 1 case the animal recovered completely within a period of 4 days, and decided improvement was manifested within a few hours.

Traumatic galactophoritis and mammitis with pyemic metastasis in domestic animals, Jovis (*Jour. Méd. Vét. et Zootech., 5. ser., 7 (1903), June, pp. 334–343; July, pp. 395–406, figs. 6*).—Detailed descriptions are given of the symptoms and pathological anatomy of various forms of mammitis affecting different parts of the udder and due to different causes. Clinical notes are given on 27 cases, nearly all of which were in cows. Particular attention is given to tuberculous mammitis and the symptoms by which it may be identified.

Epizootic abortion in cows and its prevention, J. PENBERTHY (*Jour. Comp. Path. and Ther., 16 (1903), No. 1, pp. 13–19*).—Attention is called to the etiology of the various forms of abortion observed in cattle, with especial reference to the epizootic form. In combating this disease the author considers it necessary to exercise a close supervision upon the formation of a herd, in order not to introduce any infected animals. Treatment of aborting cows is somewhat unsatisfactory.

Contagious abortion in cows, J. M. FONTAN (*Jour. Agricole [Paris], 14, (1903), No. 165, pp. 213–215*).—The symptoms and pathological anatomy of this disease are briefly described. In the prophylaxis of contagious abortion the author recommends the exercise of special care in introducing new animals into the herd and the thorough application of an antiseptic, such as corrosive sublimate, after the appearance of abortion.

Mammary actinomycosis in cows, J. KOWALEWSKY (*Jour. Méd. Vét. et Zootech., 5. ser., 7 (1903), Sept., pp. 513–529*).—Mammary actinomycosis occurs most frequently in pigs and rarely in cattle. A table is presented showing the relative frequency with which various organs of cattle are affected by actinomycosis. The author had occasion to examine 3 cases of mammary actinomycosis in cattle and detailed notes are given on the pathological anatomy. Notes are given to assist in differential diagnosis between actinomycosis and various forms of mammitis. In diagnosing this disease the author believes the best results are obtained from a microscopic study of the milk.

Actinomycosis, V. E. MERTENS (*Ztschr. Hyg. u. Infectionskrank., 42 (1903), No. 1, pp. 45–89, pls. 2*).—A study was made of the behavior of actinomyces on various culture media, and results thus obtained are compared with the published results of other investigators of this subject. During the author's investigations special attention was given to determining the cause of the formation of club-shaped structures in the mycelia of actinomyces. It is concluded from these investigations that the club-shaped structures are produced by the living mycelia as the result of degenerative processes which may affect whole hyphæ or only certain parts of them. A number of inoculation experiments were made in rabbits and notes are given on the course of the disease and the forms of actinomyces obtained from such cases.

Actinomycosis in dogs, L. BAHR (*Maanedsskr. Dyrlæger, 15 (1903), No. 6, pp. 172–196, figs. 4*).—Detailed notes are given on the pathological anatomy of this disease in a number of cases in dogs. The source of infection is discussed and the peculiarities of the disease as related to the organism of dogs are mentioned. Actinomycosis may appear in dogs in the form of tumors, ulcers, or chronic fistulous processes, and frequently leads to pleuritis or peritonitis. Apparently there are several species of actinomyces concerned in the production of the disease in dogs.

Six cases of carcinoma of the ox, A. M. TROTTER (*Jour. Comp. Path. and Ther., 16 (1903), No. 3, pp. 244–252, pl. 1, figs. 2*).—Detailed clinical and post-mortem notes are given on cases of carcinoma of the orbit, rumen, and lung in cattle. The forms of carcinoma described in this paper are epitheliomatous, and the form characterized by spheroidal cells.

Hypoderma bovis, T. P. KOCH (*Maanedsskr. Dyrlæger, 15 (1903), No. 5, pp. 129–159*).—The life history of this insect is described in great detail in connection with a critical review of the literature relating to the subject.

Pathological changes in the esophagus due to the larvæ of warble flies, C. O. JENSEN (*Maanedsskr. Dyrlæger, 15 (1903), No. 6, pp. 169–171*).—Certain pathological conditions are noted in the esophagus of cattle infested with warble flies. The author investigated the cause of these conditions with the result that the warble fly larvæ were found to be apparently responsible for the production of infiltration processes in the esophagus.

Serum therapy in sheep pox, A. BORREL (*Ann. Inst. Pasteur, 17 (1903), No. 11, pp. 732–762*).—A detailed description is presented of the course of sheep pox, the

method of vaccination against the disease, and the collection and preservation of the vaccine. Experiments were carried on for the purpose of testing the value of serum therapy in the treatment of the disease. The method was applied to 10,000 animals with excellent results. No death resulted in the vaccinated animals from infection with sheep pox, while only 2 per cent of the vaccinated sheep died of septicemia or other complications.

Verminous broncho-pneumonia of sheep, G. SAINT-HILAIRE (*Bul. Dir. Agr. et Com.* [*Tunis*], *8* (*1903*), *No. 29, pp. 510–516*).—Two species of roundworms are concerned in producing this disease in sheep, viz, *Strongylus filaria* and *S. rufescens*. These species are described and notes are given on the symptoms and pathological anatomy of the disease. In treating infested animals the use of creosote, essence of turpentine, or picrate of potash is recommended, combined with fumigation with some irritating gas. As an intratracheal injection the author recommends a mixture containing 1 part iodin and 5 parts iodid of potash to 50 parts of water, the whole to be mixed with equal parts of essence of turpentine.

Notes on parasites of sheep, J. H. STEWART and H. ATWOOD (*West Virginia Sta. Bul. 90, pp. 223–230, pls. 3*).—A description is given of *Strongylus contortus*, the common stomach worm of sheep, and notes are given on the life history of this parasite, the disease symptoms which it causes in infested sheep, and the means of combating the pest. A description of the benzine and coal-tar creosote treatments for this worm is quoted from this Department. The authors recommend the use of coal-tar creosote. Brief notes are also given on nodular disease of the intestines in lambs. This disease broke out in a flock of 60 lambs purchased by the Station, and in the prevention of the disease it is recommended that low wet lands be drained or pastured by cattle.

Vaccination of hogs, PLATSCHEK (*Berlin. Tierärztl. Wchnschr., 1903, No. 34, p. 533*).—This article is written in reply to a criticism made by Joseph that the use of a cord drawn through the mouth of hogs in vaccination would lead to the further spread of the disease, since infectious material would naturally be found in the mouth of diseased hogs. The author replies that all apparatus used in treating hogs is necessarily disinfected between each operation.

Immunization from hog cholera, (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 43, pp. 3*).—During immunization experiments attenuated and virulent liquid or dried blood, with or without the admixture of blood of immune animals, has been used. Animals thus treated have been tested by inoculation with virulent blood or by exposure to diseased animals. It has been found that immunity toward hog cholera does not necessarily imply immunity to swine plague, and this suggests the desirability of proving the character of the disease in all cases by careful autopsies.

Vaccination for swine erysipelas in Wurttemberg in 1902 (*Berlin. Tierärztl. Wchnschr., 1903, No. 31, pp. 481, 482*).—Out of 27,811 hogs which were vaccinated for this disease, all except 5 were vaccinated with small doses for protective purposes, while the other 5 were treated with curative doses. No loss due to vaccination occurred. The total quantity of serum used was 147,218 liters obtained from official sources and 6,460 liters from private sources.

Necrotic inflammation of the mouth in small pigs, L. J. LAURITSEN (*Maanedsskr. Dyrlæger, 15* (*1903*), *No. 4, pp. 121, 122*).—A number of cases of this disease in young pigs were observed by the author and the etiology appeared to be somewhat uncertain. The cases readily yielded to the author's treatment, which consisted in scraping the necrotic areas and applying antiseptic and astringent washes.

Trichinæ and trichina inspection in Denmark, ST. FRIIS (*Maanedsskr. Dyrlæger, 15* (*1903*), *No. 4, pp. 97–115*).—Notes are given on the system of inspection for trichina in Denmark, together with statistical data regarding the frequency of occurrence of this worm. A discussion followed the presentation of the paper, during which the desirability of compulsory inspection for trichina was urged.

The occurrence of trichina in the badger, Lübke (*Ztschr. Fleisch u. Milchhyg., 13 (1903), No. 4, pp. 116, 117, fig. 1*).—Trichina has frequently been found in badgers, and since these animals are used as human food in certain mountainous regions, a number of cases of trichinosis have developed as a result. The author calls attention to the fact that badgers frequently catch and eat mice and rats, and the infestation of the badgers with trichinæ is thus explained.

The significance of rabies lesions in the nervous system, F. J. Bosc (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 31, pp. 1284–1286*).—Notes are given on the lesions which develop during the progress of rabies in various parts of the nervous system. In general the lesions caused by rabies virus in the nervous system are almost identical in detail and as a whole with those of sheep pox.

The histological diagnosis of rabies in the dog, A. Rabieaux (*Ann. Soc. Agr. Sci. et Ind. Lyon, 7. ser., 10 (1902), pp. 61–72, figs. 3*).—The author describes the various lesions in the nervous system which have been mentioned by various authors as of importance in the diagnosis of rabies. Attention is called to the great importance of making an accurate and certain diagnosis of this disease, and it is urged that absolute dependence can not be placed on the lesions in the nervous system caused by the development of rabies. These lesions, however, are believed by the author to be almost always diagnostic and to assist greatly in rendering a certain diagnosis.

The isolation of rabies virus by filtration, P. Remlinger (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 33, pp. 1433, 1444*).—In order to obtain rabies virus free from contamination with micro-organisms of known size the author believes that the best results are to be obtained by repeated passage through filters small enough to exclude all other organisms.

The micro-organism of rabies discovered by Negri, M. Beck (*Fortschr. Vet. Hyg., 1 (1903), No. 9, pp. 253, 254*).—According to the author's experience the protozoan organism claimed by Negri to be the cause of rabies must be recognized as such. It is stated that the organism was found in 47 out of 72 cases of rabies.

The toxin of the organism of dog distemper, C. Phisalix and J. Lignières (*Compt. Rend. Soc. Biol. Paris, 55 (1903), Nos. 24, pp. 915–924; 25, pp. 980–982; 26, pp. 1021–1023; 27, pp. 1085–1089*).—This is a series of controversial articles relating to the general subject of the etiology and treatment of distemper of dogs. According to Phisalix if dogs are inoculated intravenously with very virulent cultures of *Pasteurella caviæ* or *P. canis* the first symptoms of inoculation are rapidly observed. *P. canis* is said to produce in artificial cultures a soluble toxin which acts on the nervous system and produces digestive disturbances.

In some of the experiments of Lignières the vaccine recommended by Physalix was found to have little or no effect in increasing the resistance of dogs to distemper, while a polyvalent vaccine obtained by Lignières appeared to prevent the fatal development of the disease in many instances. Phisalix claims that according to ordinary methods of treatment from 25 to 80 per cent of affected dogs die of the disease. In his experiments, however, only 18 out of 985 vaccinated dogs died of distemper. Detailed statistics are presented on this point and the conclusion is drawn by Phisalix that success was had in the use of his vaccination method in about 98 per cent of cases.

There is not a strict agreement between the 2 authors regarding the nature of the organism which is the cause of dog distemper, but it is believed to be a Pasteurella. Phisalix admits a lack of success in some experiments, but maintains that under ordinary conditions the use of his vaccine method is attended with excellent results. On the other hand Lignières maintains that, should the vaccine be as effective as claimed by Phisalix, it is necessary that it contain an antitoxin. Such, however, can not be the case from the nature of its preparation. Lignières admits that the vaccination method of Phisalix has an evident value, but is less certain in its results than claimed by Phisalix.

Acarian eczema in dogs, L. Scheben (*Berlin. Tierärztl. Wchnschr., 1903, No. 31, pp. 482, 483*).—In the treatment of this disease the author had good results from the use of a $4\frac{1}{2}$ per cent solution of nitrate of silver, which was used as a wash upon affected parts.

Necrosis and the necrosis bacillus, W. Ernst (*Monatsh. Prakt. Tier., 14 (1903), No. 5, pp. 193–228, figs. 14*).—The necrosis bacillus (*Streptothrix necrophora*) is described as being of almost ubiquitous occurrence and as producing a great variety of pathological lesions, according to the part or organ affected. Numerous experiments were made by the author in cultivating this organism, studying its morphology, and in inoculating small animals. It was found that the necrosis bacillus grows luxuriantly in nutrient media which remain moderately soft at the ordinary temperature of the laboratory incubator, and that the organism grows well also in milk and Martin bouillon. Growth takes place between temperatures 36 and 40° C., but most rapidly at 39° C. There are no flagella on the necrosis bacillus and no movement is to be observed. The organism is very pathogenic for mice and rabbits and less so for birds, rats, guinea pigs, and cats. In hogs, sheep, and cattle only local processes are developed as a rule. Feeding experiments with hogs and sheep failed to produce infection.

Angiomatosis capillaris maculosa in the liver of ruminants, Stroh (*Monatsh. Prakt. Tier., 14 (1903), No. 3–4, pp. 133–187, figs. 2*).—The pathological lesions produced by this disease are described by the author in great detail. As a result of numerous observations and experiments it is concluded that this disease is peculiar to the liver of ruminants. The pathological foci in the liver arises as a rule in consequence of the compression of the abdominal portion of the posterior vena cava. The disease occurs in the liver of cattle of all ages and also in sheep. As a rule the pathological process seems to have only a limited existence and gradually becomes checked.

The sequelæ of contagious coryza, J. J. Kofler (*Monatsh. Prakt. Tier., 14 (1903), No. 2, pp. 71–83*).—According to the author's experience contagious coryza may be complicated with a number of diseases, such as staggers, embolic pneumonia, iritis, petechial fever, etc.

The giant Trypanosoma discovered in the blood of bovines, A. Lingard (*Centbl. Bakt. u. Par., 1. Abt., Orig., 34 (1903), No. 2, pp. 234–238, pl. 1*).—Notes are given on the giant Trypanosoma discovered in the blood of cattle during an investigation of surra.

Trypanosomes, with special reference to surra, W. G. Bowers (*Jour. Comp. Med. and Vet. Arch., 24 (1903), No. 2, pp. 65–71*).—The author mentions the characteristic features of various species of pathogenic Trypanosoma and describes in considerable detail the organism of surra. This disease is believed to be transmitted in the Philippines through the agency of *Stomoxys calcitrans*. In the treatment of surra some success has been had with the administration of arsenic by intravenous method.

The reproduction and development of trypanosomata in the blood of animals affected with surra, A. Brauer (*Berlin. Tierärztl. Wchnschr., 1903, No. 40, pp. 613–616, figs. 7*).—According to the author's investigations trypanosomata of surra form spores in blood in which the parasites are present in large numbers. The author observed a union of the trypanosomata by their blunt ends. At certain stages the blood organisms assume forms and actions which greatly resemble those of bacteria. Division processes are observed in spores associated in large colonies. As soon as the blood parasites reach a diameter of $\frac{1}{3}$ to $\frac{1}{2}$ that of the red blood corpuscle they manifest amœboid movements and attack the red blood corpuscles, causing lesions which are easily demonstrated.

A new Trypanosoma and the disease caused by it, A. Theiler (*Jour. Comp. Path. and Ther., 16 (1903), No. 3, pp. 193–216, pl. 1, fig. 1*).—In studying a disease of cattle in South Africa which was believed to be identical with what has previously

been called biliary fever or gall sickness, the author discovered an organism which has been given the name *Trypanosoma theileri*. This organism can be quickly demonstrated by examining fresh blood of affected animals. Two forms of the parasite are observed, in one of which the centrosome lies at the posterior end, while in the other it is in the nucleus. Notes are given on the methods of reproduction of this organism, on involution forms, and agglutination. The phenomenon of agglutination is rarely observed in the case of *T. theileri*. Inoculation experiments were made on horses, dogs, sheep, goats, rabbits, guinea pigs, rats, and mice. All these experiments gave negative results, and it is therefore concluded that the organism affects only cattle. *T. theileri* was found in species of Hippobosca, which were later identified as *H. rufipes* and *H. maculata*. These flies are believed to be the natural means of transmitting the disease. Detailed notes are given on the symptoms and pathological anatomy of this disease. In the author's experience about 58 per cent of cattle were susceptible. Susceptibility was observed in cattle of all ages; the rate of mortality was 12.5 per cent, period of incubation from 4 to 6 days. Many cattle are naturally immune, and this is attributed to previous infection with the blood parasite.

The existence of a piroplasmosis in horses in Madagascar, THIROUX (*Compt. Rend. Soc. Biol. Paris, 55 (1903), No. 29, pp. 1188, 1189*).—*Piroplasma equi* is briefly described, and notes are given on its distribution with special reference to its occurrence in horses in Madagascar.

The development of the parasite of the tsetse-fly disease in mammals, E. MARTINI (*Ztschr. Hyg. u. Infectionskrank., 42 (1903), No. 2, pp. 341–350, pl. 1, figs. 10*).—The author made a study of the various forms in which this organism occurs in mammals, especially in dogs. The morphology of these forms is described in detail. It was found that the organisms were present in considerable numbers in specimens of *Stomoxys calcitrans* which had been allowed to suck the blood of infected mammals. The Trypanosoma was found in the alimentary tract of these flies for a period of 23 hours. No division stages were observed in the blood parasite, however, and the parasites appeared ultimately to be digested in the alimentary tract of the flies. Experiments instituted for the purpose of testing the possibility of transmission of the disease by such infected flies which were allowed to suck the blood of dogs gave negative results in all cases.

Hemoglobinemia in horses, C. ROCHE (*Jour. Méd. Vét. et Zootech., 5. ser., 7 (1903), July, pp. 414–416*).—In the author's experience this disease is comparatively rare. During the month of June, however, of the past year 25 cases were observed, and notes are given on the symptoms, etiology, and treatment. The author believes that the numerous sudden changes of temperature which occurred were partly responsible for the unusual prevalence of this disease. Nearly all cases responded favorably to hydrotherapy.

Equine malaria and its sequelæ, A. THEILER (*Jour. Comp. Path. and Ther., 16 (1903), No. 2, pp. 97–120*).—Malaria of horses in South Africa is said to be due to infection with *Pyroplasma equi*. Notes are given on the appearance of this organism and on inoculation experiments to determine the causal relation of the organism to the disease. Apparently 1 attack of equine malaria confers a certain amount of immunity, but experimental evidence of this proposition was not obtained by the author. The sequelæ of the disease are frequently of a serious character. The author concludes from his study that while *P. equi* is the primary cause of equine malaria, this organism predisposes to a symbiotic and secondary infection with a specific bacillus. The secondary infection may take place after complete recovery from the primary malaria.

South African horse sickness, E. C. WEBB (*Jour. Comp. Path. and Ther., 16 (1903), No. 2, pp. 120–127*).—The pathological anatomy of this disease is described on the basis of 48 post-mortem examinations. The symptoms and lesions are presented in tabular form according to the peculiar features of the different cases. As a

rule treatment is without result. The use of antiseptics as drenches or by subcutaneous and intratracheal injections has proved somewhat effective in certain cases.

Infectious cerebro-spinal meningitis in horses, H. STREIT (*Berlin. Tierärztl. Wchnschr., 1903, No. 37, pp. 577–584*).—The author discusses the literature of this subject in connection with a brief bibliography. The symptoms of the disease are described in a number of cases which the author observed. A bacteriological examination showed no micro-organisms in the spleen or blood of certain cases, while a few diplococci were found in 1 case. Diplococci were isolated from the fluid in the subarachnoid space. These organisms were cultivated and used in inoculation experiments on rabbits. In these experiments rabbits died within from 36 to 48 hours when inoculated with 1 cc. of the exudate obtained from the subarachnoid space.

Notes are given on the morphology of the micro-organism and on its behavior on various culture media. The organism is pathogenic for rabbits, guinea pigs, and white mice, but not for chickens or doves. It is destroyed by subjection to a temperature of 60° C. for 10 minutes, by treatment for 10 seconds in a 1 per cent solution of corrosive sublimate, or for 3 seconds in a 2½ per cent solution of creolin.

Primary infectious osteomyelitis in horses, FRÖHNER and KÄRNBACH (*Monatsh. Prakt. Tier., 14 (1903), No. 10, pp. 433–444, figs. 6*).—Detailed notes are given on the symptoms and pathological anatomy of this disease in 2 cases. The coffin bone and cannon bone were affected most seriously by the disease. On account of the infectious nature of the disease and the practical impossibility of curing it the author recommends that diseased animals should be killed. In very valuable horses it is believed that the foci of the disease in the affected bones may be removed with success in a considerable percentage of cases.

Glanders, F. K. KLEINE (*Ztschr. Hyg. u. Infectionskrank., 44 (1903), No. 2, pp. 183–195*).—The experiments recorded in this paper were carried out partly for the purpose of testing the correctness of the general belief that glanders bacillus gradually loses its virulence when cultivated for long periods on nutrient media. The cultures which were used by the author had been kept in the laboratory for a period of several years. It was found that these cultures produced infection in guinea pigs when inoculated into the abdominal cavity in very minute doses.

The conclusion is reached that the common belief that glanders bacilli lose their virulence in artificial cultures is based on mixed cultures, and that agglutination tests should be made to distinguish between the glanders bacilli and other associated organisms. Such tests were made by the author with the result that a number of organisms were found in glanders cultures which had nothing to do with the glanders bacillus.

Detailed notes are given on the methods for obtaining specific sera which agglutinate the glanders bacillus. During the author's experiments little success was had in immunizing guinea pigs against the true glanders bacillus. The author ascribes the apparent success of other investigators along this line to the use of mixed cultures.

Glanders among the street-car horses of Cologne, LOTHES (*Fortschr. Vet. Hyg., 1 (1903), Nos. 7, pp. 209–212; 8, pp. 237–240; 9, pp. 257–263*).—On account of the losses suffered from glanders by the street-car companies of Cologne an investigation was undertaken for the purpose of devising practical means of checking the outbreaks of this disease. A number of post-mortem examinations were made and the pathological lesions are described in detail.

Notes are also presented on the various forms which the disease assumes and on the conditions surrounding different outbreaks of glanders. Mallein injections were used on an extended scale with good results. In one instance 105 horses were injected and 14 reacted. Of these, 12 were found to exhibit pathological lesions upon post-mortem examination. The losses suffered from the destruction of glanderous horses were small as compared with the losses necessitated by the continued prevalence of the disease.

Agglutination and serum diagnosis as applied to glanders, A. RABIEAUX (*Ann. Soc. Agr. Sci. et Ind. Lyon, 7. ser., 10 (1902), pp. 45–59*).—A series of experiments was conducted by the author for the purpose of testing the applicability of the agglutination method in the diagnosis of glanders.

The author states as the result of his investigations that this is essentially a laboratory method and consequently can not replace experimental methods customarily employed under other practical conditions. Nevertheless, the method is considered as valuable and as furnishing a means of testing the reliability of other methods in the diagnosis of glanders. If the serum which is to be examined is not pure, the author claims that it is necessary to subject the mixture of serum and the glanders culture to a temperature sufficient to sterilize the serum in order to avoid the multiplication of organisms other than the glanders bacillus.

Therapeutic observations on morbus maculosus, PERL (*Berlin. Tierärztl. Wchnschr., 1903, No. 41, pp. 638, 639*).—Morbus maculosus treated with Collargol was not so readily controlled as when Ichthargan was administered. While Collargol caused a lowering of the temperature its other effects were unsatisfactory. Ichthargan, however, caused a diminution of temperature and return of the normal appetite. Potassium iodid exercised a pronounced effect in the resorption of the swellings which occurred in the progress of this disease.

The serum treatment in purpura hemorrhagica, J. H. MCLEOD (*Jour. Comp. Med. and Vet. Arch., 24 (1903), No. 3, pp. 166, 167*).—Brief notes are given on the treatment of a few cases of this disease in horses. Tonics and stimulants were administered and the animals were also treated with antistreptococcus serum in large doses. Satisfactory results were obtained from this treatment.

Botryomycosis, FRÖHNER (*Monatsh. Prakt. Tier., 14 (1903), No. 10, pp. 468–472*).—Notes are given on the occurrence of this disease in a number of cases. In one the location of the disease was near the base of the tail, while in another case the withers were affected in a manner similar to fistula. The disease was also observed in a few cases in the region of the fetlock.

Generalized botryomycosis, F. TÜRNAU (*Ztschr. Fleisch u. Milchhyg., 13 (1903), No. 10, pp. 317–319*).—The symptoms and lesions of this disease are described. In 1 case the bronchial glands and kidneys were not affected, while the surface of the lungs was covered with yellowish tubercles in large numbers. Similar tubercles were found in the liver tissue. In general the lesions in the lungs and liver closely resemble those in cases of tuberculosis.

Animal parasites, A. A. BROWN (*Jour. Dept. Agr. Victoria, 2 (1903), Nos. 1, pp. 72–74; 2, pp. 174–176*).—Brief notes on the anatomical characters of parasitic roundworms, with special accounts of lungworms in sheep and gapeworms in fowls.

Diseases of fowls, J. BARCLAY (*Imp. Dept. Agr. West Indies, Pamphlet No. 23, 1903, pp. 30–48*).—A brief account of enteric fever, roup, bronchitis, gapes, cramps, and other common diseases of fowls.

Investigation of fowl plague, the new poultry disease, R. OSTERTAG and K. WOLFFHÜGEL (*Monatsh. Prakt. Tier., 14 (1903), No. 2, pp. 49–70, figs. 2*).—The disease investigated by the authors occurred in a number of extensive outbreaks in Brunswick and elsewhere and caused great loss among fowls. Inoculation experiments showed that it is easy to transmit the disease from one hen to another, but pigeons, mice, guinea pigs, and rabbits, and even ducks and swans, were apparently resistant. The symptoms and post-mortem appearances of this disease are described in great detail. No success was had in isolating the pathogenic micro-organism, but it was found that the virus was destroyed by subjection to a temperature of 70° C. As a rule the disease results in death within from 2 to 4 days. Notes are given on the differential diagnosis of these and related poultry diseases.

An epizootic of exudative typhoid in fowls, A. MAGGIORA and G. L. VALENTI (*Ztschr. Hyg. u. Infectionskrank., 42 (1903), No. 2, pp. 185–243*).—Notes are given on

the symptoms of a disease which occurred in a number of flocks of poultry in the Province of Modena. The disease assumed various forms, such as the typhoid form, the nervous form, and the diphtheritic form. The comb and other bare portions of the head assumed a violet or blackish color; inflammatory alterations were manifest in the pleura and peritoneum, and pathological changes were observed in the larynx, pharynx, and various other organs. Several attempts were made to obtain cultures of the pathogenic organism from the blood, bone, marrow, and various organs. Although a variety of culture media was used, the results were always negative, except in cases where material was taken from fowls which had been dead for a few hours. In such cases an organism was obtained from the intestinal contents, peritoneal exudate, and from the pharynx, which appeared to be a coccobacterium, and occurred almost in pure cultures, especially in the duodenum. Inoculation experiments were made with this organism in fowls, rabbits, pigeons, and guinea pigs. An infection was produced in fowls which ran a course identical with that of spontaneous infection. It was found that the organism remained in a virulent condition in the bodies of dead fowls for a period of 45 days. The authors conclude that this disease is a form of hemorrhagic septicemia caused in part by an organism in the alimentary tract belonging to the coli group. It could not be concluded as certain from the experiments of the authors that this organism is the only cause of the disease. The virus is pathogenic for fowls and several species of birds, but is without effect upon ducks, pigeons, rabbits, guinea pigs, or white mice. It is believed that this disease is distinct from that described by Centanni as occurring in the Province of Ferrara.

Notes from practice, A. Fumagalli (*Clin. Vet., 26 (1903), No. 35, pp. 208, 209*).—Brief notes are given on actinomycosis in dogs and on enzootic meningo-encephalitis in chickens. The latter disease affected a flock of 100 fowls which came under the author's observation. The symptoms were dejection, hyperemia, and diarrhea during the later stages. The rate of mortality was very high. The cause of the disease is not understood, but the possibility of its being a form of fowl cholera is suggested.

Concerning Gurmin, Jelkmann (*Berlin. Tierärztl. Wchnschr., 1903, No. 41, pp. 637, 638*).—Gurmin is the name of a serum preparation manufactured for the treatment of contagious coryza and other infectious diseases. The author used this remedy in the treatment of 10 cases of contagious coryza in horses. It was found that Gurmin exercises a specific bactericidal action toward the organisms of this disease. The serum appears also to exercise a slight preventive action when injected into healthy horses. Good results were obtained in 10 cases and the author believes that the drug may be depended upon to exercise curative effects wherever the disease is merely a streptococcal infection and does not involve suppuration of the lymphatic glands.

Further notes on silver therapy, H. Meyer (*Berlin. Tierärztl. Wchnschr., 1903, No. 35, p. 545*).—Notes are given on the use of various silver preparations, such as Protargol, Collargol, and Ichthargan. The author believes that these remedies, especially the latter, are very valuable in the treatment of infectious diseases, where it is desired to attenuate or destroy the pathogenic bacilli in the animal body. Further experiments are required before it will be definitely known how dogs react to intravenous injections of silver preparations and how valuable these preparations may be in the cure of distemper.

The sale of animals affected with contagious diseases, V. Galtier (*Ann. Soc. Agr. Sci. et Ind. Lyon, 7. ser., 10 (1902), pp. 1–44*).—An elaborate discussion is given of the dangers attending the sale and consumption of the meat of diseased animals, together with mention of the measures which are necessary for regulating these problems.

Laws (Federal, State, and Territorial) relating to contagious and infectious diseases of animals (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 54, pp. 46*).—This bulletin is of the nature of a continuation of Bulletin 43 of the Bureau of Animal Industry, and contains copies of Federal, State, and Territorial laws relating to contagious and infectious diseases of animals enacted during the years 1902 and 1903.

TECHNOLOGY.

Report on the results of investigations into cider making, F. J. Lloyd (*London: Bd. Agr. and Fisheries, 1903, pp. 145, figs. 17*).—A report is here given of investigations made by the author under the auspices of the Bath and West and Southern Counties Society of England for the 10 years ended 1902 on problems in cider making in England. Some methods of detecting cider preservatives are given and tables showing the composition of the juice of various apples from different localities and in different years. The composition of apple juice has been found to vary with the season, the locality from which it was obtained, the variety, size of the apple, etc.

The amount of juice in an apple apparently does not depend upon size, as sometimes small apples gave a large and at other times a small proportion of juice. Generally, however, the specific gravity of the juice appears to increase as the size of the apple decreases. Tables of analyses are given, which show that dessert varieties of apples contain, as a rule, far more acid than the cider varieties. It is believed that this accounts for the difficulty experienced in making good cider from table fruit. Practically no difference was found in the analyses of frosted apples and apples of the same variety which had not been frosted. No reason could therefore be assigned why frosted apples are less suitable for cider making, as some believe, than unfrozen apples.

Apples for cider should be gathered by hand or shaken off on a cloth or large net spread under the tree. In one experiment cider made from apples which had been stored on the ground had a strong earthy flavor. Decay sets in rapidly in apples which are bruised. Analyses of the juice of apples which had been kept in a clean place but allowed to rot, showed the following composition: Acid 0.18, sugar 12.19, tannin 0.168, and solids 13.42 per cent. Juice from sound apples of the same varieties contained 0.23 per cent acid, 12.5 per cent sugar, 0.54 per cent tannin, and 13.7 per cent solids. These figures indicated that in rotting two distinct changes take place. The tannin is precipitated in large part and so does not enter the juice, and the acid is slightly diminished. There is also a loss of sugar. The apples used in this experiment were affected with "brown" rot.

The juice from the rotten apples was of a much darker color than that from the sound apples, and cleared much more rapidly when preserved in bottles. These experiments are believed to clearly show that the effects produced by allowing the apples to fall and rot on the ground are detrimental to the manufacture of good cider. This is especially true if the apples are exposed to rain. The author's experiments show that apples for cider should be picked when they have attained maximum size, but before they have commenced to ripen. They should then be stored in a dry, well ventilated room. The best cider is made in cool weather, therefore cider making should be delayed as long in the fall as possible.

It is recommended that apples be washed when they are dirty. The specific gravity of the juice of unwashed apples in one experiment was found to be 1.057, and of washed apples 1.056, thus showing the loss of solid matter in the juice due to washing to be scarcely perceptible. As regards fermentation, this proceeded more regularly and only slightly less rapidly in the juice from the washed apples than in that from the unwashed apples. The flavor of the cider made from the washed apples was considered superior to that of the unwashed fruit.

In a mill called a "scratcher" more juice was obtained than when the apples were run through a crusher, the figures being 720 lbs. of juice in 1,000 lbs. of apples run through the scratcher as compared with 650 lbs. from the same quantity of apples run through a crusher. In the scratcher the fruit was torn to pieces instead of being crushed. When a mill was used which crushed the pips a cider was produced the quality of which was inferior to that obtained when the pips were not crushed. The composition of apple pips dried at 212° F. was found to be as follows: Oil 18.60, albuminoids 33.12, carbohydrates 26.08, woody fiber 18.55, and mineral matter 3.65 per cent. In pressing out the juice from the pomace a clearer juice has been obtained when the pomace was wrapped in cloth than when straw was used, and thin cloth has been found as effective for this purpose as thick Manila cloth. By using cloths as good results are obtained in one pressing as in 2 or 3 pressings when straw is used.

In investigating the question as to whether the pomace should be pressed at once or allowed to stand some time before pressure, the results showed that no greater quantity of juice could be obtained from pomace which had been allowed to stand after grinding than from pomace which was pressed at once. By allowing the pomace to stand 24 hours before being pressed some of the tannin appeared to be precipitated and the juice was not as clear and bright as when the pomace was pressed at once.

Analyses of pressed pomace showed about 72.4 per cent water, 18.34 per cent sugar, 1.08 per cent oil, 1.27 per cent nitrogenous matter, 4.64 per cent woody fiber, and 2.27 per cent mineral matter. After the juice has been obtained it has been found desirable to keep it from the air as much as possible. For this purpose it is put into funnel-shaped vats, called keeves. When covered over so that drafts of air can not penetrate, a layer of carbonic-acid gas soon accumulates over the liquid and protects it from the air. The opinion that when the juice ferments a portion of the solid matter which is in suspension passes into solution has been found by the author to be erroneous. Fermentation does not take place to any extent until the temperature of the juice reaches 50 to 52° F. After fermentation begins it is usual for a thick brown head to form upon the juice. Sometimes, however, an abundant white frothy head, similar to that seen in beer vats, is formed. It has been held that when the head was of a white frothy nature the cider made from it would not keep well. This opinion also has been found by the author to be erroneous, although no reason could be assigned as to why the head is sometimes white and sometimes brown. A white head, however, indicates a more rapid fermentation than a brown head and a tendency for the cider to become acid. For this reason it must be racked oftener than cider which throws up a brown head. When the cider throws up a white head it is necessary to keep the temperature of the room low. In racking from the keeve into barrels it has been found desirable to filter the cider. The author has found the Invicta filter one of the best for this purpose.

After the cider has been racked from the keeve into barrels the question arises as to whether the barrel should be bunged down or not. In one experiment the specific gravity of the juice when barreled was 1.052, acid content 0.7, alcohol 0.0, sugar 10.8, and total solids 12.82 per cent. It was then bunged down tightly in the barrel. After 2 months the specific gravity was 1.010, acid 0.85, alcohol 4.55, sugar 1.87, and total solids 3.8 per cent; showing that fermentation had taken place in the tightly bunged barrel as rapidly as in a barrel of like juice which had not been bunged down. It was found that the pressure in the bunged barrel was about 2 lbs. per square inch, and that consequently the gas which had accumulated in fermentation must have escaped through the staves in the top of the barrel. From this and other experiments it is concluded that the juice should not be bunged down when racked from the keeve, but provision made for the escape of the gas in such manner that air can not be admitted to the barrel. As fermentation proceeds in the barrel lees are

formed. A better quality of cider was produced when the fermented juice was racked off from the lees before final storage instead of bunging down with the lees left in the barrel. Experiments in clearing the cider by sulphuring, and the use of such materials as blood, milk albumin, and other materials showed no advantages in their use and invariably cider which had not been clarified with finings proved superior in quality to cider which had been so clarified. Racking, however, was found very desirable. The time to rack was found dependent upon the kind of fermentation and not upon the amount of fermentation. In the author's opinion it should be racked and finally bunged down when the juice contains about 3 per cent of sugar. A table has been prepared by the author showing the percentage of sugar and alcohol in fermenting juice, when the specific gravity of the original juice is known. A cider made by blending 2 or 3 different kinds of apples has been found most desirable. The blended juice should be racked once before filtration. "Never blend after filtration." By blending a standard quality of cider may be obtained, which is impossible without blending. In storing cider it has been found best to lay the barrels down on the side. Air is less likely to be admitted in this position than when the barrel is stood on end, and hence the cider is less likely to become acid. When cider is bottled the best results have been obtained when bottled immediately after it has been blended, racked, and filtered. Bottling direct from the filter has produced a cider of far better quality than bottling from a cask 2 months later. Bottling cider which contains over 4 per cent of sugar has been found to be dangerous, as subsequent fermentation is sufficient to break most of the bottles. As a rule, the specific gravity of cider which is bottled must not be higher than 1.025, and must not contain less than 4 per cent of alcohol. When these conditions are satisfied the gravity must next be regulated according to the desire to make sweet, medium, or dry cider. For a dry cider the liquid when bottled should contain only about 2 per cent of sugar, which corresponds nearly always to a specific gravity of 1.010.

A number of experiments were made in the production of "small cider." Small cider is made by adding water to the cheese obtained in the first pressing and repressing. The amount of water which it is desirable to add to the pressed pomace was found to be about one-half of the amount of juice originally obtained from the pomace. No special advantage was found from regrinding the pomace, but the results indicated that the pomace ought to soak for at least 24 hours. As to whether hot or cold water should be used, the results seem to show that from a chemical standpoint the hot extraction is the better when it can be carried out in cold weather, but in warm seasons cold water is better because fermentation can be more readily controlled. The extraction thus obtained is deficient in both sugar and tannin. To remedy these defects it has been found desirable to add about 5 per cent of pure cane sugar and about ½ lb. of tannin to each 1,000 lbs. of juice. Pure cane sugar has been found better for this purpose than either "saccharum" or "sugar candy." Relative to the addition of tannin, it is stated that when this is added to juice obtained by the cold process of extraction the tannin acts as a precipitating agent and does not remain in the juice. With the hot-made small cider it does not cause precipitation and remains in solution. In case of the cold-made juice, therefore, the tannin must be added after clarification.

When proper control was exercised in the matter of fermentation it was found that as good cider could be obtained from the early fallen fruit as from late fruit.

Many preservatives have been tried in making cider, such as mustard, formic aldehyde, boracic acid, sodium salicylate, pasteurizing, and various patent preservatives. With all of these except formic aldehyde, whether the cider was preserved in bottles or barrels, fermentation continued nearly as rapidly as when no preservatives were added; and in no case was as good cider made as when preservatives were omitted entirely. While the formic aldehyde prevented fermentation, it caused the cider to become opaque and like very dirty milk.

After the primary alcoholic fermentation is completed, a slow secondary fermentation sets in, during which the beverage mellows and improves in quality. One of the results of this secondary fermentation was found to be a decrease in the acidity of the cider.

The effect of various yeasts on the production of cider was studied. Yeasts obtained from black grapes, white grapes, Kingston-Black apples, Gin apples, and cider yeasts from foreign sources, respectively, were used to inoculate cider. In every instance a different quality of cider was produced. The best quality of cider was obtained by blending the natural juices which had been fermented without the addition of selected yeasts, strict attention being given to cleanliness. It is believed, however, that in order to make cider of the best quality it will be necessary to secure pure yeast cultures from the apples which grow in the neighborhood. In the use of pure yeasts it was found that the juice fermented more slowly, kept clearer, and the sugar could be retained longer in it than when the juice was allowed to ferment naturally.

Experiments with oily cider tended to show that the organism causing the disease belonged to the anærobic order. Thorough aerating of the cider tended to improve its quality. Much of the "sick" cider which the author examined was found to contain sulphuretted hydrogen, which developed as a result of sulphuring the barrels. The flavor of cider was found to be greatly influenced by the quantity of nonfermentable constituents present. When undiluted apple juice was fermented in comparison with the same juice diluted with one-half its own volume of water and sufficient sugar then added to make the liquid contain the same amount as the whole juice, the resulting cider from the diluted juice had a much better flavor than that from the whole juice. Flavor is also influenced by the nature of the fermentation, as was shown when yeasts of different origin were employed in fermentation. Bacteria rather than yeasts appeared to be the main cause of those changes generally designated as secondary fermentation or ripening of cider. It is believed, as the result of 10 years' work, that the secret of success in cider making, as in dairying, is cleanliness.

Making unfermented wine (*Agr. Gaz. New South Wales, 14 (1903), No. 3, p. 256*).—Practical directions for preparing unfermented grape juice.

Alcoholic fermentation in the presence of sulphurous acid, A. LEBEDEV (*Selsk. Khoz. i Lyesov., 208 (1903), Jan., pp. 194–200*).—The author reports experiments in which satisfactory fermentation was obtained in wine must containing 1 gm. of sulphurous acid (SO_2) per liter.—P. FIREMAN.

The technology of sugar, J. G. MCINTOSH (*London: Scott, Greenwood & Co.; New York: D. Van Nostrand Co., 1903, pp. XIV + 408, figs. 83*).—Different sections of this book deal with classification of sugars, beet sugar, cane sugar, sugar refining, and selection of sugars.

Manual guide for the manufacture of sugar, R. TEYSSIER (*Manual guide de la fabrication du sucre. Paris: C. Naud, 1904, pp. 425, figs. 129*).—This book is said to be intended for the use of sugar makers, directors, and chemists of sugar factories, etc., and more especially for managers and overseers.

Decorticating ramie (*Indian Agr., 28 (1903), No. 7, p. 217*).—A patented method based upon the use of more or less concentrated sea water or a solution having the approximate composition of sea water for freeing the fiber from gummy substances is briefly described.

A short text-book of chemical technology, G. SCHULTZ and J. HOFER (*Kurzes Lehrbuch der chemischen Technologie. Stuttgart: Ferdinand Enke, 1903, pp. 364, figs. 151*).—The subjects treated in this book are fuels and the generation of heat; water; sulphur and sulphur compounds; alkali salts; hydrochloric and nitric acids; inflamables and explosives; commercial fertilizers; cement, mortar, and artificial stone; glass and waterglass; pottery and porcelain; metallurgy; fats and oils; soaps, waxes,

etherial oils; caoutchouc and gutta-percha: dry distillation: coloring matters: sugar making; wine making; beer brewing; distillation of spirits; and leather.

Agricultural technology, including sugar making, milling, baking, and starch and glucose making, E. SAILLARD (*Technologie agricole, sucrerie, meunerie, boulangerie, féculerie, amidonnerie, glucoserie. Paris: J. B. Baillière & Sons, 1903, pp. 423, figs. 163; rev. in Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 43, pp. 502, 503*).—This volume, which is one of the series entitled *Encyclopédie agricole*, describes in detail some of the industries dependent upon agriculture. The introduction is by P. Regnard.

AGRICULTURAL ENGINEERING.

Irrigation, W. J. ALLEN (*Agr. Gaz. New South Wales, 14 (1903), No. 12, pp. 1143–1148, figs. 3*).—A brief general discussion of the value of irrigation as an insurance against drought, and an account of results obtained by irrigation with artesian water at Pera Bore, near Bourke, New South Wales.

Desert irrigation in the far West, L. R. FREEMAN (*Amer. Mo. Rev. of Reviews, 29 (1904), No. 3, pp. 305–311, figs. 10*).—A popular account of irrigation in southern California, mainly in the region of Imperial.

Irrigation and drainage, E. RISLER and G. WERY (*Irrigations et drainage. Paris: J. B. Baillière & Sons, 1904, pp. 516, figs. 126*).—This is one of the volumes of *Encyclopédie agricole* published under the direction of G. Wery. It discusses the interrelations of water, soil, and plant; the occurrence of water in different geological formations; the use of water in agriculture; and protection against water (drainage).

Proceedings of the Iowa State Drainage Convention (*Proc. Iowa State Drainage Conv. 1904, pp. 48, fig. 1*).—Proceedings of the convention held at Iowa State College January 15 and 16, 1904. While general drainage questions were discussed to some extent, attention was mainly given to the subject of drainage laws, and a committee was appointed to draft a law for Iowa and to urge its passage.

Drainage of farm lands, C. G. ELLIOTT (*U. S. Dept. Agr., Farmers' Bul. 187, pp. 40, figs. 19*).—A revised edition of Farmers' Bulletin 40, Farm Drainage, issued in 1896 (E. S. R., 8, p. 351).

Laws relating to construction of drains, with an appendix of blank forms (*Lansing, Mich.: Secretary of State, 1903, pp. 144*).—A compilation.

A system of waterworks for the farm, C. GRAY (*Iowa Agr., 4 (1904), No. 5, pp. 196–200, figs. 2*).—The air-pressure system is described.

The disposal of sewage from private residences, A. MARSTON (*Iowa Agr., 4 (1904), No. 5, pp. 204, 205, fig. 1*).—A simple system using a series of underground septic tanks made of barrels is described.

Hydrometry, a practical guide to water measurements, W. MÜLLER (*Hydrometrie, praktische Anleitung zur Wassermessung. Hannover: Jänecke Bros., 1903, pp. VI+150, pls. 3, figs. 81*).—Discusses the newer methods, apparatus, and experiments.

Second annual report of the State Board of Public Roads of the State of Rhode Island, 1903 (*Providence, R. I.: State Bd. Pub. Roads, 1904, pp. 35, pls. 29*).—This is a summary of the operations of this Board during the year 1903 under provision of the act of 1902 establishing a State highway system in Rhode Island and appropriating $100,000 for the construction, maintenance, and improvement of the highways of the State. Various sections of highways completed or in course of construction in Providence, Newport, Kent, Washington, and Bristol counties are described and illustrated. For the year 1904 the Board recommends an appropriation of at least $125,000.

A government cement-making plant (*Engineer. News, 51 (1904), No. 8, pp. 177, 178*).—A discussion of the proposed plant in connection with the construction of the reservoir dam in Salt River Valley.

Grain pressures in deep bins, J. A. JAMIESON (*Engineer. News, 51 (1904), No. 10, pp. 236–243, figs. 9*).—The detailed results of tests on full-sized bins of a railway elevator and on model bins are reported and discussed. A method of calculation of the pressure is explained which gives results closely agreeing with those obtained in actual tests.

A sanitarium for wheat, A. INKERSLEY (*Amer. Inventor, 12 (1904), No. 6, pp. 123–125, figs. 6*).—This is an account of an elevator on the northwestern end of Lake Superior near Port Arthur, Ontario, which is designed "for treating diseased and wet wheat in whatever manner its condition demands." It is provided with coils and fans for heating and drying the wheat and for removing smutty and other diseased grains.

The electric plow, F. BRUTSCHKE (*Deut. Landw. Presse, 31 (1904), No. 13, pp. 99, 100, fig. 1*).—A brief note on the recent progress in construction and use of the electric plow.

A fiber machine, G. CARLE (*Bul. Agr. Algérie et Tunisie, 10 (1904), No. 1, pp. 5–7*).—A short account of tests of the Boeken fiber machine on a variety of plants.

A beet header and harvester, PYRO (*Ing. Agr. Gembloux, 14 (1904), No. 7, pp. 287–303, figs. 6*).—A machine for removing the tops of beets while they are still in the ground, and another for harvesting the topped roots, are described.

Agricultural machinery in the United States and the wages of labor, F. BRUTSCHKE (*Die landwirtschaftlichen Maschinen in den Vereinigten Staaten von Amerika und der Arbeiterersatz. Berlin: Deut. Landw. Gesell., 1904, pp. 79, figs. 62*).—This is an account of a tour of inspection through the United States, and deals with general agricultural conditions as well as the special forms of farm machinery used in different parts of the country.

MISCELLANEOUS.

Fourteenth Annual Report of Arizona Station, 1903 (*Arizona Sta. Rpt. 1903, pp. 315–350*).—This includes the organization list of the station; a financial statement for the fiscal year ended June 30, 1903; and reports of the director and heads of departments, containing a general review of the work of the station, and more detailed reports upon special lines of work which are noted elsewhere in this issue.

Fifteenth Annual Report of Connecticut Storrs Station, 1903 (*Connecticut Storrs Sta. Rpt. 1903, pp. 202*).—This includes the organization list of the station; a list of station publications available for distribution; financial statements for the fiscal years ended June 30, 1902 and 1903; reports of the director for the two years; departmental reports; and miscellaneous articles abstracted elsewhere.

Annual Report of Florida Station, 1902 (*Florida Sta. Rpt. 1902, pp. 29*).—This includes the organization list of the station; a report of the director; a financial statement for the fiscal years ended June 30, 1901 and 1902; a subject list of the bulletins of the station; and reports of the agriculturist, chemist, entomologist, botanist and horticulturist, and the veterinarian, covering in a general way the different lines of station work during the year. The report of the agriculturist contains also the results of a feeding experiment with steers (see p. 893); and the report of the chemist, an analysis of the edible portion of the avocado or alligator pear, which is as follows: Water 72.77, protein 2.18, fat 17.26, crude fiber 1.87, nitrogen-free extract 4.47, and ash 1.45 per cent.

Sixteenth Annual Report of Georgia Station, 1903 (*Georgia Sta. Rpt. 1903, pp. 12*).—This includes the organization list of the station; a statement by the president of the board of directors; a general review of station work during the year, by the director; and a financial statement for the fiscal year ended June 30, 1903.

Sixteenth Annual Report of Indiana Station, 1903 (*Indiana Sta. Rpt. 1903, pp. 34*).—This includes the organization list of the station; reports of the director and

heads of departments; lists of exchanges and station publications, and a financial statement for the fiscal year ended June 30, 1903.

Twelfth Annual Report of Kentucky Station, 1899 (*Kentucky Sta. Rpt. 1899, pp. XL*).—This includes the organization list of the station; a financial statement for the fiscal year ended June 30, 1899; and reports of the director and heads of departments, parts of which are noted elsewhere. Appended to the report proper are reprints of Bulletins 80–85 of the station on the following subjects: Some pests likely to be disseminated from nurseries, and the nursery inspection law (E. S. R., 11, p. 169); a method of avoiding lettuce rot (E. S. R., 11, p. 261); potato scab experiments made in 1898 (E. S. R., 11, p. 260); commercial fertilizers (E. S. R., 11, p. 627); wheat (E. S. R., 11, p. 731); the elms and their diseases (E. S. R., 12, p. 157); and commercial fertilizers (E. S. R., 12, p. 130).

Sixteenth Annual Report of New York Cornell Station, 1903 (*New York Cornell Sta. Rpt. 1903, pp. L+452*).—The report proper includes the organization list of the station; a report of the director; a financial statement for the fiscal year ended June 30, 1903; reports of the heads of departments; and reports on cooperative experiments in progress.

Appendix I contains reprints of Bulletins 203–211 of the station on the following subjects: The care and handling of milk (E. S. R., 14, p. 387); cooperative experiments on the cost of egg production (E. S. R., 14, p. 486); shade trees (E. S. R., 14, p. 452); sixth report of extension work (E. S. R., 14, p. 616); pink rot, an attendant of apple scab (E. S. R., 14, p. 668); the grape-root worm—further experiments and cultural suggestions (E. S. R., 14, p. 888); distinctive characteristics of the species of the genus Lecanium (E. S. R., 14, p. 887); commercial bean growing in New York (E. S. R., 14, p. 959); and cooperative poultry experiments—the yearly record of three flocks (E. S. R., 15, p. 178). Appendix II contains a detailed financial statement for the fiscal year ended June 30, 1903; and Appendix III, reprints of Reading Lessons for Farmers' Wives, Nos. 6–10; Home Nature Study Course, Nos. 25–32; and 11 numbers of the Junior Naturalist Monthly, issued during 1902 and 1903. A list of the publications of the station and of the extension department of the college of agriculture is appended.

Sixteenth Annual Report of South Carolina Station, 1903 (*South Carolina Sta. Rpt. 1903, pp. 26*).—This includes the organization list of the station; a financial statement for the fiscal year ended June 30, 1903; and departmental reports reviewing the different lines of station work during the year. The report of the chemist contains a summary of the results of fertilizer inspection during a number of years, but more particularly during 1902 and 1903.

Sixteenth Annual Report of Tennessee Station, 1903 (*Tennessee Sta. Rpt. 1903, pp. 89–104, figs. 2*).—This includes the organization list of the station; a report of the director on the staff, policy, lines of work, equipment, and needs of the station; departmental reports summarizing briefly the different lines of station work; and a financial statement for the fiscal year ended June 30, 1903.

Eleventh Annual Report of Washington Station, 1901 (*Washington Sta. Rpt. 1901, pp. 8*).—A report of the director, and a financial statement for the fiscal year ended June 30, 1901.

Twelfth Annual Report of Washington Station, 1902 (*Washington Sta. Rpt. 1902, pp. 12*).—Reports of the director, agriculturist, horticulturist, and veterinarian; and a financial statement for the fiscal year ended June 30, 1902.

Fifteenth Annual Report of West Virginia Station, 1902 (*West Virginia Sta. Rpt. 1902, pp. 35*).—This includes the organization list of the station; a financial statement for the fiscal year ended June 30, 1902; and a report of the director reviewing the different lines of station work during the year.

Eighth Annual Report of the Pennsylvania Department of Agriculture, 1902, II (*Pennsylvania Dept. Agr. Rpt. 1902, pt. 2, pp. 328*).—This includes the

proceedings of the meetings of the board of agriculture held during the year, and of the annual meeting of the State horticultural association. Papers selected from those read before the horticultural society and at farmers' institutes are also included, as well as lists of the officers of the various agricultural organizations in the State.

Experiment Station Work, XXIII (*U. S. Dept. Agr., Farmers' Bul. 186, pp. 32, figs. 9*).—This number contains articles on the following subjects: Losses in manure, macaroni wheats, sterilizing greenhouse soils, tomatoes under glass, protection of peach buds, dandelions in lawns, apple pomace for cows, rations for laying hens, early molting of hens, evaporation from incubator eggs, the keeping quality of butter, and curing cheese in cold storage.

Experiment Station Work, XXIV (*U. S. Dept. Agr., Farmers' Bul. 190, pp. 32, figs. 14*).—This number contains articles on the following subjects: Cost of eggs in winter, the chicken mite, soiling crops, profitable and unprofitable cows, methods of milking, coating cheese with paraffin, the octagonal silo, ventilation of stables, and disposal of diseased carcasses.

Timely hints for farmers (*Arizona Sta. Bul. 47, pp. 295–317, figs. 2*).—This is made up of reprints of press bulletins issued during the period from October 20, 1902, to May 1, 1903, treating of the following subjects: Strawberry culture (see p. 873), skim milk for pigs (see p. 900), watermelon growing (see p. 870), combating the flat-headed borer, the melon plant louse and the "manteca" disease, and the use of branding fluid (see p. 893).

Southern agriculture; its condition and needs, D. D. WALLACE (*Pop. Sci. Mo., 64 (1904), No. 3, pp. 245–261*).

Agriculture in Austrian Alpine regions, V. ZAILER (*Inaug. Diss., Univ. Jena, 1903, pp. 138*).—The geography, geology, climate, population, labor conditions, and land ownership of these regions are described in a general way, and the cultivation of the soil and management of orchards, vineyards, meadow lands, and forests are treated more in detail. The raising of horses, cattle, and other live stock is discussed and special attention is given to the mountain dairy industry.

Yearbook of the German Agricultural Association, 1903 (*Jahrb. Deut. Landw. Gesell., 18 (1903), pp. XVIII+716*).—This contains the proceedings of the different meetings of the association held during 1903.

NOTES.

Alabama College and Station.—N. C. Rew, a graduate of the Iowa State College of Agriculture and the Mechanic Arts, has been appointed assistant in animal industry in the college and station, vice J. M. Jones, who has resigned to engage in farming in Alabama.

California Station.—J. H. Barber, formerly superintendent of the Sierra Foothill Station at Jackson, has been transferred to the Pomona Substation, where he has become assistant superintendent. The superintendent of the latter station also has charge of cooperative experiments carried on in the orange groves of southern California. H. J. Quayle, assistant entomologist, has been for some time investigating the scale insects of the prune orchards at Hanford, in the San Joaquin Valley. The Watsonville Orchard Association has provided funds for the continuation of the codling moth investigations which were begun last year by Prof. C. W. Woodworth and his assistants with the cooperation of the association. The San Rafael Improvement Club has inaugurated a campaign of extermination against the mosquito pest under the direction of the station entomologist. A small shed adjoining the station building, once used as a stable, has been fitted up with office and laboratories for the bacteriological and veterinary department, which has given up its rooms in the main building to the viticultural department.

Connecticut College.—The third annual summer school for teachers and others in nature and country life will be held July 6 to 29, 1904. Instruction by specialists will be provided in ornithology and entomology, botany, floriculture, landscape gardening, forestry, fruit and vegetable growing, dairying, poultry culture, and other farm operations. There will be special lectures by Dr. C. F. Hodge of Clark University, Dr. M. A. Bigelow of Teachers' College, Columbia University, and several principals of the State normal training schools.

Hawaii Station.—An examination of soils by E. C. Shorey, the station chemist, shows nitrogen to be present in the form of pyridine compounds. Several compounds have been identified and one has been isolated. The subject is being further investigated. Dr. Shorey finds from an examination of the bark of the wattle (*Acacia decurrens*) that this bark carries 29 per cent of tannin. The station has about 15 acres of Acacia trees on its grounds.

Iowa College and Station.—The State legislature has made the following appropriations for the college and station: For additional maintenance fund, $50,000 annually; for completing the central building, $95,000; for beginning the construction of a heating plant, $54,500; for a dairy building, $45,000; equipment for the same, $10,000; for a new dairy farm, $22,000, and equipment of the same, $7,000; poultry department, $500; additional maintenance for the experiment station, $15,000 annually; good roads investigations, $3,500 annually; and engineering investigations, $3,000 annually. The above appropriations include an aggregate of $84,000 for the dairy department. Plans for the dairy building are now being made, and it is hoped that the building may be completed in the early fall. W. H. Olin, of the station, has arranged with A. E. Cook, proprietor of the Brookmont Farms, near Odebolt, for a cooperative experiment with clover. This will be a practical test on a business scale of raising clover, using oats, barley, and corn as nurse crops. Nineteen hundred and

twenty acres, 3 full sections, will be used in the experiment, the seed and labor being furnished by Mr. Cook, while the station will supervise the work and make accurate observations on the growth of the clover under the different conditions of seeding. A cooperative experiment is also in progress at the same farm in growing barley of 3 varieties, specially selected seed of each being used. The experiment covers 900 acres. P. G. Holden, agronomist, conducted a 3-days' special train tour in northern Iowa in April, for the purpose of giving instruction on seed corn and improved methods of corn growing. A special train was provided by one of the railroad companies, and addresses of 20 minutes were made at various points, a long day coach being used as the lecture hall. In this car were arranged charts, samples of seed corn, and other material for illustrating the lectures on corn and the methods of seed selection. This novel undertaking was eminently successful, and large crowds of farmers gathered to listen to the addresses. The newspapers speak enthusiastically of the enterprise and the benefits which may be expected to follow.

Mississippi Station.—The recent legislature appropriated $14,000 for a substation at McNeill for the period of two years, and also provided for the establishment of two other branch stations, one in the brown loam and one in the Delta region. An appropriation of $3,000 was made for each of these stations to start the work. This, together with the contributions of the communities in which the stations are located, will enable the work to be organized.

Cornell University.—The bill appropriating $250,000 for buildings and equipment for the college of agriculture was passed by both branches of the legislature previous to adjournment. The opposition to it, previously noted, was continued before the governor, but the latter signed the bill early in May. The university will add about $40,000, making a grand total of $290,000 for buildings. The university will take over the dairy building and adapt it for other purposes, and a new site adjacent to the veterinary department and the college farms will be selected for the agricultural buildings.

Porto Rico Station.—F. D. Gardner, who has been in charge of the station since its organization, has resigned to reenter the service of the Bureau of Soils, in charge of soil management. He is succeeded by D. W. May, formerly connected with this Office, and for two years past at the head of the department of animal husbandry in the Kentucky Station. Mr. May is a graduate of the Missouri Agricultural College, where he spent some time in postgraduate work and served for a period as farm superintendent. He has had experience in southern New Mexico and has considerable familiarity with subtropical agriculture. He brings to his work a thorough understanding of the spirit and methods of experiment station work, a working knowledge of the Spanish language, and good administrative ability, which will stand him in good stead in his new station. G. P. Clinton, of the Connecticut State Station, has spent several weeks in the island investigating the diseases of citrus fruits, coffee, and other products.

Rhode Island College.—The legislature has appropriated $3,000 for repairs to the college buildings, and increased the appropriation for labor fund and demonstration work, which last year was $3,000, to $4,000, to be divided equally between these two objects.

Vermont College.—C. L. Stygles has been appointed dairyman, vice E. S. Gregg.

Wisconsin University and Station.—Charles W. Stoddard has been appointed instructor in agricultural physics to succeed F. J. Wells, who, as previously noted, died early in March. Mr. Stoddard was reared upon a farm in Wisconsin, and is a graduate of the Brooklyn Polytechnic Institute and Columbia College, where he also spent some time in postgraduate work. His training has been especially along the lines of chemistry, physics, and plant physiology.

A New Plant Introduction Garden.—The Bureau of Plant Industry of this Department has established a plant introduction garden at Chico, California. The great increase in the work of plant introduction during the past two years, and the

systematizing of the introduction and distribution of seeds and plants, have made the need of better facilities for caring for, propagating, and testing introduced plants and seeds imperative. After a thorough examination of different parts of the State of California by P. H. Dorsett, William Taylor, and W. W. Tracy, of this Department, assisted by A. V. Stubenrauch of the California Station, Chico was finally selected as the site of the garden; and a tract provided by the county for that purpose has been turned over to the Department. Chico is located in Butte County in the northern part of the State, nearly 100 miles north of Sacramento. The State has maintained a forestry station there for a number of years. While the climate is too severe for the safe propagation of citrus fruits less hardy than the lemon, the general conditions of climate and soil are such as to promote an extraordinarily healthy growth of all other plant life. It is thought that the Chico climate will be representative of a much larger range of available territory than the forestless regions farther south. The question of water was also an important item in selecting a location; at Chico the necessity for irrigation will be confined to annual crops and newly planted trees, and established trees will not require irrigation.

It is the intention of the Bureau of Plant Industry to gather at this garden a large and representative collection of economic plants of all kinds, more particularly of fruits, and to propagate such new varieties as are found worthy of further introduction, at least to the extent necessary to make a preliminary distribution. As the collection increases the garden will afford valuable facilities for plant breeding and for studies in botany and horticulture, such as can only be carried on where a wide range of plants are available. The garden will also be used very largely for planting small samples of seeds, in order to increase the stock of seed sufficiently for a preliminary distribution. In the past, when only small quantities of seed have been available, these have frequently been lost in the first test, so that even if the test proved favorable a further trial could not be made. In future it is planned to grow an increased supply of all the small lots of seeds which are introduced before any distribution is made, so that a small quantity of stock seed may be kept on hand to fall back upon, in case the variety proves desirable and it is not practicable to secure the seed elsewhere. Work at the new garden has already been commenced, with P. H. Dorsett in charge as superintendent.

In addition to the above garden, the Bureau has arranged for the following testing stations in different parts of the country. A palm garden has been located on a tract of 15 acres of land at Mecca, in the Colorado Desert, where the different varieties of date palms will be tested, and also other plants adapted to those regions under irrigation, the water being furnished by an artesian well. The city of San Antonio, Tex., has turned over to the Bureau 125 acres of land near that city, and the local water company has agreed to furnish abundant water for irrigation free of charge. This will give opportunity for testing plants in the semiarid belt, and also for work in plant breeding and selection. At North Galveston, Tex., the Department has acquired a tract of 60 acres of land to be used primarily as a rice farm. This farm lies in the prairie belt of Texas, where abundant irrigation water is easily available, and where rice can be grown and harvested by machinery. All the varieties of introduced rice are being tested at this place, as well as other crops adapted to the conditions. The pine woods farm, including 160 acres of land at De Quincy, La., is representative of the pine woods region in which the soil is thin and underlaid with hardpan, making it difficult to cultivate the ordinary crops. At this farm the plants and cultural methods suited to the region, which extends more or less throughout the Gulf States, are to be worked out. Four cereal testing stations are being maintained—one each in Texas, Nebraska, North Dakota, and South Dakota. These latter are more or less temporary in nature and will be abandoned as soon as the work there is completed. The Bureau continues to maintain a subtropical garden at Miami, Fla.

California Polytechnic School.—A copy of the second annual catalogue of this school has been received from Dr. Leroy Anderson, the director. The school, it will be remembered, opened last September, and the catalogue shows twenty students in attendance. Courses of study, with practical work, are offered in agriculture, mechanics, and domestic science. A temporary dairy room and a carpenter shop are fitted up in the basement of the main building, and there are lecture and laboratory rooms for chemistry and physics, botany and entomology. The farm consists of 280 acres of land and contains a small orchard of apples, oranges, limes, and grapes. A good beginning has been made with live stock, and it is planned ultimately to produce all the dairy and poultry products used by the school upon the farm. The auspicious opening of the school and the fact that it has attracted students from quite a distance is encouragement for the belief that a career of wide influence and usefulness is open to it.

Agricultural Education and Research in India.—The previous announcement (E. S. R., 15, p. 733) regarding the establishment of an institution for agricultural education and research at Pusa, in the Darbhangah District of Bengal, with an endowment provided by Mr. Henry Phipps, of Pittsburg, is confirmed by an article in the London *Times*, which is noted in *Nature* for April 7 and *Science* for April 22. The college is to be known as the Imperial Agricultural College, and it is hoped will be ready to receive students a year from next fall. The principal of the institution is Mr. Bernard Coventry, who has been manager of the Dalsingh Serai estate. The staff of the station is to consist of 2 chemists—one being also a bacteriologist, 2 botanists—one cryptogamic and the other "biological," and an entomologist. In commenting upon the new institution *Nature* says:

"This scheme ought to grow into an institution of the utmost value to India, a country which is full of agricultural industries, involving great interests, yet proceeding wholly by rule of thumb tempered by occasional analyses performed in London. Systematic investigations of the conditions of the industry on the spot have been wanting except latterly among the tea planters of Ceylon and Assam. Indigo growing affords a case in point; for years it was obvious that the natural product was going to meet with severe if not ruinous competition, yet nothing was done until the artificial indigo had reached the position of being able to undersell the Indian article, then at last a chemist and a bacteriologist were hurried out to try to save the failing industry. . . . The new institute at Pusa will be well situated among some of the best agricultural developments in India, so that the scientific staff will have an opportunity of learning where their skill can be of service to the cultivator, and of trying to keep this or that industry in a healthy condition instead of being called upon to resuscitate it when in extremis. There may be even now a chance for the grower of indigo if only he is given some of the systematic scientific effort which has hitherto been the monopoly of his competitor."

Agricultural Schools in Brazil.—Milton M. Underdown, writing in *The Country Gentleman* for April 28, 1904, describes the conditions respecting agricultural instruction in Brazil, and the ups and downs of one practical school in particular. He speaks of the state experiment station at São Paulo as "a very creditable institution," but his general account of the condition of agricultural education in that country is not encouraging.

Miscellaneous.—Prof. F. Lamson-Scribner has resigned his position as Chief of the Bureau of Agriculture of the Philippines and has reentered the service of this Department in the Bureau of Plant Industry. He will be in charge of the latter's exhibit at St. Louis during the exposition.

Hon. Levi Stockbridge, for many years professor of agriculture at the Massachusetts Agricultural College, died at the home of his son, Dr. H. E. Stockbridge, Lake City, Fla., May 3, after a short illness. He was 84 years of age.

Dr. J. Wortmann, the director of the horticultural academy at Geisenheim, has lately been made an advisory member of the German Health Office on questions relating to agriculture and forestry. He succeeds Dr. R. Goethe, also his predecessor in office at Geisenheim, who has retired.

A joint resolution providing for the printing of the annual report of this Office was passed by Congress a few days before adjournment. It provides for 8,000 copies of the report, 5,000 of which will be for the use of the Department, and makes it one of the reports to be prepared and published annually without further provision of Congress. This report contains the review of the work and expenditures of the experiment stations, reports on the work in irrigation and nutrition, and miscellaneous papers relating to agricultural education and experimentation.

Among the bills presented in Congress late in the session, which failed of passage, was one to establish an agricultural experiment station in the Sixth Congressional District of Mississippi, with an appropriation of $10,000; one to establish a system of primary schools of agriculture in the Territories and insular dependencies of the United States, to be located upon farms, and to give practical as well as theoretical instruction in farming, stock raising, farm engineering, and "the simple mechanic arts required in the country," the course of instruction to occupy not less than 5 years; and a bill to create a Bureau of Agricultural Education in the Department of Agriculture, for the purpose of devising the best methods of promoting agricultural education throughout the United States, and to study the conditions and needs of each Territory and the island possessions.

A bill for promoting agricultural education and nature study in public elementary schools has been introduced in the House of Commons, according to a note in *Mark Lane Express*. Its object is to provide for the teaching of agricultural and horticultural subjects, to give facilities for nature study, and generally by means of object lessons to cultivate habits of observation and inquiry on the part of the pupil. To this end it is proposed to maintain school gardens and collections of materials necessary for the practical illustration and application of the instruction given. These studies would be optional in urban schools, but compulsory in all schools situated in rural and semirural districts. The bill is said to have the support of several prominent members.

The Central Society for the Beet Sugar Industry in Austria-Hungary is preparing to celebrate the fiftieth anniversary of its establishment June 6, at its general meeting to be held in Vienna. The society was founded August 4, 1854, and now embraces all the sugar factories and refineries of Austria-Hungary. It maintains a chemical-technical experiment station for beet-sugar manufacture, with a commercial laboratory, under the directorship of Friedrich Strohmer, located in the society's building in Vienna, which also serves as headquaters for the numerous sugar organizations.

A departmental committee has been appointed by the president of the board of agriculture for the double purpose of inquiring into and reporting upon the present condition of fruit culture in Great Britain, and of taking steps to advance and encourage the industry.

The Association of German Scientists and Physicians will meet this year at Breslau, September 18–24.

Flora and Sylva is the title of a new English publication, Vol. I, No. 1 of which appeared in April, 1903. It is a monthly review devoted to gardens, woodlands, trees, flowers, new and rare plants, and fruits. Special attention has been given to clear drawings and colored plates, to the use of large, clear type, and a high grade of paper. The magazine will be found especially valuable to botanists. The first nine numbers have been bound and indexed, and appear as Volume I.

O

EXPERIMENT STATION RECORD.

VOL. XV. JUNE, 1904. No. 10.

An important phase of food and feeding stuff inspection is the determination of the nature of adulteration. The kind of materials employed as adulterants, and the extent to which foreign materials may occur naturally as impurities or are purposely admixed in the process of manufacture or preparation, is often of quite as much interest as the composition of the inspected products with reference to an accepted standard. While ordinarily harmless themselves, these materials are not selected on account of their healthfulness and are usually a dead weight, serving no useful purpose to the consumer. A knowledge of their general character and the means of detecting them strengthens the hands of those charged with the inspection, and aids in providing efficient laws to enable their control.

The materials employed as adulterants change from time to time, and are often of such a nature as to make their detection quite difficult. This is heightened by the variety of materials employed, by special preparation which alters their true character, and by the unexpectedness of their use. While some of them can be detected by chemical means, a large proportion require the use of the microscope, and for this purpose a knowledge of the anatomy and structure of a great variety of seeds and other parts of vegetable products, as well as of the food products themselves, is of the highest importance.

The histological studies which have been carried on for several years past by Mr. A. L. Winton, of the Connecticut State Station, constitute the most extensive and thorough investigations of the kind which have been reported in this country, and are worthy of special commendation both on account of their high character and their wide application. As furnishing a basis for the identification of admixed materials and studies of the nature of adulteration they are fundamental, and form a most important contribution to the development of food inspection work.

Mr. Winton's work in this line began several years ago at the Pharmacological Institute of the University of Gratz, Austria, under Prof. Josef Möller, who has given much attention to investigation of this character. The anatomy of the maize cob was studied with a view to the detection of ground cobs in wheat and rye bran. It soon became apparent that European investigators, who have accumulated the bulk of the information available to food chemists regarding the microscopic

structure of vegetable materials, had overlooked many distinctively American products with which we should be familiar. This first paper was followed by similar studies of the different parts of the cocoanut, the shells of which are extensively employed for adulterating spices, and of a variety of small fruits, including field and cultivated strawberries, raspberries, blackberries, currants, gooseberries, cranberries, and huckleberries. These studies of small fruits are of special importance in the examination of jams, preserves, and similar products.

Later, studies were reported on twelve varieties of sorghum, including broom corn, Kafir corn, durra, and milo maize, for the purpose of their identification when ground for cattle food or adulterants. In an investigation of American wheat screenings, the materials separated included broken and shriveled wheat, straw and chaff, dust, and the seeds of numerous weeds, among which black bindweed, green and yellow foxtail, darnel, and chess were especially studied. The last report of the station describes the anatomy of a number of oil-bearing seeds, such as hemp, upland cotton, sesame, madia, niger, and poppy seed, with special reference to the microscopic examination of cattle foods.

This partial list gives an idea of the scope and extent of Mr. Winton's investigation, and it should be added that a considerable number of important studies remain unpublished. In all of this work carefully executed drawings have been made of separate parts of the material under examination and their histological elements, which, together with the descriptive text, enable their identification in admixtures. To facilitate this and make the determination more certain, distinctive features have been sought out and special tests devised, and a convenient micropolariscope has been described; all of which characterizes the investigations as ingenious and painstaking to a degree, and thoroughly scientific in their execution.

The paucity of data which is applicable to the identification of materials used as adulterants of foods and feeding stuffs is rather surprising when we consider the wide interest in inspection work in this country. The number of books containing material of value in this connection is exceedingly limited. The results of isolated investigations in this country have been published from time to time in botanical and pharmaceutical journals, but much of this work is not applicable to the matter in hand, and it suffers from being fragmentary and widely scattered.

The Bureau of Chemistry of this Department has published some work bearing on the subject, and is at present devoting considerable attention to histological studies of food products and adulterants. The work which Mr. Winton has done, so far as it has been published, has appealed strongly to food chemists, and has been eagerly embraced by them and made a part of their working stock in trade. But the field is a broad one and the work of a time-consuming character.

Moreover, the attention which any single institution can devote to it is necessarily small, and as the results are of uniform value wherever food inspection is carried on in this country, it is too much to expect a single station to cover the whole field. While Mr. Winton is a pioneer in this work, he has not preempted the whole field, and would no doubt rejoice to see his efforts seconded at many places.

Investigation of this sort can not be regarded as strictly in the field of the chemist and need not be restricted to him. It is essentially botanical in its character and methods, and much valuable assistance could be rendered by botanists in conducting these histological studies, who would find in them a line of investigation of increasing interest and practical utility. Indeed, this would seem to be an inviting and profitable opening to young botanists seeking a special line of work, and afford greater opportunity for original contributions than some of the more hackneyed lines. The subject, however, is one in which prospective food chemists should perfect themselves, and it illustrates the growing importance of broad training for men who are to enter this field.

It is obviously impracticable in most institutions to divide the work of inspection, assigning the microscopical examination to a botanist and restricting the chemist to the chemical analysis. The most practical plan seems to be for one man to master both lines of work, and although he need not himself execute all of the details, he should be thoroughly familiar with them and competent to interpret the results. Such preparation calls for suitable courses of instruction, to which very little attention has yet been given in this country, although the subject has a recognized place in many continental universities. It calls for a combination of chemical and botanical studies, which are already on the curriculum of nearly every college and school of technology, but which are not as yet brought together so as to constitute a prescribed course. The growth of both State and Government work in the inspection of foods and feeding stuffs, as well as the increased employment of men of special training in packing houses, canneries, flouring mills, glucose factories, baking establishments, confectionery works, and the like, would seem to make it worth while for at least a few institutions to provide courses suited to the needs of such men.

The desirability of the analyst conducting some research work, to prevent him from getting into a rut and becoming a mere rule-of-thumb worker, is quite as apparent in this as in any other line of routine work. Studies of this character, which can be taken up at odd times, will do much to relieve the dull grind of routine analysis and to keep the chemist fresh for his work.

The death of Emile Duclaux removes a prominent and conspicuous worker in a field bordering closely on agriculture. His name is a familiar one to readers of this journal, for so much of his work in recent years related to some phase of agricultural science that special

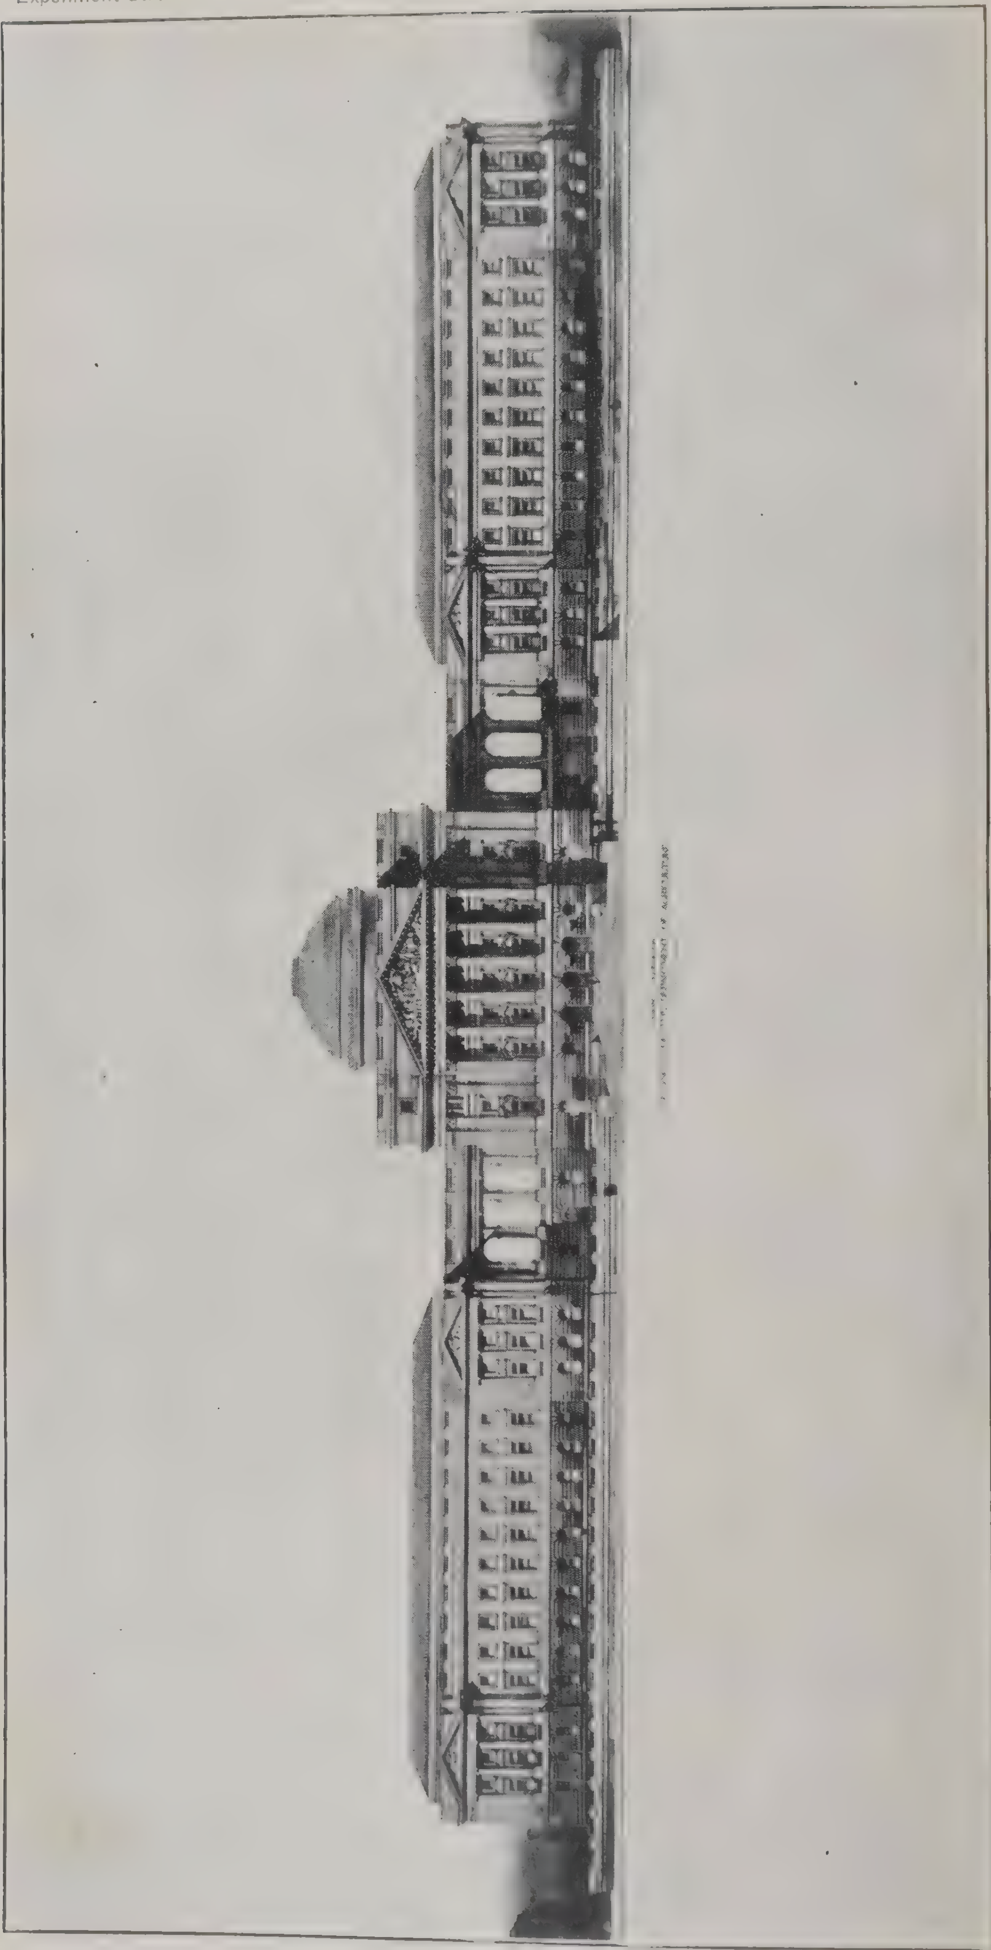
effort was made to follow it. Trained as a chemist and physicist, and with noteworthy contributions to his credit in both of these sciences, his most important work was biological and biochemic. In this respect he was like Pasteur, with whom he early became associated and whom he succeeded as director of Pasteur Institute upon the death of the great leader nine years ago.

Duclaux's training as an investigator was obtained under Pasteur at the École Normale, where he served as *préparateur* to Pasteur for about three years. He assisted the latter in his celebrated investigations on the causes of diseases in wines and upon silkworm diseases. He occupied successively the chairs of chemistry at Clermont, of physics at Lyons, and of physics and meteorology at the Institut National Agronomique in Paris. The latter position he accepted in 1878, and in 1888 he became titular professor of biology in the Sorbonne, which position he held at his death. He was also the head of the Laboratory of Fermentations, established in 1888 as a department of the Institut National Agronomique. With the establishment of the Pasteur Institute, his course of instruction and biochemic laboratory were transferred there. He founded the *Annales de l'Institut Pasteur* in 1887, in which many of his papers and reviews were published.

The list of Duclaux's original contributions to scientific journals contains upwards of eighty papers, and includes, besides technical articles on chemistry, physics, and meteorology, studies on ferments and fermentation, enzyms, the coagulation of albumen, the aging of wine, the chemistry of carbohydrates, the biology of the soil, the physiology of digestion, and the chemistry and bacteriology of dairying. On the latter subject he was for many years the leading investigator in France. He made extensive studies on the rancidity of butter and the relation of bacteria and molds to these changes; and he was prominent in the early stages of the discussion of cheese ripening, assigning an important place to the peptonizing lactic bacteria, to which he gave the group name of Tyrothrix species.

Duclaux also published two books on dairying which are standard, viz, *Principes de Laiterie*, which formed a part of the Encyclopedia of Agriculture and Horticulture, and *Le Lait, Études Chimiques et Microbiologiques*, the last edition of which appeared in 1894. His most important work was the *Traité de Microbiologie*, commenced in 1889, four volumes of which had appeared. The fifth volume was nearly completed at his death, and two more were contemplated.

While Duclaux will probably be best remembered by his researches upon enzyms and fermentation and the chemical processes associated with the life and activities of micro-organisms, his remarkable versatility brought him into a position of prominence in many lines, in which his name will long be associated with the history of investigation. His death occurred May 3, at the age of 64 years.



FRONT ELEVATION OF BUILDINGS FOR THE DEPARTMENT OF AGRICULTURE.

NEW BUILDINGS OF THE DEPARTMENT OF AGRICULTURE.

In 1901 Congress authorized the preparation of plans for an agricultural building, as a preliminary step toward securing adequate permanent quarters for the National Department of Agriculture. On the basis of plans and estimates which were made, an appropriation of two and one-half million dollars was asked, which the Congress of 1902 reduced to one and one-half million. With this reduced amount it was decided to provide laboratory and office accommodations for the bureaus and divisions occupying rented buildings, and to leave the administration building to be built later when further appropriation should be made.

A building committee consisting of Doctors B. T. Galloway, D. E. Salmon, and A. C. True was appointed by Secretary Wilson to consider in detail the special needs of the Department, and to arrange for building plans. Messrs. Rankin, Kellogg, & Crane, of Philadelphia, were selected as architects, and preliminary plans were drawn; but controversy arose over the location of the building, which involved the general plans of the commission for the beautification of Washington, and pending the decision little progress could be made in working out the details of the building.

A location was definitely determined upon early in May, 130 feet in rear (to the south) of the present main building, and fronting on the 890-foot parkway projected from the Capitol to the Washington Monument. The building will face north, and when completed will consist of an administration building as a central feature, with L-shaped wings on either side, the short arms of the wings extending to the rear. (Pl. III). This will occupy all the available space back to B street SW., and will necessitate the condemnation and closing of that street and a part of the square adjoining it when future extensions are made.

The location with reference to the present buildings is shown in fig. 10. It will be seen that, with the exception of the frame building used as a museum and several ranges of greenhouses, the buildings need not be disturbed for the present. The grass garden, which lies between the statistical building and the museum, will have to be moved, and the proximity of the vegetation house (V. H.) and a small building for photographing plants (P. G.) will necessitate their being done away with. The fireproof building used for storing records and documents, the stable, and other storage buildings will be left for the present. The museum contains numerous offices, and provision for these will be made in rented quarters, as the building will be torn down this summer.

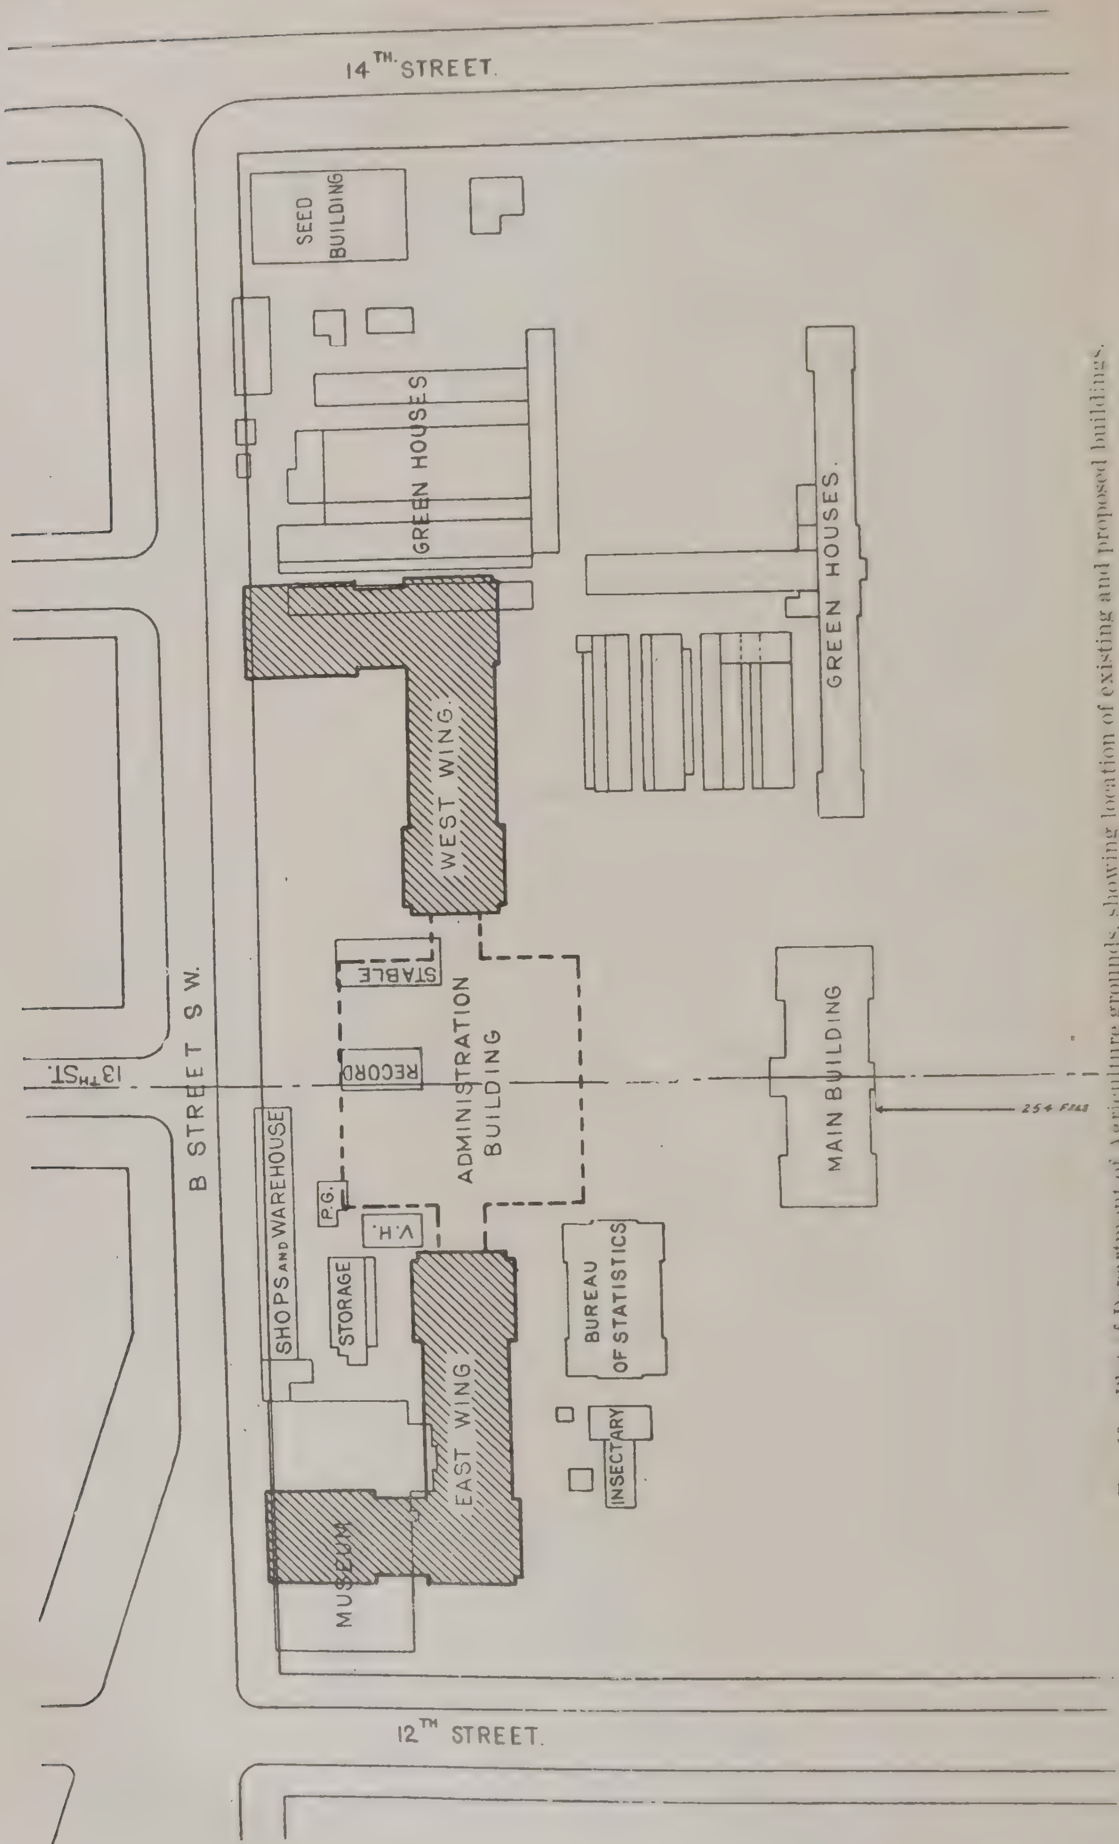


FIG. 10.—Plat of Department of Agriculture grounds, showing location of existing and proposed buildings.

The administration building will be designed solely for office and library purposes, and will be five stories high. The laboratories will be in the wings, which for the present at least will also contain some offices. Only the two wings are to be erected at this time, and these will appear as independent structures, separated by an opening of 220 feet. When these are connected by the administration building an imposing front of approximately 750 feet will be presented, the central building projecting 35 feet beyond the front line of the wings.

The wings will have a frontage of 256 feet each, and the ells will extend 100 feet from the front line to the rear. They will be four stories in height, above a high basement and a subbasement, and about 60 feet in width (from front to rear). Both wings will be exactly alike in size, construction, and arrangement of the rooms. The basement in each case will be about 12 feet high and mainly above ground, so that it may be used for laboratories and certain mechanical operations. The first and second stories will be 16 feet 3 inches, the third story 15 feet 7½ inches, and the fourth story 13 feet 9 inches in height, with a low air space above.

Corridors about 12 feet wide, running the entire length, will divide each wing in half, giving a series of communicating rooms on either side. These rooms will be units of about 20 by 22 feet in the clear, the windows and doors being so arranged that the rooms may be divided if desired by temporary partitions, making an office and a laboratory, or two office rooms, about 11 by 20 feet. The partitions dividing the rooms at right angles to the corridors will consist of two four-inch brick walls, 14 inches apart and tied together, thus providing a series of continuous open spaces extening from the subbasement to the attic. These hollow partitions will carry the hot-air flues and the flues for ventilation. Each room will have two hot-air flues, two ventilating outlets, and two flues for the ventilation of hoods. The room ventilation will be downward, the flues for each wing connecting in the subbasement with two vent passages leading to two vent shafts, each provided with a fan for discharging the air. The hoods will be ventilated by an up-draft, the flues terminating in the attic, which is left as one large room, and the fumes being drawn out of that by fans. The hot-air flues will be of galvanized iron and all the vent flues of terra cotta.

The subbasement will be given up entirely to the heating and ventilating system, and to conduits carrying the supply pipes. Heat will be supplied by indirect radiation, the steam being furnished by a power plant located in a special building already provided for. There will be no direct radiators except at the ends of the corridors and in the toilet rooms. The incoming air will pass through filters to remove the dust, and then through the primary heaters which will raise it to a tempera-

ture of about 75°, regardless of the outside temperature. The tempered air will be circulated by two fans and discharge into a large plenum chamber, from which tempered air passages will run to various parts of the building. In the plenum chamber the tempered air will be sprayed with moisture to give it the proper degree of humidity. Supplementary heaters, located under each tier of rooms, will heat a part of the air to 110°, and at the bottom of each pair of flues will be mixing dampers for controlling the amount of hot air mixed with the tempered air. These dampers will be actuated by thermostats located in the rooms above, so that the heat of each room will be absolutely under control and can be cut off independently of any other room.

Provision will be made for supplying each laboratory room with hot and cold water, distilled water, gas, live steam, compressed air, and suction, as well as with electricity for light and power. All pumps and machinery for maintaining the supplies of these will be located without the building in the power house. The equipment of the latter will include a plant for generating the electricty used for various purposes.

At six points in each wing there will be pipe shafts which will conduct the risers from the supply pipes in the subbasement, the laterals for each room being brought out horizontally and suspended from the ceiling of the room below, whence they will be brought up through the floor at the desired points. All piping will thus be exposed, and the pipe shafts will be provided with doors so that the risers will be easily accessible. In each of the double partitions between the rooms and next to the outside wall will be a lead-lined soil pipe to carry the waste.

The details of equipment for the various laboratories will be worked out later, after the assignment of the space has been made. Work tables, sinks, hoods, and other fittings will be installed to suit the requirements of the different kinds of work, but in the construction of the building there will be no special provisions for a chemical laboratory, a soil laboratory, a botanical laboratory, and the like, such as are usually made in buildings of this kind. The facilities provided throughout the two wings will be so complete as to admit of adapting the rooms to a great variety of purposes, and to allow changes or extension of quarters to be made readily at any time in future. This will avoid the tearing up of floors and special equipment, and will be a great advantage in an institution like the Department, whose work is growing rapidly and whose special needs are changing from time to time.

Each wing will have three elevators, one of which will probably be used for freight; and on each floor will be located three large toilets, suitably ventilated, and provided with open plumbing and marble fittings, together with janitors' storerooms.

The buildings will be either of marble or granite, with solid masonry walls, the floors being either of steel with fireproof construction between, or of reenforced concrete. The corridor floors will be of Terrazzo with marble borders, and the laboratories of concrete, maple floors being used in the offices. The walls and ceilings will be of cement plaster. The total floor space provided by each building is 80,000 square feet, including the corridors. This leaves about 55,000 square feet in each building available for office and laboratory rooms.

The construction of the building will be in charge of Captain John S. Sewell, of the War Department, as supervising engineer; R. Barnard Talcott, consulting mechanical engineer; and S. Franklin Gardner, mechanical engineer and superintendent.

The final plans and specifications are now being prepared, and it is expected that contracts will be let and the work of construction begun during the present summer.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

On the losses of sulphur in charring and in ashing plant substances; and on the accurate determination of sulphur in organic substances, W. E. Barlow (*Jour. Amer. Chem. Soc., 26 (1904), No. 4, pp. 341–367, figs. 3*).—This article gives details of studies of a large number of methods of incinerating organic substances carried out at Göttingen University under direction of Prof. B. Tollens. The general conclusions reached are as follows:

"(1) In ashing a plant substance, a protein or a coal in the ordinary manner, without addition of alkali, a loss of sulphur always takes place. This loss is always considerable, and may be, in some cases, enormous, even when precautions are taken to insure a low temperature and a slow and regular ashing. It is caused by the conversion of organic sulphur into volatile sulphur compounds and into sulphur dioxid and trioxid during the charring and ashing. A certain part of these is retained by the bases, especially by the alkalis, but in presence of phosphoric and silicic acids, which expel sulphuric acid at a red heat, the amount retained in the ash may be very small or even nothing.

"(2) The loss takes place even when there is a quantity of alkaline base present more than sufficient to combine all the acid.

"(3) The loss is diminished (but by no means entirely avoided) by the addition of amounts of sodium carbonate up to twice the weight of the substance to be ashed. The additional effect of adding more sodium carbonate is practically nothing.

"(4) The loss of sulphur is not entirely prevented either by the addition of calcium acetate before ashing (Tucker); or, of magnesium oxid and sodium carbonate together (Eschka); or by evaporation with potassium hydroxid followed by oxidation with potassium nitrate; or by evaporation with nitric acid and potassium nitrate before ashing (Fraps). In all these cases the gases still contain sulphur.

"(5) By far the greater part of the loss of sulphur occurs during the preliminary charring, a much smaller part during the burning of the charred mass to ash.

"(6) Combustion in a stream of oxygen, with absorption of the sulphur-containing products of charring and combustion either in heated sodium carbonate in the combustion tube or in a special apparatus, gives, under proper conditions, absolute values for the total sulphur. Such results are, however, exceedingly difficult, if not quite impossible, to attain by either the original Berthelot method or the Sauer method. The writer considers that he has ascertained and described the arrangement of apparatus and the details of manipulation which render possible the attainment of such accurate results with ease and certainty. It is essential to burn the escaping gases completely with an excess of oxygen, introduced laterally at a certain point in the combustion tube, before absorbing the sulphuric acid from them."

Investigations on the accurate determination of sulphur in plant substances and other organic materials, W. E. Barlow (*Inaug. Diss., Univ. Göttingen, 1903, pp. 87, figs. 3, dgm. 1; abs. by B. Tollens, in Jour. Landw., 51 (1903), No. 3,*

pp. 289–313, figs. 2).—This is the detailed report of investigations on the determination of sulphur in organic substances, the general results of which are noted above from another source.

Contributions from the agricultural chemical laboratory at Göttingen, B. TOLLENS (*Jour. Landw., 51* (*1903*), *No. 4, pp. 355–369*).—This is a brief summary of the numerous contributions from this laboratory which have appeared during the last 10 or 12 years.

Ash in feed stuffs, M. HAVENHILL (*Iowa Agr., 4* (*1904*), *No. 6, pp. 230–233*).—A compilation of analyses with a discussion of the function of the ash constituents in nutrition.

The precipitation of magnesium oxalate with calcium oxalate, N. KNIGHT (*Chem. News, 89* (*1904*), *No. 2313, pp. 146, 147*).—Analyses of dolomite rock by different students are reported, which show that the amount of magnesium oxalate which will be precipitated with calcium oxalate varies from an almost inappreciable amount to a considerable quantity. In the author's opinion "it is therefore always better to dissolve the unwashed precipitates of calcium and magnesium in warm hydrochloric acid, then to add ammonia to precipitate the calcium. After standing a suitable time, the calcium may be filtered, and the filtrate can be added to the solution containing the main portion of the magnesium, or the two portions can be separately treated."

A new method for the determination of free lime and on so-called "dead burnt" lime, E. H. KEISER and S. W. FORDER (*Amer. Chem. Jour., 31* (*1904*), *No. 2, pp. 153–162, fig. 1*).—The method proposed is carried out as follows:

Heat 0.2 to 0.5 gm. of the material in a platinum crucible to drive off moisture, or in case of cements, heat over a blast lamp for a few minutes to expel carbon dioxid, cool in a desiccator, and weigh. Add a few drops of recently boiled distilled water and place the crucible in a brass protector consisting of a cylindrical box provided with a screw top carrying a brass inlet and outlet tube, the thread of the cap being made air-tight with a little white lead and oil. Place the protector in an air bath and raise the temperature to 85° C., allowing it to remain at this point for 30 minutes. Draw a slow current of air freed from carbon dioxid and moisture through the apparatus and raise the temperature to 185° C., maintaining the temperature at this point for 30 minutes. Cool the crucible in a desiccator and weigh, the increase in weight giving the amount of water taken up by the quicklime to form calcium hydroxid.

Satisfactory tests of the method with different materials under a variety of conditions are reported.

A portable outfit for the determination of carbonic acid, dissolved oxygen, and alkalinity in drinking water, F. B. FORBES (*Jour. Amer. Chem. Soc., 26* (*1904*), *No. 4, pp. 382–388, figs. 3*).—Outfits for determination of dissolved oxygen by the Winkler method, free carbonic acid by Seyler's method, and alkalinity or fixed carbonic acid by Hehner's method are described.

Sprengel's method for colorimetric determination of nitrates, L. W. ANDREWS (*Jour. Amer. Chem. Soc., 26* (*1904*), *No. 4, pp. 388–391*).—This article briefly reports experiments in which it was shown that the yellow color obtained in Sprengel's method is not due to the formation of picric acid but to paranitrophenol.

The determination of nitrogen in food materials and physiological products, H. C. SHERMAN, C. B. McLAUGHLIN, and E. OSTERBERG (*Jour. Amer. Chem. Soc., 26* (*1904*), *No. 4, pp. 367–371*).—In tests with 17 animal and vegetable substances several modifications of the Kjeldahl method were compared as regards the time required for the complete transformation of the nitrogen.

When the sample was digested with sulphuric acid and mercury or with sulphuric acid and potassium sulphate, the transformation of the nitrogen was rarely complete when the solution became colorless or of a faint straw color. Continuing the diges-

tion for 2 hours longer gave higher results, the average difference being about 1 per cent of the amount of nitrogen present. When the sample was digested with both mercury and potassium sulphate slightly higher results were obtained and the time required for digestion was reduced, though it was still necessary to continue the boiling beyond the point at which the solution became colorless. The results were not appreciably affected by the addition of copper sulphate or potassium permanganate to the reagents mentioned.

The following procedure is recommended for the determination of nitrogen existing in the form of proteids and related compounds: "Treat the sample with 20 cc. of concentrated sulphuric acid and 0.7 to 1 gm. of mercury, heat gently until frothing subsides, and then add 10 to 15 gm. of potassium sulphate and boil. Usually the solution becomes colorless in less than 30 minutes, and the transformation of nitrogen into ammonium sulphate is complete within an hour." A further study with organic compounds of known structure is contemplated.

Method for the determination of proteids in plants, L. Beulaygue (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 11, pp. 701–703*).—The method described is believed to be more accurate and rapid than that of Stutzer and Hirschler.

The rapid determination of fat by means of carbon tetrachlorid, A. P. Bryant (*Jour. Amer. Chem. Soc., 26 (1904), No. 5, pp. 568–573, fig. 1*).—A comparison of carbon tetrachlorid with more common reagents for the extraction of fat led the author to the conclusion that the tetrachlorid is very satisfactory for this purpose, especially in the commercial analysis of foods and feeding stuffs. It was found very rapid in its action, "two hours apparently sufficing for complete extraction in all cases. It is uninflammable, thus reducing the danger of explosion and fire to a minimum, [and] it is inexpensive."

From the figures showing the results of comparative tests the following are quoted: In four of the samples of vegetable origin the amount of ether extract was 0.12, 0.14, 0.17, and 4.05 per cent, respectively, the carbon tetrachlorid extract in corresponding samples being 0.12, 0.15, 0.17, and 4.06 per cent, respectively. Practically as close agreement was found in the case of other samples. As compared with carbon bisulphid, the carbon tetrachlorid extract in several samples of vegetable origin was 10.7, 11, and 11 per cent, respectively, and the carbon bisulphid extract was 10.1, 10.8, and 10.7 per cent, respectively. In the case of air-dried pork the amount of ether extract was 71.3 per cent and the carbon tetrachlorid extract 72.6 per cent.

In extracting fat with carbon tetrachlorid the Knorr extraction apparatus was used, the flasks being heated on a water bath with live steam and protected with copper shields in the form of half cones, in order to prevent condensation of the carbon tetrachlorid in the lower part of the apparatus.

Observations on the composition of potato starch, A. Fernbach (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 7, pp. 428–430*).

Concerning the acid content of different sorts of flour and other analytical data, A. Fachinato (*Gaz. Chim. Ital., 33 (1903), II, pp. 543–555; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, p. 299*).—In the author's opinion, the estimation of the acid present in an alcoholic extract of flour is especially useful as a means of judging of its quality. Phenolphthalein is used as an indicator.

Note on the hydrolysis of edestin, E. Abderhalden (*Ztschr. Physiol. Chem., 40 (1903), No. 3–4, pp. 249, 250*).—A note supplementing the investigation previously reported (E. S. R., 14, p. 1044).

The examination of meat, yeast, and other extracts for xanthin bodies. II, The xanthin bodies of yeast extracts, K. Micko (*Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, pp. 257–270*).—Analytical methods are described and results reported.

The oxidation of gelatin with permanganates, G. Zickgraf (*Ztschr. Physiol. Chem., 41 (1904), No. 3, pp. 259–272*).—Oxidizing gelatin with different permanga-

nates, the author obtained varying amounts of guanidin picrate. When calcium permanganate was used another oxidation product was also obtained, the chemical characteristics of which are briefly described.

Salmon oil, B. DE GREIFF (*Chem. Rev. Fett u. Harz-Ind., 10 (1903), p. 223; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 7, p. 418*).—Analytical data are reported regarding salmon oil, which is manufactured in large quantities in British Columbia.

Studies on the odor of sprat oil and cod-liver oil, L. SERVAIS (*Chem. Rev. Fett u. Harz-Ind., 10 (1903), p. 231; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 7, pp. 418, 419*).—Chemical studies are briefly reported.

The detection of artificial coloring matters in foods and condiments, E. SPAETH (*Pharm. Centralhalle, 44 (1903), pp. 117, 118; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, p. 310*).—The use of sodium salicylate for the extraction of artificial coloring matter from jams, flour preparations, etc., is recommended.

Short text-book of food chemistry, RÖTTGER (*Kurzes Lehrbuch der Nahrungsmittelchemie. Leipzig: J. A. Barth, 1903, 2. ed., pp. 698; rev. in Hyg. Rundschau, 14 (1904), No. 6, p. 283*).—A new edition of this text-book.

Progress in the chemistry of the fermentation industries during the last three years, O. MOHR (*Ztschr. Angew. Chem., 17 (1904), Nos. 1, pp. 10–17; 2, pp. 49–51*).—A review.

Extracts from the proceedings of the Association of Official Agricultural Chemists, 1903 (*U. S. Dept. Agr., Bureau of Chemistry Circ. 13, pp. 14*).—This is an advance circular giving the recommendations of referees as adopted, and the motions and appointments affecting the work of 1904.

BOTANY.

The development and structure of vegetation, F. E. CLEMENTS (*Lincoln: Univ. Nebraska, Bot. Survey, 1904, No. 7, pp. 175*).—This constitutes an enunciation of the principles on phologeny and structure of vegetation, which have been the basis of the author's investigations covering a period of about 6 years. The principles were first given as hypotheses in 1898, and have been subject to constant test in the field since that time, the present publication giving the author's conclusions relating to plant ecology.

The principal portion of the work deals with the physical factors of the prairie formation in Nebraska. The principles of association, invasion, and zonation are discussed at length, and an attempt is made to systematically consider them in considerable detail as well as to introduce the principles of succession and alternation as factors in plant life. The author states that the various hypotheses have been repeatedly confirmed, and they are now presented as a working basis for those interested in similar lines of investigation.

The different factors discussed are association; invasion, which includes migration and what the author terms "ecesis," or the phenomena exhibited by the organism from the time of its introduction until it becomes thoroughly established in a formation; succession, zonation, and alternation. These are treated historically, after which the phenomena are discussed; and each chapter concludes with numerous references to the literature of the subject.

Nitrogen bacteria and legumes, C. G. HOPKINS (*Illinois Sta. Bul. 94, pp. 307–328, figs. 5*).—A description is given of the action of bacteria in the preparation of plant food for assimilation by the plant and the function of the nitrogen-gathering bacteria. The results of a number of investigations with red clover, cowpeas, soy beans, alfalfa, and sweet-clover bacteria are given. In many instances where failures have followed the attempt to secure a good growth of these plants, soil inoculation

has proved of great benefit. After a small portion of soil has been introduced and the plants develop tubers upon their roots, there seems to be a rather rapid spread of the organisms throughout the soil. For the growth of the different crops, applications of soil at the rate of from 200 lbs. to a ton per acre is recommended where the cost would not be too great. Smaller applications would hardly be expected to give a marked effect on the yield the first season, although the effect might be sufficient to secure a good growth during subsequent years.

A report is given of the effect of bacteria on the development of cowpeas, in which the dry matter and nitrogen content of the tops, roots, and tubercles of 10 average plants, grown with and without bacteria, were compared from 3 series of plants. In each case a decided increase in the amount of nitrogen was noted where bacteria were present. The experiments with alfalfa and sweet clover have shown that bacteria from sweet clover tubercles are very efficient as a source for the inoculation of alfalfa soils.

The author states that while some Illinois soils are becoming deficient in phosphorus and lime, ground limestone may be applied to such soils with marked benefit and profit, especially for the growing of legumes; but there is abundant evidence that one of the dominant causes of unsatisfactory growth is absence of the proper nitrogen-gathering bacteria. It is believed that the bacteria will not live indefinitely in the soils without the intervention of leguminous crops, but further investigation is needed to establish this fact.

Three edible toadstools, J. C. Arthur (*Indiana Sta. Bul. 98, pp. 45–50, pls. 7*).—The author describes *Coprinus micaceus*, *C. atramentarius*, and *C. comatus*, and gives suggestions for their collection and preparation for the table.

On the growth of higher plants in the presence of a mixture of algæ and bacteria, R. Bouilhac and E. Giustiniani (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 5, pp. 293–296*).—An account is given of experiments with buckwheat, white mustard, maize, and cresses, the results of which confirm those obtained in experiments previously reported (E. S. R., 15, p. 753), and show that nonleguminous plants are capable of utilizing the atmospheric nitrogen which is fixed by algæ and bacteria, the nitrogenous matter being produced by the micro-organisms with sufficient rapidity to permit rapid development of the higher plants.

METEOROLOGY—CLIMATOLOGY.

Meteorological observations, C. D. Woods (*Maine Sta. Bul. 99, pp. 210–212*).—A summary of monthly averages of observations at Orono, Me., during 1903, on atmospheric pressure, precipitation, cloudiness, and wind movement, with means for temperature and precipitation for 35 years, and monthly and annual precipitation for the same year at 20 different places in Maine. The annual summary for Orono is as follows: Pressure 29.81 in., temperature 42.83° F. (mean for 35 years 42.3), precipitation 37.61 in. (mean for 35 years 44.57 in.), snowfall 64.9 in. (average for 35 years 92.1).

Meteorological observations, J. E. Ostrander and F. F. Henshaw (*Massachusetts Sta. Met. Buls. 181, 182, 183, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during January, February, and March, 1904. The data are briefly discussed in general notes on the weather of each month.

Meteorological summary for 1902, C. A. Patton (*Ohio Sta. Bul. 143, pp. 131–143*).—This summary includes notes on the weather and tabulated daily and monthly records of observations at the station at Wooster, Ohio, on temperature, precipitation, cloudiness, direction of the wind, etc., and for comparison, similar

data for previous years and for other parts of the State. The following is a summary of results:

Summary of meteorological observations in Ohio.

	For the experiment station.		For the State.	
	1902.	1888–1902.	1902.	1883–1902.
Temperature (° F.):				
Mean	49.5	49.2	50.6	50.8
Highest	(May 4) 97.0	(Aug. 8, 1891) 99.0	(July 8) 100.0	(July 4, 1897) 113.0
Lowest	(Feb. 5) − 9.0	(Feb. 10, 1899) −21.0	(Feb. 14) −17.0	(Feb. 10, 1899) −39.0

Prevailing direction of wind.	SW.	SW.	SW.	SW.

Meteorological chart of the Great Lakes, A. J. HENRY and N. B. CONGER (*U. S. Dept. Agr., Weather Bureau, Meteorological Chart of the Great Lakes, 1903, No. 2, pp. 17, chart 1*).—This is the usual summary of observations for the season of 1903 on storms, atmospheric precipitation and lake levels, open and closing of navigation, wrecks and casualties, etc.

Rainfall at variety experiment stations, Barbados (*Rpt. Agr. Work, Imp. Dept. Agr. West Indies, 1901–1903, pp. 75, 76*).—Monthly rainfall (December, 1901, to May, 1903) at 10 different stations is reported.

Composition of Barbados rainfall (*Rpt. Agr. Work, Imp. Dept. Agr. West Indies, 1901–1903, p. 3*).—The monthly rainfall (December, 1901, to May, 1903) and the content of chlorin and nitrogen (ammonia and nitrates) are reported.

The weather during the agricultural year 1902–3, F. J. BRODIE (*Jour. Roy. Agr. Soc. England, 64 (1903), pp. 410–419*).—A general discussion with tabulated data on the weather conditions of Great Britain during the period.

The Philippine Islands and their people, H. GANNETT (*Nat. Geogr. Mag., 15 (1904), No. 3, pp. 91–112, figs. 13*).—Contains a section on the climate of the islands.

Simultaneous solar and terrestrial changes, J. N. LOCKYER (*Nature [London], 69 (1904), No. 1789, pp. 351–357; abs. in Science, n. ser., 19 (1904), No. 483, p. 556*).

AIR—WATER—SOILS.

On the presence of formaldehyde in the atmosphere, H. HENRIET (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 4, pp. 203–205*).—Observations at Montsouris observatory covering a period of one year, 1903, showed the presence in the air of 1 to 5 parts of formaldehyde to 100,000 parts by weight of air.

Potable waters in southwest Lancashire, J. C. BROWN (*Chem. News, 89 (1904), No. 2301, pp. 6–9*).—Detailed studies of a number of surface, deep-well, and shallow-well or spring waters are reported.

Soil treatment for peaty swamp lands, including reference to sand and "alkali" soils, C. G. HOPKINS (*Illinois Sta. Bul. 93, pp. 273–303, figs. 5*).—This bulletin summarizes the information regarding these lands which has been secured in connection with the general survey made by the station of Illinois soils, as well as the results of experiments made on a number of typical areas. It is shown that there are many thousand acres of peaty swamp land in northern and north central Illinois, much of which produces almost no crops on account of a deficiency of pot-

ash. Some of these soils after years of cultivation are found to be deficient in nitrogen, which can be most economically supplied by means of leguminous crops.

"Certain kinds of farm manure produce fairly good results on some peaty swamp soils, but commonly it is better farm practice to use the manure on other kinds of soil and buy potassium for the peaty swamp soils. . . . While heavy applications of potassium must sometimes be made at first, with proper management only light applications will be required after a few years. . . . The so-called 'alkali' soils of Illinois, which are also being investigated, are not the same as peaty swamp soils."

Treatment and utilization of flood-damaged lands, A. M. Ten Eyck, H. F. Roberts, and A. Dickens (*Kansas Sta. Bul. 121, pp. 133-162, figs. 16*).—A general description is given of the effects of the flood which lasted from May 28 to June 5, 1903. In addition to the direct loss of farm products and buildings, great damage was suffered in the washing away of fertile soils and covering of cultivated fields with sand to depths varying from a few inches to several feet. Some areas were covered with comparatively infertile mud and other areas were badly damaged by being so water soaked that elaborate systems of drainage became necessary.

General recommendations are made regarding the treatment of washed and buried lands so as to restore their fertility as far as possible. The greatest amount of washing naturally occurred on cultivated lands, while lands covered with alfalfa were little affected. Recommendations are also made regarding the use of sand-binding grasses for areas covered with sand. Under similar conditions comparatively quick returns may be obtained on planting trees suitable for post production. For this purpose catalpa, black locust, Osage orange, Carolina poplar, etc., were recommended.

On the distribution of potash in cultivated soil, J. Dumont (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 4, pp. 215-217*).—The results of determinations of potash in the particles of different degrees of fineness in two soils are reported. These show that in one soil five-sixths of the total potash occurred in the fine particles, the clay itself containing one-fifth. In the other soil seven-tenths of the potash was found in the coarser sand, the finer particles, and especially the clay, containing only a very small proportion. The bearing of these facts on the assimilability of the potash of the soil is briefly discussed.

Analyses of soils of São Paulo, G. d'Utra (*Bol. Agr. São Paulo, 4. ser., 1903, No. 12, pp. 551-557*).—Chemical analyses of 91 samples are reported.

FERTILIZERS.

The preservation of hen manure, C. D. Woods and J. M. Bartlett (*Maine Sta. Bul. 98, pp. 199-204*).—A compilation of analyses of hen manure is given, with results of tests of the efficiency of various preservative materials, including kainit, plaster (gypsum), acid phosphate, and sawdust. Both kainit and acid phosphate prevented practically all loss of nitrogen. The gypsum was somewhat less efficient. The use of sawdust materially improved the mechanical condition of the manure. The management and value of hen manure as a fertilizer are briefly discussed.

Barnyard manure, W. H. Beal (*U. S. Dept. Agr., Farmers' Bul. 192, pp. 32, figs. 4*).—A revision of Farmers' Bulletin 21 (E. S. R., 6, p. 521).

Fertilizers, A. M. Muckenfuss (*Arkansas Sta. Bul. 81, pp. 83-96*).—This bulletin reports analyses of fertilizers registered in Arkansas during 1904, with some general notes on the use of fertilizers.

Analyses of commercial fertilizers, M. A. Scovell et al. (*Kentucky Sta. Bul. 112, pp. 227-264*).—Results of analyses of 161 samples of fertilizers are reported. Of these, 27 samples, "representing 24 brands and 15 firms, fell so far below the guaranteed analyses in phosphoric acid, nitrogen, or potash, or any two or all three of these ingredients, that this could not be accounted for by variations in sampling or analysis."

Licensed commercial fertilizers, F. W. Woll (*Wisconsin Sta. Bul. 109, pp. 5, 9, 10*).—Analyses of 17 samples of fertilizers are reported, with the text of the State fertilizer law.

Special investigations on phosphates and the causes which modify their assimilability, C. Schreiber (*Recherches spéciales sur les phosphates et les causes qui modifient leur absorbabilité. Maeseyck: Vanderdonck-Robyns, 1903, pp. 35, fig. 1*).—Investigations extending over a series of years are reported which show that Thomas slag and mineral phosphates are more effective as fertilizers on acid peaty soils than superphosphates. Slag gives better results than precipitated phosphate, especially on sandy soils, and liming reduces the action of mineral phosphates but increases the assimilability of the phosphoric acid of humus soils.

On the rôle of phosphorus in mineral deposits, L. De Launay (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 5, pp. 308–310*).

The saline deposits of California, G. E. Bailey (*California State Min. Bureau Bul. 24, pp. 216, figs. 98, maps 5*).—This is a report of a geological reconnaissance of the southeastern portion of California, and deals with the general climatic and geologic conditions of the Great Basin, the deposits of borates, carbonates, chlorids, and nitrates of the region, with a list of elevations, a bibliography, and an account of the California State Mining Bureau.

The portion of this report relating to nitrates is of special agricultural interest. The similarity of the California nitrate beds to the Chilean deposits is pointed out. The history, location, quality, and extent of the California deposits are discussed. It is stated that nearly all the niter beds so far discovered are situated in the northern part of San Bernardino County, extending across the boundary line into the southern part of Inyo County. "They are found along the shore lines, or old beaches, that mark the boundary of Death Valley as it was during the Eocene times." Chemical analyses are reported which show percentages of niter varying from 7.28 to 61.2 associated with varying quantities of sodium chlorid, sodium sulphate, calcium sulphate, magnesium sulphate, and iodin compounds.

While it is not possible to estimate with any degree of accuracy the extent and value of these deposits, "the facts so far as obtained show the existence of quantities on a scale large enough to be of national interest. The analyses show that niter exists in some of the claims rich enough to rival the beds of Chile."

The Chilean nitrate trade (*Engineer. and Min. Jour., 77 (1904), No. 13, p. 510*).—The total export during 1903 is reported at 31,683,294 quintals (1,606,343.01 tons). Of this amount the United States consumed 5,914,275 quintals (299,853.74 tons).

The most profitable agriculture with the cheapest manuring, H. Droop (*Neue Bahnen in der Landwirthschaft, vol. 3. Lohnendster Ackerbau bei billigster Düngung. Heidelberg: Moriell, 1903, pp. IX+228, figs. 9*).

FIELD CROPS.

Alfalfa in Alabama, J. F. Duggar (*Alabama College Sta. Bul. 127, pp. 47, figs. 2*).—This bulletin discusses alfalfa culture in Alabama, describes the results of experiments made at the station, and presents the experience of a number of alfalfa growers in different parts of the State. Special mention is made of the Alabama soils adapted to the culture of this crop, and several methods of soil inoculation are outlined.

Estimates from different farmers indicate that usually after the first season 4 cuttings of alfalfa can be made, and that on good land a total of from 3 to 6 tons of hay per acre may be obtained. The first cutting is usually made about the first of May, and sometimes even earlier.

The author believes that from the data at hand well-drained black bottoms and drained alluvial lime bottoms with a little sand may be regarded as first class; black,

shelly gray, or rich chocolate uplands as second class; and poor, stiff red or post-oak land and poor gray to white prairie, as third-class alfalfa lands.

Tabulated results of fertilizer experiments made at the station show that 80 lbs. of nitrate of soda per acre, applied with the seed in the spring, was ineffective, while 6 tons of stable manure per acre, applied in February to fall-sown alfalfa, more than doubled the yield. In general spring and fall sown plats yielded at the rate of about 1 ton of hay per acre the first summer. A plat receiving 18 tons of stable manure per acre yielded 3.4 tons of hay per acre the third season after the application; and a plat given 20 bbls. of lime per acre, at the time the manure was applied to the other plat, gave practically the same yield. Large quantities of lime and manure applied together did not give an increase the third year after application as compared with either used alone. A plat of sandy soil of fair quality inoculated with earth from an old alfalfa field and treated with 1,000 lbs. of slaked lime per acre, gave a total yield for the season of 2,266 lbs. of hay per acre as compared with practically nothing on the check plats.

The general failure on all these plats was due to winterkilling. An adjacent plat sown with crimson clover at the time the alfalfa was sown yielded 6,100 lbs. of hay per acre, and produced that same season 13,000 lbs. of sorghum hay per acre. From cooperative experiments it is learned that on prairie lands an application of 200 lbs. of cotton-seed meal, 240 lbs. of acid phosphate, with 200 or 100 lbs. of kainit per acre has given good results with alfalfa. The use of stable manure also produced good yields.

Plants taken in April from plats sown the preceding October showed a large supply of tubercles on inoculated and limed soil, and an absence of tubercles on soil neither limed nor inoculated. It has been found that earth from melilotus or bur clover fields will serve to inoculate the soil for alfalfa.

From observations made during 8 years the author concludes that in central Alabama fall sowing of alfalfa should be done from September 15 to October 15, and spring sowing from March 1 to 20. Broadcasting 20 lbs. of seed per acre has in general given the best results at the station when the crop was grown for hay. When used for green feed small areas may be profitably drilled and cultivated. In some of the tests crab grass increased rapidly on the alfalfa plats from one cutting to another.

Directions for the breeding of corn, L. H. SMITH (*Illinois Sta. Circ. 74, pp. 10*).—This circular briefly describes the methods followed and recommended by the Illinois Station for the improvement of corn by systematic selection and breeding. This matter has been presented at greater length in previous publications of the station (E. S. R., 14, p. 855; 15, p. 352).

Kherson oats, T. L. LYON (*Nebraska Sta. Bul. 82, pp. 8*).—This Russian variety is described as being well suited to central and western Nebraska on account of its habits of growth. Results obtained at the station and by farmers throughout the State are reported. In 1900 this variety yielded at the rate of 52.6 bu. per acre on about 2 acres of land, standing first among a number of varieties grown in comparison. In 1902 it yielded 41.7 bu. per acre, being followed by Texas Red, and Sixty Day, another Russian variety, with yields of 33 and 29.6 bu. per acre, respectively. The varieties were all sown March 26, but the two Russian sorts were ripe July 5, while the Texas Red did not mature until July 16.

The result of a variety test conducted in 1903 places the Kherson oats at the head of the list, with a yield of 68 bu. per acre, followed by Texas Red, Canada Red, and Sixty Day with 57.5, 53.1, and 52.4 bu. per acre, respectively. The yields obtained in the cooperative tests which have been in progress for 3 years are given in a table.

Work of the experiment station and laboratories of the Hawaiian Sugar Planters' Association, C. F. ECKART (*Hawaiian [Sugar Planters'] Sta. Rpt. 1903, pp. 1-74, dgms. 2*).—This report includes further results of previously described work (E. S. R., 14, p. 565). As in former years Lahaina and Rose Bamboo cane were grown

in connection with these experiments. The yields obtained with different amounts of irrigation water is shown in the following table:

Volume of irrigation water in its relation to the yield of cane.

Irrigation.	Cane per acre, 1903.		Average weight of cane.		Average of 1901 and 1903.
	Lahaina.	Rose Bamboo.	1901.	1903.	
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*
One inch per week	146,362	118,425	308,805	132,393	220,599
Two inches per week	152,866	130,157	390,080	141,511	265,795
Three inches per week	160,882	136,778	285,343	148,830	217,086
Two inches every two weeks	141,773	121,349	328,657	131,561	230,109
Three inches every three weeks	115,579	118,077	226,170	116,828	171,499

Irrigation was discontinued when the rains were sufficient, and the volume of irrigation water as given in the table simply means the maximum quantity applied for the given period of time. Data with reference to soil moisture show that the plat receiving 1 in. of irrigation water per week contained on an average 30.84 per cent of water at 1 ft. in depth after irrigation, and 23.87 per cent before the next irrigation. The corresponding figures for the plats receiving 2 in. per week, 3 in. per week, and 3 in. in 3 weeks were 30.62 and 26.83, 35.90 and 31.81, and 32.74 and 16.73 per cent, respectively. The highest percentage of moisture, 31.38 per cent, was maintained in the plat irrigated at the rate of 3 in. per week, and the lowest, 27.43 per cent, in the plat irrigated at the rate of 3 in. in 3 weeks. In 1901 the plat receiving 2 in. per week produced the largest yield, while in 1903 the plat receiving 3 in. per week gave the best yield, but the total quantity of water received by the two plats was very much the same. Lahaina cane gave the best results with 3 in. of water per week and Rose Bamboo with 2 in. A series of tables is given showing analytical results, together with the quantities of water used per acre and per pound of sugar produced. Some of the data, being the averages for the 2 varieties, are shown in the following table:

Quantity of water in its relation to the production of sugar and solid matter.

Irrigation.	Water used per acre.	Sugar produced per acre.	Water per lb. of sugar.	Water per lb. of solid matter.
	Gallons.	*Pounds.*	*Gallons.*	*Gallons.*
One inch per week	3,571,022	21,911	163.9	39.9
Two inches per week	5,118,800	22,889	223.6	58.2
Three inches per week	6,666,578	23,992	277.8	71.0
Two inches every two weeks	3,652,484	22,258	164.1	41.0
Three inches every three weeks	3,733,946	19,184	194.6	46.5

Three inches of water per week furnished 57 in. of water more to the crop than 2 in. per week, and the difference in yield of sugar amounted to 1,103 lbs. This is equivalent to a requirement of 1,403 gal. of water for every additional pound of sugar produced under the heavier irrigation. A comparison of the results with 3 in. and 1 in. of water per week shows that 1,487 gal. were required per pound of increase. The author states that while the larger volumes of water gave an increase in sugar in these experiments, such increase would, under some conditions, be obtained at a loss.

The water-absorptive power of the station soil is given as 40.74 per cent, and at a depth of 1 ft. the soil on the 3 in. per week plat contained on an average 77 per cent of the water it could hold. The average results of 18 irrigations show that at 1 ft. in depth the soil contained 25.65 per cent of moisture before and 28.61 per

cent after irrigating. For 2 ft. in depth the corresponding figures were 29.67 and 31.99 per cent, and for 3 ft., 33.61 and 34.86 per cent, respectively.

Data obtained in experiments on saline irrigation are given, and some of the results are presented in the following table:

Irrigation experiments with salt water.

Salt per gallon.	Salt added per acre.	Cane per acre.	Purity of juice.	Sucrose in cane.	Sugar per acre.
Grains.	*Pounds.*	*Pounds.*	*Per cent.*	*Per cent.*	*Pounds.*
50	14,159	135,675	91.46	16.2	21,979
100	28,318	92,754	91.18	16.38	15,193
150	42,477	102,744	89.99	15.22	16,638
200	56,636	79,860	90.42	14.63	11,684

These results indicate that excessive quantities of salt in irrigation water reduce the yield and lessen the availability. The juices showed a material, though disproportionate, increase in chlorin as the salt was increased.

In the stripping experiments reported, one plat was stripped in June, 1901, one in March and October, 1902, and another in March, August, and November, 1902. The results are summarized in the following table:

Results of stripping experiments.

Number of strippings.	Cane per acre.	Sucrose in cane.	Sugar per acre.	Density (Brix).	Sucrose in juice.	Glucose in juice.	Purity.
	Pounds.	*Per cent.*	*Pounds.*	°	*Per cent.*	*Per cent.*	*Per ct.*
None	150,950	17.14	25,873	20.62	19.15	0.311	92.87
1	156,467	17.00	26,599	20.78	19.00	.258	91.43
2	142,586	17.45	24,881	21.18	19.50	.241	92.06
3	140,031	16.24	22,741	19.82	18.15	.369	91.57

These results, however, are not as yet considered conclusive or generally applicable and the experiments will be continued.

A preliminary report on 21 varieties of cane shows a wide divergence in quality and yield. The density of the juice varied from 20.47 to 14.20° Brix, the sucrose from 19.15 to 11.3 per cent, the glucose from 1.58 to 0.169 per cent, and the purity from 93.32 to 79.57. In productiveness, Demarara No. 117 headed the list with a yield of 333,670 lbs. of cane and 43,010 lbs. of sugar per acre; and Badilla, a New Guinea variety, stood last with a yield of 43,560 lbs. of cane and 7,466 lbs. of sugar. Bud variation in Big Ribbon cane is used for the production of new varieties, but the results in their present state are as yet inconclusive. The character of cane from seed cane of normal Big Ribbon and several of its sports is briefly described.

The results with fertilizer experiments in which the essential plant food elements are furnished in different combinations at the rate of 100 lbs. per acre are reported in exhaustive tables. These experiments are as yet incomplete, and no conclusions have been reached.

In a second fertilizer experiment, begun in June, 1901, nitrogen, phosphoric acid, and potash were each applied at the rate of 150 lbs. per acre. The test was made with Lahaina and Rose Bamboo cane harvested in April, 1903. Both varieties produced the most cane from nitrogen and phosphoric acid with potash omitted. This plat also gave the highest yield of sugar with Lahaina, while with Rose Bamboo the plat receiving the three elements owing to a superior quality of juice gave the best yield. Lahaina responded better to high fertilization than Rose Bamboo, the greatest gain in sugar with Lahaina being 6,053 lbs. and with Rose Bamboo only 900 lbs. The gains from fertilization in the solid matter of the cane ranged from 3,367 to 12,488 lbs. with Lahaina and from 678 to 1,973 lbs. with Rose Bamboo. The gain

in the solid matter of the leaves with Lahaina ranged from 11,452 to 13,528 lbs. and with Rose Bamboo from 6,324 to 12,521 lbs. The fertilization stimulated leaf growth in Rose Bamboo and in the case of its greatest gain in total solid matter, 14,494 lbs., 86 per cent was in the leaves, while the corresponding gain with Lahaina was 25,614 lbs., of which only 51 per cent was in the leaves.

Experiments in fertilization with 200 lbs. each of nitrogen, phosphoric acid, and potash in various combinations were made simultaneously with the experiments just described. These tests, made in duplicate, occupied 12 plats, 2 of which received no fertilizer. The largest gain with both varieties was made where the 3 elements were applied in the form of ground bone, nitrate of soda, and sulphate of potash. The average gain for the 2 varieties was 3,360 lbs. of sugar. In the experiments with 100 lbs. of each element, applied in the forms of nitrate of soda, double superphosphate and sulphate of potash, the average gain for the 2 varieties was 4,289 lbs. of sugar. The loss due to heavy fertilization was in some instances very material.

A report on fertilization containing data to which reference has been made in the experiments above noted is reproduced. This deals largely with statistics concerning the use of fertilizers in Hawaii and the value and the application of the results obtained at the station.

The sugar cane in Egypt, W. TIEMANN (*Altrincham, England: International Sugar Journal, 1903, pp. XI+74, pls. 16, figs. 9*).—This deals with general cultivation, the sugar content of the cane, tillage of the soil, manuring mediums, manuring of the sugar cane, the arrangement of field experiments, field experiments during 1897–1900.

The complete story of Vineland sweets (*Amer. Agr., 73 (1904), No. 13, pp. 367, 370, figs. 2*).—An account of methods observed in the culture of sweet potatoes at Vineland, N. J. In fertilizing this crop a formula is used which calls for about 3 per cent of ammonia, 8 per cent of phosphoric acid, and 10 per cent of potash, and costs from $28 to $30 a ton. The cost of fertilizing an acre is about $20. The fertilizer is scattered directly in the furrows and the rows ridged over it.

Wheat growing on the Laramie Plains, B. C. BUFFUM (*Wyoming Sta. Bul. 60, pp. 39, pls. 7*).—A description of the Laramie Plains is given, and culture and variety tests with wheat at Laramie are reviewed. During the several years the work has been in progress (E. S. R., 11, p. 547), over 500 varieties representing different types and species have been grown. In 1902 a field of spelt yielded 2,907 lbs. per acre, amounting to 48.5 bu. at 60 lbs. per bushel, but the weight per measured bushel is much lower. Polish wheat (*Triticum polonicum*) has given an average yield of 23.6 bu. per acre on the station farm; macaroni wheat (*T. durum*) produced 19.2 bu. per acre in 1902, and one variety, Kubanka, yielded at the rate of 31.3 bu. per acre. Of Egyptian wheat (*T. compositum*), the Sevenhead variety yielded 28.6 bu. per acre in a field trial. This species produced only ordinary yields and did not prove more prolific than other types of wheat. These, together with a list of varieties of common wheat (*T. vulgare*), have been successfully grown at an elevation of over 7,000 ft. Each species of wheat is briefly described.

Of more than 150 varieties of winter wheat none was found sufficiently hardy for the locality. Winter rye has been successfully grown. Attention is called to the importance of early varieties, and those which ripen later than the first week in September are not recommended. The earliest and best yielding varieties for a number of years are enumerated. Of 300 varieties in 1903, 60 were ripe before September 1. From all the trials made the author makes the following selection of varieties which he deems recommendable: *Smooth wheats*—White Russian, Velvet Chaff, Scotch Fife, Saskatchewan, Nox, Jacinth, Sonora, Australian Club, Chili, Niagara, Amethyst, and Defiance; *Bearded wheats*—Pride of America, Doty, Soft Australian, Champion, Moscow, and Bearded Onyx.

The adaptability of wheats to the conditions which obtain in the locality, by means of improvement through breeding and selection, is discussed. Quite com-

plete directions for the culture of wheat on the Laramie Plains and other plateau lands are given.

The manuring of grass lands, A. D. HALL (*Jour. Roy. Agr. Soc. England, 64 (1903), pp. 76–109, figs. 4*).—English experiments which have been made in recent years on the possibility of improving pasturage by different systems of manuring are summarized and discussed. Of the general conclusions, the following are of special interest:

"It is better to lay up the same land for hay each year, grazing the aftermath only, and, in the same way, always to graze other land rather than graze and hay in alternate years. In this way we obtain the fullest development of those grasses and clovers which are suited to haying and grazing, respectively. For the same reason the system of manuring once adopted should be varied as little as possible, for even manures as similar as nitrate of soda and sulphate of ammonia encourage different kinds of grass.

"On poor land any large expenditure on manures will be wasted; the character of the herbage must be slowly re-formed; a full manuring is only utilized when there are plenty of strong and vigorous grasses or clovers among the vegetation."

The estate of Quednau, an example of modern methods of cultivation, A. BACKHAUS (*Das Versuchsgut Quednau, ein Beispiel der Angewandten Modernen Betriebslehre. Berlin: Paul Parey, 1903, pp. 270, figs. 44*).—In this volume an account is presented of the opportunities offered on large agricultural estates for testing and applying modern methods of culture. Historical notes are given on the estate of Quednau. A detailed description is presented of the plan upon which the estate is laid out and of various experiments which have been organized and carried out, especially on the subjects of fertilizers, cultivation of cereals, grasses, and roots, feeding animals, electro-culture, and the control of weeds and fungus diseases.

HORTICULTURE.

Experiment on the manuring of cabbages (*County Council Northumberland, Education Com., Rpt. 1903, p. 102*).—Experiments in manuring cabbages were made on soil of medium loam from 15 to 18 in. deep. The field had not been manured previously for 40 years. The largest number of salable heads was secured on the plat fertilized with 30 tons of barnyard manure, 225 lbs. of sulphate of ammonia, 650 lbs. of basic slag, and 175 lbs. of muriate of potash. Fully as good results were obtained when 300 lbs. of nitrate of soda was used in place of the 225 lbs. of sulphate of ammonia. The increased yields obtained when these fertilizers were used were 10 tons greater than when 30 tons per acre of barnyard manure was used alone.

Experiment on the manuring of carrots (*County Council Northumberland, Education Com., Rpt. 1903, p. 103*).—The carrots were grown in rows 17 in. apart. The soil was so poor that heavy applications of manure were necessary. The best results were secured from the use of 30 tons of barnyard manure combined with 350 lbs. of slag, 110 lbs. of sulphate of ammonia, and 175 lbs. of muriate of potash. The yield in this case was about 25 per cent greater than where barnyard manure alone was used.

Burbank's new rhubarb (*California Fruit Grower, 29 (1904), No. 822, p. 1*).—A letter is quoted from Luther Burbank in which the characteristics of his recently produced variety of rhubarb are given. This variety produces edible stalks throughout the year. Instead of the strongly acid taste of the older varieties it has a fruity flavor resembling that of the strawberry or raspberry. The plant has not yet been sufficiently multiplied to permit of its introduction to the public.

Iron absorption by spinach; manuring with iron salts, O. VON CZADEK (*Ztschr. Landw. Versuchsw. Oesterr., 7 (1904), No. 2, pp. 65–67*).—An experiment was made to determine whether the iron content of plants could be increased by fertiliz-

ing them with iron salts. Three pots were filled with 11.5 kg. each of earth. One pot received in addition 0.5 per cent of iron hydrate and another 2 per cent of iron hydrate. The third pot was used as a control.

Spinach was grown in each pot. That in the pot containing 2 per cent of iron hydrate made a poor growth as compared with that in the other pots. The plants in all 3 pots were analyzed with reference to the amount of iron in the dry substance. Spinach grown in the control pot contained 0.03 per cent of iron; in the pot fertilized with 0.5 per cent of iron hydrate 0.18 per cent of iron, and in the pot fertilized with 2 per cent of iron hydrate 0.23 per cent of iron. It is thus seen that in both cases where iron salts were used the amount of iron in the plant was increased, although in the latter case the amount of iron used was excessive and injured the growth of the plants.

The results indicate that the iron content of certain plants may be increased, and this fact the author considers may be useful when it is desired to increase the content of iron in food used for medicinal purposes.

Field culture of watermelons and muskmelons in southern Russia, N. Kitschunow (*Möller's Deut. Gart. Ztg., 19 (1904), No. 8, pp. 91–94, figs. 5*).—An account is given of the methods observed in southern Russia in the field culture of watermelons and muskmelons, with descriptions and illustrations of a number of different varieties of each.

The garden and the orchard (*Bul. Maine Dept. Agr., 3 (1904), No. 1, pp. 53, figs. 2, dgm. 1*).—This consists of a number of popular articles on various phases of orcharding and gardening, with reports from the various counties of the State on the condition of crops.

Report of the School of Horticulture of Nova Scotia, F. C. Sears (*Halifax, Nova Scotia: School of Horticulture, 1904, pp. 82, pls. 4, figs. 8*).—This is an account of the attendance and work done at the School of Horticulture located at Wolfville, Nova Scotia, during the year 1903. Data are given as to meteorological conditions, fruit now growing in the orchards of the school and the results secured in the use of a number of cover crops, and on certain spraying experiments.

It has been found possible to completely eradicate black knot from a plum orchard which was so seriously affected as to suggest complete eradication as the only successful remedy. In the treatment of this disease all the trees the first year were cut back so severely as to remove all the knots, and in removing each knot the limb for 6 inches underneath was also removed. All the trimmings were then gathered and burned. During the summer the orchard was sprayed 3 times with Bordeaux mixture, and in the fall the knots were again removed and burned. The following season the knots were removed as soon as they appeared, and for this purpose the orchard was gone over twice, once in July and again in August. When the wood was soft it was found possible to pare off a knot instead of cutting away the entire branch on which it grew. This treatment appears to be effective in completely controlling the disease.

The results with cover crops indicated that crimson clover, tares or vetches, and alfalfa are the best cover crops for that province. Crimson clover is believed especially promising. The work of the school in establishing model orchards throughout Nova Scotia has been increased until at the present time there are 23 of these orchards. A table is given showing the number of trees of the different kinds of fruits planted which died during the winter of 1903.

Fruit trees frozen in 1904, M. B. Waite (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 51, pt. 3, pp. 7*).—The author gives an account of his examination of the orchards around Marlboro and Milton on the Hudson River, and also those located at South Glastonbury, Conn., with reference to the damage done to fruit buds by freezing during the winter, with suggestions as to the treatment to be followed in pruning the trees to overcome the effects of freezing.

Nearly 10 per cent of the peach orchards visited were found to be in a completely frozen condition and entirely dead. With others there was slightly less injury, while about a third of the trees were only moderately frozen. The trees most injured were usually those which were planted at low elevations. The injury was greatest above the snow line. It is believed that all those trees on which the bark is stuck tight about 2 ft. above the ground may be expected to live, and many which have the bark partially loosened may recover. Moderate pruning is recommended, to be followed by good cultivation, and unless the land is in very good condition a moderate amount of fertilizer should be added. It is believed that if the buds can push out in the tops growth will extend downward, and in many cases a complete covering of new sound wood can be obtained even over the most injured part on the trunk. Such trees even with dead, black hearts have been found to produce very satisfactorily in Michigan orchards.

"The aim should be, with good cultivation and fertilization, to grow the tree out of the injury. Stable manure will probably answer the requirement in some cases. Nitrate of soda at the rate of 200 lbs. per acre may be preferable in other cases. The choice of the writer would be a complete fertilizer consisting of nitrate of soda, acid phosphate or bone meal, and muriate of potash. Such a fertilizer applied just at the time growth is starting would result in the best possible benefit from the nitrate."

Japanese plums were injured to about the same extent as peaches, and should be handled in about the same manner. Domestic plums were not injured to any great extent. Injury to grapes was noticed to some extent, 2-year vines which reached above the snow line being apparently killed in some cases. In the nursery peach trees were frozen down to the snow line, and all that portion above the snow killed. Such stock is considered perfectly satisfactory for low-headed trees. Where the trees have less than 6 in. of live wood it may be desirable to allow one sprout to grow, and train up a new tree from this sprout after planting in the orchard. Japanese plums in the nursery were killed to about the same extent as peaches. They should be treated in the same way.

Only a few nursery apple trees were hurt sufficiently to cause their rejection. Pear trees were found very severely damaged in the Hudson Valley, apparently to a greater extent than peaches. Pear trees do not possess the same ability to overcome the effects of freezing that peaches do. It is recommended, therefore, that trees under 2 or 3 years of age which are badly frozen should be cut off below the snow line and allowed to sprout.

"All the sprouts that start may be permitted to grow the first year, and if a tall head is preferred they may be pinched back, except the one which is to form the new stem, when they have grown a foot or so. The foliage from these pinched shoots will help contribute to the life and vigor of the tree. In case of badly frozen bearing trees, where the tree is dead and the bark is discolored, of course, they should be dug out; but where there is any vitality left in the bark it may be well to allow the trees to remain at least the first season until it can be determined to what extent they are injured. It takes several years to bring a pear tree into bearing—at least two or three times as long as a peach tree—and one should therefore be correspondingly cautious in cutting down pear trees."

Securing hardy apple roots, A. T. ERWIN (*Orange Judd Farmer, 36 (1904), No. 9, p. 252*).—Attention is called by the author to the serious problem of the root killing of apples in the Northwest. In the East apples are propagated for the most part on French stocks. Experiments are cited in which it is shown that American stocks are much hardier in the Northwest than French stocks, and that the roots of seedling apples grown from Vermont seed are more vigorous and hardier than imported French seedling roots. Farmers are urged to save their apple seeds, especially of the varieties Duchess and Wealthy, and dispose of them to nurserymen who in general are alive to the greater value and hardiness of American stocks.

Stringfellow trees, H. W. Collingwood (*Rural New Yorker, 63 (1904), No. 2824, pp. 206, 217, figs. 5*).—The author gives an account of the planting and growth of a large number of peach trees which were root pruned and set out according to the Stringfellow method; that is, the tops were cut back to a stick 12 to 15 in. long and all side roots cut off so as to leave a stem below ground "as smooth as a lead pencil."

The field in which these trees were set consisted of very light and stony land that had not been plowed for 30 years. Part of it was so poor that only a few coarse weeds would grow on it, while another part was covered with brush and small trees. Before setting out the trees the field was not cleared except for a small space about each tree. In setting the trees the holes were made about 10 in. deep with a crowbar; a little sand was then put in and then the peach tree. More sand was put about the tree, water poured in, and the hole was filled up with earth, packing it firmly around the stub thus planted.

The behavior of trees so treated during the first and second years is noted in detail, and illustrations given of some of the trees. Relative to the final results the author states the case as follows: "From my experience I conclude that trees will certainly live when planted in this way. With me they root deeper and head lower than trees with long roots in large holes. I am quite sure of this. They make a slower growth the first season, but when fully established make wood enough for practical purposes. This method of planting is rapid and cheap. The chief disadvantages that occur to me are as follows: With the small crowbar hole you are likely to leave an air space at the bottom of the root. This will kill or stunt the tree. With a larger hole you can be sure that the soil is packed firmly around the root. While I think the tree without any side roots and packed in a small hole will root deeper, it is better in our practice to leave stubs from 1 to 2 in. long at the side. This anchors the tree firmly in the soil. It will not be whirled about by the wind or lifted by the frost."

Picking and packing apples, C. S. Crandall (*Trans. Illinois Hort. Soc., n. ser., 37 (1903), pp. 575–591*).—Directions are given for picking and packing apples, with statistics on results obtained from an examination of 45 barrels of apples with regard to uniformity in size of fruits, defects caused by decay, apple scab, codling moth, and curculio.

The apple package, J. C. Blair (*Trans. Illinois Hort. Soc., n. ser., 37 (1903), pp. 143–168*).—The author collected a large number of packages of apples as put upon the market from a number of different sections of the United States. The measurements of these are given and the methods observed in packing described. In addition, a discussion is given of the relative value of boxes and barrels in marketing apples, and many quotations taken from trade publications are given.

The results are also given of experiments made at the experiment station at Urbana in packing apples in boxes and selling in the Chicago market. Relative to the value of boxes for apples, the opinion appears to be quite general that only fancy grades of apples should be put up in these fancy packages.

Growing Flat China peaches from seed, G. Monks (*Queensland Agr. Jour., 14 (1904), No. 2, p. 132*).—An account is given of growing Flat China peaches from seed. Many of the seeds would not germinate until after they were cracked. It is especially noted that they fruited true to variety.

Persimmons, A. Dickens (*Industrialist, 30 (1904), No. 20, pp. 307–316, figs. 8*).—A general article on the persimmon, with an account of experiments in growing seedling persimmons at the Kansas Experiment Station. Illustrations showing the seedlings at different stages of growth and the characteristics of flowers, fruit, and tree are included. The average growth of the seedling has been about 18 in. the first year.

Some seedlings at the station have borne only sterile flowers. "The idea that the sterile-flowered trees are necessary for the successful pollination of the others seems

to be erroneous, for trees growing miles from a sterile-flowered one are known to have borne good crops of fruit regularly." In these investigations blossoms of the perfect-flowered varieties have been covered to insure self-pollination, and fruits have been thus secured. It is stated that sterile-flowered trees may be top-grafted with scions from bearing trees. No difference has been noted in the fruit produced from imperfect pistillate flowers and fruit from perfect flowers.

The varieties Daniel Boone, Early Bearing, and Hicks bore fruit 4 years after grafting and 2 years after setting in the orchard. Notes taken from the station records are given on American Honey Seedling, Daniel Boone, Early Bearing, and Hicks.

An experience with persimmon seeds, F. O. HARRINGTON (*Rural New Yorker, 63 (1904), No. 2824, p. 207*).—The author states that he has been successful in sprouting persimmon seeds only after subjecting them to the softening influence of frost. It is thought, however, that they may sprout when treated in the same manner as the dry seed of honey and black locusts. With the latter, the author puts the seeds in a pan and pours on a couple of quarts of boiling water. It is allowed to stand in this 24 hours, when the water is poured off and boiling water again poured on, and the process repeated 24 hours later. It is thought that persimmon seed thus treated would be likely to grow without subjecting it to freezing.

The fig in Georgia, H. N. STARNES (*Georgia Sta. Bul. 61, pp. 47–74, pls. 15*).—The author classifies the various kinds of figs grown in this country, gives detailed directions for the culture of figs in the South, and presents a system of classification of the figs commonly grown in the South based on the form of the leaf.

Some 25 or 26 varieties of figs have been grown at the station and these have been grouped into 5 classes known as Okra, Maple, Spoon-bill, and Oak-leaf types. Illustrations are given of the leaves of the different types and of each variety within the type. Twenty-five varieties grown at the station are described in detail. The idea involved is to systematize present knowledge of varieties and to establish a basis for a more correct nomenclature for southern figs. Plate illustrations are given of the fruit of 18 varieties of figs, of correct methods of pruning figs in the South, and of fig cuttings.

Fertilizer experiments with pineapples and bananas (*Ann. Rpt. Dept. Pub. Gardens and Plantations and Bd. Agr. [Jamaica], 1903, pp. 16–19*).—The tabulated results secured in experiments in 6 different localities with pines and in 9 different localities with bananas, using from 1 to 13 different fertilizer formulas in each case, are given.

In only one case with pineapples was the addition of fertilizers to the soil found beneficial. In one of the experiments in which a test was made of the effect of fertilizers on "monstrous" plants, the results indicated that neither slag, superphosphate, mixed phosphate, or sulphate of potash had any effect in checking the formation of such fruits. With the bananas a number of soils were found on which the addition of fertilizers proved effective in securing increased crops.

A chemical manure for the banana (*Jour. Jamaica Agr. Soc., 8 (1904), No. 3, pp. 97, 98*).—This article is based on the report of M. Teissonnier, director of the Experimental Garden at Conakry, French Guinea, and relates to the manuring of the banana plant in that State. The soils in Guinea in general are lacking in potash and phosphoric acid.

The formula which has been definitely determined upon after 2 years' experimentation at the experimental garden is as follows: Nitrogen 5.47 per cent, potash 11.02 per cent, phosphoric acid 10.2 per cent, and lime 8.17 per cent. About 13 lbs. of this mixture is applied to each clump of bananas during the dry season in fractional applications, 2 lbs. being applied per month. In addition to this it is recommended that the plants receive twice yearly composts of barnyard manure. The cost of manuring is about 1½ francs for each clump of bananas, or about 1,500 francs per hectare per year.

Cultivation of temperate fruit in the West Indies (*Agr. News [Barbados], 3 (1904), No. 48, p. 55*).—Some data are given on the success obtained in the culture of a number of temperate fruits at different elevations in the West Indies. It appears that strawberries may be successfully grown on low lands, while with other fruit like apples, cherries, pears, etc., success is only attained at the higher elevations, and then only to a limited extent. It is believed doubtful to grow these fruits on a remunerative scale.

Chemistry of the dog rose, K. Wittmann (*Ztschr. Landw. Versuchsw. Oesterr., 7 (1904), No. 2, pp. 68–74*).—The fruit of the dog rose (*Rosa canina*), which is sometimes used in preserves, was analyzed by the author with reference to food constituents of the fruit and mineral matter in the ash. Samples of these fruits were obtained in different years and in a number of different localities, and the results of the analyses of these are tabulated.

Averaging the data the results appear as follows: Water 32 per cent, extract 30 per cent. The dried fruit contained 6 per cent of albumin, 5 per cent of acid, 3.5 per cent of tannin, 18 per cent of sugar, and 3 per cent of ash. Attention is called to the fact that the more common orchard fruits seldom contain more than 0.5 per cent of ash. The lime and ash of the dog fruit varied from 23.18 to 29.41 per cent, the potash from 2 to 4.5 per cent, and the phosphoric acid averaged about 9.4 per cent.

An experiment in shading strawberries, O. M. Taylor and V. A. Clark (*New York State Sta. Bul. 246, pp. 35–58, pls. 2*).—An account is given of the growing of strawberries under shade for two seasons in three different localities in New York. The material used for shading was a thin kind of cheese cloth known as "Bombay." It cost about 4 cts. a yard, and when sewed together and hemmed, with rings attached for securing it, the first cost was at the rate of about $350 per acre. The cover was stretched about 20 in. above the ground. A heavier grade of cloth was used in one experiment.

A record is given showing the temperature of the air underneath the cloth and outside, cloudiness, and evaporation. Generally speaking, the temperature of the air underneath the cloth was a little higher than outside. This was especially true on bright, sunshiny days. For the whole period the temperature underneath the cloth averaged 2.8° higher than outside. The temperature of the soil averaged 1.4° warmer in the morning and 1° warmer at night under the cover than outside. The ground was slightly more moist and the air more humid underneath the cloth than outside. The cloth tempered the severity of the wind so that when a stiff breeze was blowing outside there was not enough wind under the cover to move a sheet of paper lying on the ground. The intensity of light was considerably modified by the covering, while the evaporation was diminished about half, the figures for 19 days being an evaporation of 5⅛ in. in the open and 2½ in. underneath the cover.

The strawberry plants developed normally underneath the shade. This was especially marked during the dry season of 1903, when many plants in the open were killed or seriously injured. As the result of a heavy frost it was observed that many of the leaves and all of the buds of any size not under the cover were dead, while underneath the shade none of the leaves were injured. The injury to the buds of Wilson and Haverland was as follows: With Wilson only 8.6 per cent of the buds shaded were injured, while 80 per cent of those not shaded were injured; with Haverland 6.5 per cent of the shaded buds were injured, while of those not shaded 89.4 per cent were injured. Shading appeared to slightly increase the susceptibility of strawberry plants to leaf blight, and in one case more mildew was observed under the shade than outside. Pollination of the plants was as complete underneath the covering as outside.

As regards the yield, only when thin cheese cloth shade was employed was there any increase. With the heavier grade of cloth there was a marked decrease in yield with every variety grown, and in no case was the increase in yield sufficient to com-

pensate for the cost of the shade. In the case of the lighter grade of cheese cloth there was a considerable increase in the size of the berries obtained; but with the heavier grade no difference was observable in the size of the berries grown underneath the cloth and outside. With the lighter cloth 13 qts. picked underneath the canvas contained 1,102 berries, while 13 qts. picked outside contained 1,452 berries, which shows that the berries were about 15 per cent larger from the shaded plants.

The shaded berries appeared to be a little brighter and glossier than those grown outside, but the difference was not marked. The texture of the berries was not noticeably different except in the case of Marshall, which appeared to be softer and more melting in the mouth than those grown outside. Shaded Ridgeway berries were also softer than those grown outside, and their shipping quality was injured. Analyses were made of berries grown under shade and those grown in the open. The following table shows the comparative composition of the two sorts:

Acid and sugar content of shaded and unshaded strawberries.

	Acid as malic acid.	Sugar as invert sugar.
	Per cent.	*Per cent.*
Marshall:		
Not shaded	1.38	6.54
Shaded	1.27	6.11
Ridgeway:		
Not shaded	1.64	6.35
Shaded	1.59	5.56

From the data given in the above table it is seen that the shaded berries, while slightly less acid than those grown in the open, also contained a smaller percentage of sugar.

In conclusion the authors discuss the effects of shading on plants in general, and the general applicability of shading as a cultural practice. It is believed that shading as a horticultural practice is likely to be most useful in localities having a high percentage of sunshine, a rather light rainfall, and considerable wind with a consequent high rate of evaporation. These conditions are most prevalent in much of the Southwest.

Shading strawberries, F. H. HALL, O. M. TAYLOR, and V. A. CLARK (*New York State Sta. Bul. 246, popular ed., pp. 8, fig. 1*).—A popular summary of the above bulletin.

Some experiments in ringing the Zante, A. J. PERKINS (*Jour. Agr. and Ind. South Australia, 7 (1904), No. 7, pp. 383–385, figs. 3*).—Attention is called to the defective healing of the wounds made when Zante currant vines are ringed and the wounds left exposed to the direct rays of the sun. It was believed that if the wounds were covered over they would heal better. Experiments were therefore made in covering the wounds with grafting wax, bandaging over with a strip of waxed calico, and coating with wax and then bandaging over with waxed calico.

Three weeks after the operations were performed the wounds that had been simply waxed had begun to callus over, while those that had been bandaged had completely healed. No difference was observed between the healing of the wounds that had been simply bandaged and those that had been both waxed and bandaged. As the setting and development of the fruit was equally good on all vines, and as the injury resulting from the wounds which healed over rapidly must have been less serious than where they healed over more slowly, as was the case when the wound was left uncovered, the practice of bandaging is strongly recommended.

It is believed that in ringing by this method a girdle of bark ⅛ to ¼ in. in width may be safely removed if immediately bandaged with waxed cloth. It is considered easier to make this comparatively wide girdle and bandage it than to make a very narrow girdle and not bandage.

The effects of grafting on grapes, L. DANIEL and C. LAURENT (*Jour. Agr. Prat., n. ser., 7 (1904), No. 9, pp. 293, 294*).—Some notes are given on the changes observed in the structure of the leaves of vines as a result of grafting. Analyses are also given of wines obtained from grapes of the same variety grafted on Rupestis du Lot and on 41B Millardet. From the data given the authors conclude that the wine obtained from grafted vines differs sensibly from the wine obtained from vines that have not been grafted. The variations of the different constituents are dependent upon the nature of the varieties.

End-to-end grafting of vines. Tests at Elsenburg, F. T. BIOLETTI (*Agr. Jour. Cape Good Hope, 24 (1904), No. 3, pp. 330–335, figs. 4*).—In experiments at the college it has been found that a skillful grafter could make 300 end-to-end grafts per hour, while by the method of tongue grafting, usually employed, 100 grafts per hour was rapid work. Students who had never grafted before were able to make but 15 tongue grafts with grapes, while by the end-to-end method they averaged 120 grafts per hour.

When grape grafts made by the 2 methods were set in the field there was but little difference observed in their growth when made by skilled workmen. In the case of unskilled workmen the end-to-end grafts grew almost as well as those made by the skilled grafters, while the growth of ordinary tongue-grafted grapes made by unskilled workmen were almost a total failure. When the grafts were uncovered to remove the scion roots it was found that the roots were less numerous on the end-to-end grafts and the work was also much facilitated and hastened by the absence of tying material. On the whole, the results are believed to be much in favor of the end-to-end method of grafting.

Detailed directions are given for end-to-end grafts, and plans shown by which stock and scion may be regularly cut at the same angle, and thus fit more perfectly.

Wine statistics for 1900 and 1901 (*Arb. K. Gesundheitsamte, 20 (1903), No. 2, pp. 155–242*).—Analyses are given of a large number of wines grown in the different parts of Germany in the years 1900 and 1901. The locality from which the wine was made, the variety of grapes used, and the character of the soil on which the grapes grew are given in each instance.

The Jordan and the almond industry, F. GILLET (*Pacific Rural Press, 67 (1904), No. 9, pp. 132, 133*).—The author has planted, in cooperation with this Department, a number of Jordan almond trees and distributed propagating wood to a large number of growers in California. He has also collected information on the amount of almonds imported into the United States from various countries, the comparative weight of nuts and kernels of different varieties of almonds, and other information on the planting of Jordan almonds and its probable adaptability to California conditions.

The Jordan almond is principally used for sugared and blanched almonds. It is imported into this country almost entirely as shelled almonds. There are 6 grades, varying in size from the first grade or "Mammoth" to the sixth or smallest grade, known as "Donkeys." It requires about 75 Jordan almonds for a pound. These contain about 3½ oz. of kernel. It is thus seen that it requires about 4 lbs. of Jordan almonds to produce 1 lb. of shelled kernels; while with the Nonpareil variety, which contains about 240 nuts per pound, 2 lbs. will produce a pound of shelled almonds. The author has found the Jordan the earliest variety of almond to bloom on the Pacific coast. It is believed there will always be a demand for this variety, though the quality may not be quite as good as that of the imported nuts. This, however, is a matter which is still to be determined.

Trees and fruit in North Dakota, C. B. WALDRON (*North Dakota Sta. Bul. 59, pp. 355–385, figs. 7*).—The value of trees and shrubs about the home for ornamentation is pointed out, as well as the necessity of windbreaks of shrubs and trees for growing fruit in North Dakota. Methods of planting trees, size and cost of trees, best methods of cultivation, and the kind of trees most useful for planting in North

Dakota, are discussed. Trees planted for groves should be spaced about 2 ft. apart in the row, with the rows about 8 ft. apart. The elm, ash, and basswood may be used for permanent trees; while trees like the box elder, which makes a quick growth, may be used simply as nurse trees.

Every other tree in the row should be a nurse tree. Other timber trees successful in North Dakota are the silver maple, white willow, golden Russian willow, burr oak, white poplar, hackberry, and American white birch. Directions are given for planting trees in lawns and along streets, and for the best methods of pruning.

The best methods of growing and pruning ornamental and protective hedges are discussed, and also the various kinds of shrubs and trees which may be used for this purpose. The golden Russian willow is considered especially satisfactory for hedges, since it grows readily from cuttings and is very ornamental, and when desired will develop sufficiently to furnish protection for stock.

Strawberries have been successfully grown nearly every year since the station windbreaks have grown large enough to afford protection. For this fruit the shelter should be along the south, as destructive winds come from that quarter. Of the strawberries which have been grown the heaviest yielding varieties mentioned in the decreasing order of their productiveness are Warfield, Tennessee, Prolific, Emperor, Senator Dunlap, Sample, Wm. Belt, Beder Wood, Drouth King, and New York. A very large number of wild plums are growing at the station, and these have proved a very satisfactory fruit.

Some Russian apples have been grown, and in addition Lyman Prolific, Wealthy, Patten Greening, and several crabs as well as other varieties of apples. Apples appear to do best when headed very low. Trees which are headed right at the ground after the original tree has been killed back often prove the most profitable. In setting out trees in Dakota it appears desirable to plant them from 6 in. to a foot deeper than they grew in the nursery. It is not thought advisable to attempt to grow apples without a shelter belt on the south and west side of the orchard. Two-year-old trees, or even root grafts, are believed most suitable for setting out in the orchard.

Trees and shrubs for shade and ornament, F. CRANEFIELD (*Wisconsin Sta. Bul. 108, pp. 60, figs. 47*).—The author discusses the characteristics and value of a large number of trees and shrubs which may be grown for shade and ornament in Wisconsin. Numerous illustrations are given showing the various effects which may be obtained in using different trees and shrubs. The appendix contains lists of the deciduous and evergreen trees and shrubs which have been tested at the station and found satisfactory, as well as a list of those which have been found unsatisfactory. In addition, a list is given of native shrubs desirable for planting on home grounds, and tables showing the comparative height at maturity of different shrubs.

Forcing lilacs after preliminary etherization, G. BELLAIR (*Rev. Hort.* [*Paris*], *76* (*1904*), *No. 4, p. 84*).—In the experiments here noted lilacs etherized for 89 hours flowered 17 days after putting in the forcing house. Snowballs (*Viburnum opulus sterilis*) etherized for the same period attained full flower development 25 days after putting in the forcing house. In these experiments the lilacs were forced at a temperature of 25° C.

DISEASES OF PLANTS.

Potato experiments in 1903, C. D. WOODS (*Maine Sta. Bul. 98, pp. 181–192*).—The experiments reported in this bulletin include a variety test of resistance to blight, study of the effect of Bug Death and Paris green on healthy potatoes and the use of prepared and quick lime in the preparation of Bordeaux mixture. Several rows of a number of varieties of potatoes were planted, a few of each variety being sprayed with Paris green to kill potato beetles and the other half being sprayed with Bordeaux mixture and Paris green. The latter application was made six times during the season.

The results of these experiments are presented in tabular form. It was found that there was a marked difference in the resisting power of different varieties to blight. As a rule early varieties were first attacked. The yield from early varieties was about the same whether dug in September or October, while the yield of late varieties was greatest when dug at the latter date. The yield was sufficiently increased to more than repay the cost of spraying. Bug Death at the rate of 25 pounds per acre for each application was sufficient to destroy the potato beetles, but no larger yields were obtained when this material was used than when the potatoes were sprayed with Paris green. It was found that prepared lime was more convenient to use than lump lime. The cost per pound was greater, but its use caused a saving in time.

Studies in potato rosette, II, A. D. SELBY (*Ohio Sta. Bul. 145, pp. 15–28, figs. 4*).—In continuation of a report on potato rosette (E. S. R., 15, p. 268), an account is given of experiments conducted in 1903 for the prevention of this disease. Rosette seems to be almost universal in its occurrence on early potatoes, causing from 5 to 25 per cent of the plants to be diseased. The preliminary experiments with formalin for the prevention of this disease were so promising that they were continued and comparisons made with formalin, sodium sulphid, lime, potassium sulphid, and corrosive sublimate. Three varieties of potatoes were used in the experiments, the conditions of the different lots being made the same as nearly as possible.

Summing up the results, the author says that they are somewhat variable where the tubers were planted on badly infected soil, but strongly marked and decisive where planted on uncontaminated soil. The results obtained do not show any great difference between the efficiency of sodium sulphid and formalin as a means of treating the seed tubers, yet the simplicity of the formalin treatment is decidedly in its favor.

Investigations in rotation have shown that a three-crop rotation of potatoes is not sufficient for the elimination of this disease. The author recommends for the prevention of potato rosette that all seed potatoes be treated before planting by immersing them for 2 hours in a solution of formalin containing 1 lb. of formalin in 30 gal. of water.

A brief description is given of tomato rosette and a rosette disease of lettuce, both of which are to be the subject of future investigation.

Leaf spot of tobacco, C. J. KONING (*Bladvlekken op Tabak. Amsterdam: J. H. de Bussey, 1903, pp. 8, pl. 1*).—The appearance of this disease is briefly described and notes given on its distribution. The author observed that infection frequently took place through injuries in the leaves caused by the rubbing of leaves together during wind storms.

The bitter rot of apples, W. B. ALWOOD (*Virginia Sta. Bul. 142, pp. 249–279, figs. 15*).—A discussion is given regarding the scientific and common name for the fungus which causes this disease. The author adopts the name *Glomorella rufomaculans*. The fungus is most injurious to fruit, both grape and apple, when nearly at maturity, but it is often observed at much earlier stages. In badly infested orchards composed of unusually susceptible varieties of apple trees, the disease can not be readily controlled. Detailed notes are given on the appearance of the disease, the microscopic character of the fungus, germination of the spores, and character of the mycelium.

In studying the sources of infection evidence was obtained that mummied fruits are largely responsible for spreading the disease. No evidence was obtained to show that cankers on the branches were connected with this disease. Bitter rot was found on trees where no cankered limbs could be discovered, and vice versa. Among the most susceptible varieties are the Albemarle Pippin, York Imperial, Ben Davis, and Winesap. In controlling this disease it is recommended that mummied fruits be removed and destroyed and the trees sprayed with Bordeaux mixture after July 1. Winter treatments appear to have no beneficial results.

Wither-tip and other diseases of citrus trees and fruits caused by Colletotrichum glœosporioides, P. H. ROLFS (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 52, pp. 22, pls. 6*).—During experiments carried out by the author it was found that this fungus was the cause of wither-tip on orange, pomelo, and lemon twigs; leaf spot on the leaves of various citrus trees; and anthracnose on lime blossoms and fruit twigs and on lemon twigs, as well as lemon spot on ripe lemons and canker on limes. These various troubles must, therefore, be considered as different forms of the same disease.

The disease occurs in Florida, West Indies, South America, Australia, and Malta, and causes extensive injuries in some localities. Infection apparently takes place at the tip of twigs or at the edge of the leaf. Fruit infection may be due to bruising the skin. The lime is the most seriously attacked of the various citrus trees. Notes are given on the dangers of infection in lemons while in the coloring house or coloring bed.

The measures to be adopted in preventing the disease depend upon its form. For lemon spot, sulphur spray is recommended as well as ammoniacal solution of copper carbonate. Lime trees may be sprayed with Bordeaux mixture. In isolated trees affected twigs may be cut out and destroyed. Beneficial results may also be obtained from thorough cultivation and from the use of fertilizers which contain plenty of potash.

A Glœosporium rot of cherries, A. OSTERWALDER (*Centbl. Bakt. u. Par., 2. Abt., 11 (1903), No. 6-7, pp. 225, 226, pl. 1*).—A brief account is given of a disease of both red and black cherries, which is said to be due to a species of Glœosporium. The fungus produces a very characteristic appearance upon the fruit and develops a conspicuous stroma beneath the epidermis. The mycelium is colorless. A technical description of the organism is given, and it is compared with *G. fructigenum* and *G. versicolor* which are probably identical, as shown by the investigations of several authors. Infection experiments showed that spores introduced into cherries produced the characteristic spots within 5 to 10 days.

Lectures on the diseases of the sugar cane, L. LEWTON-BRAIN (*Imp. Dept. Agr. West Indies, Pamphlet 29, 1904, pp. 51, fig. 1*).—A series of lectures delivered before the Barbados Agricultural Society, in which the structure and functions of the various parts of the sugar-cane plant are described, and the effects produced by fungi and other agents in destroying the normal activities of the plant are shown.

Following the preliminary statements, three of the more destructive cane diseases are described and suggestions given for combating them. Those described are the rind disease, due to *Trichosphæria sacchari*, the pineapple disease caused by *Thielariopsis ethaceticus*, and the root disease caused by *Marasmius sacchari*. Care in selecting seed cane, cultivation, and rotation where the disease has gained a foothold are recommended, as well as treatment of the cuttings with Bordeaux mixture before planting. The use of this fungicide for preventing attacks of the pineapple disease has given good results. Where the fungi have become well established all diseased canes, trash, etc., should be rigorously destroyed by burning.

ENTOMOLOGY.

Third report of the State entomologist, W. E. BRITTON (*Connecticut State Sta. Rpt. 1903, pt. 3, pp. 199-286, pls. 8, figs. 16*).—A copy is presented of the insect pest law of the State of Connecticut and notes are given on the organization of the office of the State entomologist, publications of this office, and inspection of nurseries. It is hinted that a compulsory fumigation law is contemplated. The nurseries in Connecticut are said to be in about the same condition as during the season of 1902.

A general review is presented of insect conditions during the year under report, with special reference to plant lice, scale insects, tent caterpillars, elm-leaf beetles, etc.

Directions are given for sending insects by mail and a tabulated list is presented of insects and other pests received by the State entomologist for identification. Bulletins 143 of the station (E. S. R., 15, p. 58) and 144 (E. S. R., 15, p. 594) are reprinted. Brief notes are also given on apple aphis, pear psylla, onion thrips, currant borer, cabbage butterfly, *Phengodes laticollis*, etc.

Fourth report of the State entomologist and plant pathologist of Virginia, J. L. Phillips (*Virginia Sta. Spec. Bul., 1903, pp. 63, figs. 13*).—A copy is given of the amended crop-pest law of Virginia and of the rules and regulations which define the duties of the State entomologist.

The field work during the 2 years (1901–1903) covered by this report included the inspection of nurseries and orchards for the purpose of learning the extent and severity of infestation by the San José scale and various insecticide operations in combating this insect. The chief insecticides used were kerosene emulsion, whale-oil soap, and lime-sulphur wash, from all of which satisfactory results were obtained. Recommendations are made concerning the formulas for use in preparing these insecticides. Brief notes are also given on natural enemies of the San José scale and on crown gall of apples.

Monthly bulletin of the division of zoology, H. A. Surface (*Pennsylvania State Dept. Agr., Mo. Bul. Div. Zool., 1 (1904), No. 11–12, pp. 64, pls. 8, figs. 9*).—Notes are given on methods of preventing various plant diseases and on injurious insects such as San José scale, scurfy scale, oyster-shell bark-louse, apple-tree tent caterpillar, etc. Mention is made of the natural enemies of these insects and most efficient means for combating them. Brief notes are also given on bee keeping, spring frosts, and migration of native birds.

Monthly bulletin of the division of zoology, H. A. Surface (*Pennsylvania State Dept. Agr., Mo. Bul. Div. Zool., 2 (1904), No. 1, pp. 32, pls. 4, figs. 2*).—Brief notes on injuries to trees by freezing, mice, and rabbits. Mention is also made of more important injurious insects of the month of May, methods of poisoning cut worms, destruction of apple-tree borers, and San José scale. Directions are also given for the preparation of various insecticides.

Annual report for 1903 of the zoologist, C. Warburton (*Jour. Roy. Agr. Soc. England, 64 (1903), pp. 310–327, figs. 7*).—Biological and economic notes are given on a number of fruit pests and forest insects. These include the currant gall-mite, raspberry moth, willow weevil, and several species of insects injurious to oak, pine, elm, and beech.

Entomological notes, C. Fuller (*Natal Agr. Jour. and Min. Rec., 7 (1904), No. 2, pp. 121–128, figs. 11*).—Notes are given on the habits and life history of *Sesamia fusca*, which is reported as very injurious to corn, and also on the bollworm, cutworms, and gallworms on potatoes. Recommendations were also made regarding the methods of controlling these pests.

Report of observations made by the Entomological Department of the State Agricultural Institute in 1903, Poskin (*Bul. Agr. [Brussels], 20 (1904), No. 1, pp. 56–66*).—A general review is presented regarding the entomological conditions during the season 1903. The author pays particular attention to a discussion of the habits, life history, and means of combating *Gryllotalpa vulgaris*, *Harpalus ruficornis*, and a number of strawberry insects, including crane flies, white grubs, wireworms, cutworms, and *Otiorhynchus sulcatus*.

Report on injurious insects for 1903, W. M. Schøyen (*Beretning om Skadeinsekter og Plantesygdomme i 1903. Christiania: Grondahl & Søn, 1903, pp. 36, figs. 26*).—As usual in the author's annual reports, notes are given on the prevalence of a variety of injurious insects and fungus diseases. These pests are classified according to the plants which they most affect. Special attention is given to the insect pests of cereals, grasses, peas, cabbage, potatoes, celery, fruit trees, forest trees, and ornamental plants. Detailed notes are given on the injuries to strawberries caused by a nematode worm (*Aphelenchus fragariæ*).

Report on the work of the section for plant protection, 1902-3, C. Brick (*Ber. Tät. Abt. Pflanzenschutz, Hamburg, 1902-3, pp. 10*).—During the year under report a much larger quantity of American fruit was imported through Hamburg than ever before. Notes are given on the varieties of fruit represented in these importations and on the extent of infestation with San José scale and other insect and fungus diseases.

More than one-half of the apples imported were Baldwins. A small percentage of apples from all parts of the country were infested with San José scale; some specimens were also found of Forbes scale, scurfy scale, Putnam scale, and oyster-shell bark-louse. Mention is also made of a number of fungus diseases which were found on apples. From Central and South America palms were imported which proved to be infested with a considerable variety of scale insects. Notes are also given on the conditions of nursery stock and plants imported from Japan.

The crop pest law of Georgia (*Georgia State Bd. Ent. Bul. 10, pp. 10*).—A copy is given of the law of Georgia regarding the special inspection of nurseries and nursery stock, the control of insect and fungus diseases, together with the rules and regulations adopted by the State Board of Entomology for this purpose.

Common corn insects, J. M. Stedman (*Mo. Bul. Missouri State Bd. Agr., 3 (1904), No. 11, pp. 11-17*).—Notes are given on the habits, life history, and means of combating chinch bug, corn-root aphis, cutworms, wireworms, and bollworms.

The cotton caterpillar, W. Newell (*Georgia State Bd. Ent. Bul. 9, pp. 14, figs. 4*).—The cotton caterpillar is said to have caused considerable destruction in various parts of Georgia during the season 1903. Notes are given on the life history, habits, and natural enemies of this pest. Experiments were made in dusting cotton plants with a mixture containing 1 part Paris green and 4 parts air-slaked lime. This method was compared with spraying by means of solutions of Paris green and arsenate of lead.

The results of these insecticide applications were encouraging in all cases. Spraying with Paris green seemed to be rather more effective than arsenate of lead or Paris green in a dry form. The chief advantage of the last named method is the ease and rapidity of its application. In wet weather it is recommended that the cotton plants be sprayed with a mixture of arsenate of lead at the rate of 3 lbs. to 50 gal. of water.

The potato beetle, F. Sherman, Jr. (*North Carolina Dept. Agr., Ent. Circ. 9, pp. 8, figs. 2*).—Notes on the distribution, life history, food habits, and means of combating the potato beetle. The remedies most strongly recommended by the author are Bordeaux mixture and Paris green, Paris green and limewater, and Paris green and air-slaked lime.

Holaniara picescens, a beetle injurious to sugar cane, W. Van Deventer (*Meded. Proefstat. Suikerriet West Java, 1904, No. 70, pp. 9, pl. 1*).—This beetle attacks the plant canes, causing great losses in some parts of Java, and is also injurious to the stems of tobacco. Notes are given on its habits and life history. During the author's experiments with insecticides in combating this pest it was found that while in the soil the beetle could be destroyed by using spoiled molasses, which seemed to be quite harmless to the cane cuttings.

Relative resistance of leaf-hopper eggs to hydrocyanic-acid gas, corrosive sublimate, and carbolic acid, C. F. Eckart (*Hawaiian [Sugar Planters'] Sta. Rpt. 1903, pp. 75-80*).—Experiments were made for the purpose of testing certain chemicals and their effects upon the eggs of leaf hoppers of sugar cane. Sections of infested sugar cane were cut and submitted to treatment by these different substances at varying strengths. The solutions of carbolic acid were found to be ineffective in destroying the eggs, while corrosive sublimate and hydrocyanic-acid gas gave more satisfactory results. The vitality of the sugar cane, however, was injured by too long exposure to hydrocyanic-acid gas or by dipping in too strong solutions of corrosive sublimate.

The Hessian fly in 1902-3, H. GARMAN (*Kentucky Sta. Bul. 111, pp. 211-224*).—A series of wheat plats was sown at different stages, beginning September 15 and ending November 10. On September 22, 3 plats were sown for the purpose of testing insecticides. One of these plats was not treated, while the other 2 were divided into equal parts and treated with dilute kerosene emulsion, Paris green and lime, Bordeaux mixture, and lime dust, respectively.

In the spring it was found that many culms had been destroyed entirely and the earlier sowings gave evidence of the greater injury. The plat treated with Bordeaux mixture showed only 19 per cent of infested plants, while later in the spring the percentage of infestation was increased to 43. At harvest time it was found that the effect of late planting was not entirely obliterated. The late-sown plats seemed to be less vigorous than those which were planted earlier. The results in yield of grain were in favor of treated plats planted September 22. Among the plats which were untreated the one which was planted October 6 gave the best yield. The early-sown wheat was harder than the late-sown wheat. A test was made of the germinating power of seed wheat from early and late plantings.

It appeared from this test that the time of planting had little effect upon the germination of the seed. A careful investigation was made to determine whether the Hessian fly infested rye, and no case of infestation could be found, even in the vicinity of the most extensively infested wheat fields. Under especially favorable conditions it seems probable that there may be even more than 3 broods in parts of Kentucky between the time of planting and harvesting wheat. Notes are given on the habits and life history of this insect.

In applying insecticide treatment for Hessian fly the results of the author's experiments indicate that considerable benefit may be obtained, but that this benefit may not be enough to overcome the expense of the application. No treatment is required in the fall, provided the wheat is sown between October 6 and 15. When the insect attacks the wheat in the spring, however, it appears desirable to apply a cheap insecticide, such as kerosene emulsion (4 times) or Bordeaux mixture.

The harlequin cabbage bug, F. SHERMAN, Jr. (*North Carolina Dept. Agr., Ent. Circ. 8, pp. 7, fig. 1*).—Notes are given on the habits, life history, and means of combating this pest. The author recommends the use of trap crops, hand-picking of insects, late planting, and clean culture.

Some experiences with lime, sulphur, and salt washes. Two common scale insects, C. O. HOUGHTON (*Delaware Sta. Bul. 64, pp. 33-48, pls. 3*).—A test was made with boiled and unboiled lime-sulphur-salt washes in 2 localities in the State. Several formulas were used in the preparation of the washes. When the wash was made without boiling it was prepared according to the following formula: Lime 10 lbs., sulphur 5 lbs., caustic soda $1\frac{1}{4}$ lbs., water 15 gal. This wash gave good results, but on the whole was not as satisfactory as the lime-sulphur-salt wash in experiments at Newark.

In experiments at Felton, Elberta peach trees 6 to 7 years old were sprayed just before the buds opened. No injury was done to the trees and practically no difference was observed in the results produced by the boiled and unboiled mixtures. It is recommended that the mixture be applied warm, since the best strength is obtained at that time. The wash is immediately cooled upon being broken up into fine particles by the nozzle and does not come in contact with the tree in a warm condition. If allowed to stand for a few hours, however, the solution becomes considerably weakened and the formation of yellow sliver-like crystals takes place.

A test was also made to determine the proper length of the period of boiling. This period has varied in different experiments from 40 minutes to 4 hours or more. As a result of the author's experiments it was concluded that nearly all of the sulphur can be dissolved within 15 minutes, and a period of 15 to 30 minutes is recommended as giving as good results as a longer period of boiling. The author also recommended that not too much copper sulphate be added to the lime-sulphur wash.

Notes are given on the habits, life history, and means of combating oyster-shell bark-louse and scurfy bark-louse.

Nursery inspection and San José scale, H. GARMAN (*Kentucky Sta. Bul. 110, pp. 195–210, pls. 5, fig. 1*).—This pest is said to have increased considerably in distribution throughout Kentucky during the past 2 years. Notes are given on its present distribution in the State. The author presents a general account of the most satisfactory methods of treating this insect.

The preparation of the lime-sulphur-salt wash is described, with notes on various formulas for this insecticide. Early winter is said to be the best time to spray. Notes are also given on the cost of materials and labor in spraying with this wash, on the use of oil soaps, and on fumigation with hydrocyanic-acid gas. A brief description is given of power pumps and steam cookers. Mention is made of the more important insect and fungus diseases which have thus far been found to occur in Kentucky nurseries. It is recommended that all nursery stock suspected of being infested with San José scale should be fumigated with hydrocyanic-acid gas.

Experiments on the control of the San José scale, T. B. SYMONS (*Maryland Sta. Bul. 90, pp. 24, figs. 4*).—A general account is given of the introduction of the San José scale in Maryland, its distribution, habits, and life history. A series of experiments was conducted in combating this insect with various insecticides applied in spring, summer, and early and late fall.

The results of these experiments are presented in a tabular form. From a study of the experiments it is concluded that whale-oil soap can be applied as a summer treatment in strengths varying from 1 lb. to 2 gal. of water to 1 lb. to 1 gal. of water, without danger to the foliage of apple or peach trees. Only the unprotected insects, however, are killed by this treatment. For summer treatment a 20 per cent kerosene emulsion with soap gave most satisfactory results, while 20 to 25 per cent lime-kerosene emulsion was almost equally effective. Oregon wash was effective but injured the foliage.

Similar results were obtained with crude-petroleum emulsion. All of the early fall applications were effective against the scale, but injured the foliage to some extent. Kerosene emulsion appeared to be the best insecticide for that season of the year. Lime-sulphur-salt wash appeared to be the best remedy for application in November and December. The treatment most strongly recommended by the author is the application of this remedy in the spring just before the buds begin to swell. The wash is about equally effective with or without salt.

The lime-sulphur-soda wash for orchard treatment, P. J. PARROTT, S. A. BEACH, and H. O. WOODWORTH (*New York State Sta. Bul. 247, pp. 59–81, figs. 4*).—The purposes of the experiments reported in this bulletin were to determine the comparative merits of 1 application of sulphur wash in the dormant season (supplemented or not with Bordeaux arsenical mixtures), the usual applications of the Bordeaux arsenical mixtures, the value of the sulphur wash in combating scale and other insects as well as fungus diseases, and the extent to which sulphur wash can be used in replacing Bordeaux arsenical mixtures.

The number of trees upon which the experiments were made was 1,440, consisting of apple, plum, pear, peach, quince, and cherry. The formulas used in the preparation of Bordeaux arsenical mixture and lime-sulphur-caustic-soda wash are given. The application of the sulphur wash was made between March 25 and April 29. The sulphur wash apparently destroyed from 60 to 80 per cent of scales on apple trees and was rather more effective on peach, plum, and pear trees, most of the branches of which were entirely cleared of scales. In a comparative test of the Bordeaux arsenical mixture and sulphur wash in the treatment of codling moth the sound fruit from trees treated with Bordeaux arsenical mixture averaged 98.6 per cent, while that from trees treated with sulphur wash amounted to 75.1 per cent. The application of sulphur wash appeared to reduce greatly the injuries of the early spring leaf-eating

caterpillars. On sprayed trees 13.9 per cent of the leaves and 9 per cent of the apples were injured, while on unsprayed trees 71.7 of the leaves and 50 per cent of the fruit were injured.

The experiments with lime-sulphur-caustic-soda wash indicate that the wash prepared in this way may not give as uniformly good results in the treatment of scale insects as does the common lime-sulphur-salt wash prepared by boiling. The wash proved to be beneficial not only in destroying the insects already mentioned, but in preventing the development of peach leaf-curl and apple scab. The wash is therefore considered to have valuable fungicidal properties.

Sulphur sprays for orchard trees, F. H. HALL ET AL. (*New York State Sta. Bul. 247, popular ed., pp. 11, figs. 2*).—A popular summary of the above bulletin.

Experiments with sulphur sprays for the fall treatment of the San José scale, P. J. PARROTT and J. S. HOUSER (*Ohio Sta. Bul. 144, pp. 13, pls. 4*).—Since sprays containing sulphur seemed to promise good results when used in the fall, a number of experiments were made by the authors to test the value of these remedies when thus applied. In experiments with lime-sulphur-salt wash an orchard was selected which contained 41 peach and 57 plum trees. The wash contained 15 lbs. each of lime, sulphur, and salt per 50 gal. of water, and was boiled for 1 hour.

The results of the application were not immediately manifested, but became apparent during the following season. More new wood and more foliage was produced upon the sprayed than upon the control trees. The San José scale appeared to be practically exterminated as the result of spraying the peach trees. On the plum trees, however, less satisfactory results were obtained. The Oregon wash was tested on peach and plum trees; the formula used contained 15 lbs. of lime, 15 lbs. of sulphur, and 1½ lbs. of copper sulphate per 50 gal. of water. As a rule the trees were much benefited by the treatment.

A soda-sulphur wash containing 20 lbs. of lime, 10 lbs. of sulphur, 10 lbs. of salt, and 5 lbs. of caustic soda per 50 gal. of water, was applied to a number of apple trees. This wash appeared to have little effect in destroying the scale. The formula for the lime-sulphur-salt wash preferred by the authors contains 50 lbs. each of lime, sulphur, and salt per 150 gal. of water, and it is recommended that the mixture be boiled for 1 hour. In fall spraying it is recommended that the application be made as soon as the majority of the leaves have fallen.

Some results with the lime and sulphur washes in Ohio, A. F. BURGESS (*Proc. Soc. Prom. Agr. Sci., 1904, pp. 134–141, pl. 1*).—Experiments were carried on in Ohio during which apple, peach, and pear trees were sprayed with the California and Oregon washes. These treatments were compared with treatment by means of kerosene oil. Formulas are given for the preparation of the washes, together with notes on the cost of materials. The sulphur washes were applied March 14 to 20.

The results of these experiments indicate clearly that the lime and sulphur wash is the most satisfactory winter treatment for the San José scale. It may be applied at any time after the leaves have fallen and is applied more easily if diluted with hot water. The wash has no appreciable effect upon the trees and destroys nearly all of the scale insects. It was also observed that peach leaf-curl was almost entirely prevented by the application of the lime-sulphur wash.

The mulberry scale (Diaspis pentagona), G. LEONARDI (*Bol. R. Scuola Superiore Agr. Portici, 2. ser., 1903, No. 8, pp. 23, figs. 2*).—This scale insect is described in detail in all its stages, and notes are given on its life history. The female scales and young larvæ are most injurious. In combating the pest the author recommends the exercise of strict precaution in quarantining trees received from infested localities, the destruction of badly infested trees, and spraying with kerosene emulsion and emulsions made of heavy tar oils. Copies are given of municipal decrees regarding means of combating this insect, and a list of infested localities is added.

The scale disease of the carob tree, P. GENNADIUS (*Cyprus Jour., 1 (1904), No.*

2, pp. 4, 5).—Notes are given on the habits, life history, and means of combating a number of scale insects which occur in the carob tree in Cyprus. The most important scale insects on this tree are *Lecanium ceratoniæ*, *Mytilaspis ceratoniæ*, *Aspidiotus ceratoniæ*, and *Aonidia aurantii*.

The Coccidæ of Kansas, S. J. Hunter (*Univ. of Kansas, pp. XI+80, pls. 20, fig. 1*).—In this volume the author has brought together a series of 4 articles on the Coccidæ of Kansas. A brief introduction on the study of scale insects is added and also an index.

Winter spraying for the apple aphis, J. M. Aldrich (*Idaho Sta. Bul. 40, pp. 273–288, fig. 1*).—Two species of apple aphis are noted as occurring in Idaho, viz, *Aphis sorbi* and *A. pomi*. The latter is the only one which is sufficiently common to be of economic importance. It apparently does not occur in Idaho upon any wild shrubs or plants. The eggs in this State are laid in October and November and hatch toward the last of April.

Spraying experiments were carried out for the purpose of finding, if possible, a satisfactory treatment for the winter eggs. In these experiments the following substances were used: Pure kerosene, kerosene emulsions of different strengths, sulphur and lime made by different formulas, and a 10 per cent crude-petroleum emulsion. The application of these insecticides was made on April 16 and an examination of the orchard on May 7 indicated that the most successful remedy was the sulphur-lime wash in 1:1:4 proportion. Pure kerosene injured the trees, but destroyed all the eggs. Kerosene emulsion injured the foliage somewhat and did not kill all of the eggs. In case of slight infestation or small trees the eggs may be destroyed by crushing with the hand or by dipping the branches in a pail nearly full of a quassia and whale-oil soap solution, or a similar insecticide.

The woolly aphis, C. Fuller (*Natal Agr. Jour. and Min. Rec., 7 (1904), No. 3, pp. 241–246, pl. 1, figs. 3*).—The author discusses the habits and life history of this insect with especial reference to the injury which it causes to apple trees. In combating the aerial form of the pest, the author recommends kerosene emulsion; for the underground form, tobacco dust and hot water have proved effective.

Means of combating rose aphis, A. Hempel (*Bol. Agr. São Paulo, 4. ser., 1903, No. 12, pp. 558, 559*).—Brief notes are given on the use of sheep dips, creolin, kerosene emulsion, etc., in destroying *Siphonophora rosæ*.

Two enemies of orange trees, A. Hempel (*Bol. Agr. São Paulo, 5. ser., 1904, No. 1, pp. 10–21, figs. 3*).—Descriptive and economic notes are given on *Aleurodes citri* and *A. horridus*. The usual treatments which have proved successful in combating these insects are recommended and notes are given on the parasitic insects and fungus diseases which assist in controlling the pests.

Experiments in the control of the olive fly, A. Berlese (*Bol. Uffic. Min. Agr., Ind. e Com. [Rome], 2 (1904), No. 1, pp. 46–75*).—A detailed account is given of the distribution and injuries caused by this fly in Apulia. The injurious attacks of various scale insects are also described, especially those of *Lecanium oleæ*. The injuries due to scale insects are sometimes attributed to the olive fly. In controlling the latter species, the author recommends the destruction or insecticidal treatment of infested olives, together with the use of arsenical sprays.

Lysol and its use in controlling the phylloxera (*Chron. Agr. Canton Vaud, 17 (1904), No. 6, pp. 203–205*).—Attention is called to the exceedingly satisfactory results which have followed the use of lysol in controlling phylloxera. Several badly infested vineyards have been entirely freed from this pest by spraying the trunks of the grapevines for three seasons. The chief advantage in this method consists in the fact that the winter eggs of the insect are destroyed and this obviates the necessity of applying treatment to the underground form of the insect.

The grape leaf hopper (Typhlocyba comes), M. V. Slingerland (*N. Y. Cornell Sta. Bul. 215, pp. 82–102, pls. 9, figs. 4*).—This insect appeared in unusually large

numbers, especially in the Chautauqua grape district in 1901 and 1902. The pest is a native American species and is widely distributed throughout the country. In Chautauqua County, N. Y., it occurred in largest numbers in parts of vineyards near woods or other locations suitable for hibernation.

The insect is described in its different stages and notes are given on its life history. Its food plants include all varieties of grapes, especially the Clinton, Delaware, and Concord, together with the Virginia creeper. The life history of the insect was worked over in detail. It was found that the eggs are usually laid singly on the under side of the leaves. The young nymphs remain in the same situation, where they suck the juices of the leaves. According to the author there is but one whole brood and a partial second brood in New York per year. The adult leaf hoppers seek a location for hibernating about October 1.

It is supposed that this pest is kept in check to some extent by unfavorable weather conditions. There are only a few natural enemies which prey upon the leaf hopper. In experiments with artificial remedies the author cooperated with J. Craig. A series of experiments with sticky shields was carried out, during which a practical form of shield was finally devised. The best time to use sticky shields is late in May or early in June, and the best sticky substance, according to the author's experiments, is a mixture of melted resin in the proportion of 1 qt. to 1 pt. of castor oil.

Spraying experiments showed that the adults could be killed by a mechanical mixture of kerosene and water, containing from 15 to 25 per cent of the oil, while the nymphs were destroyed by spraying with kerosene emulsion, tobacco decoction, or whale-oil soap. Trap lanterns were found to be useless. Considerable benefit may accrue, however, from burning grass or other rubbish under which the hoppers may hibernate. The author's general recommendations for combating this insect include the burning of grass, weeds, and leaves in the neighborhood of vineyards, late fall or early spring plowing for the purpose of burying hibernating leaf hoppers, the use of sticky shields early in June, and spraying with a 20 to 25 per cent mechanical mixture of kerosene and water, or with whale-oil soap at the rate of 1 lb. to 10 gal. of water.

Pathological and physiological observations on coffee, A. ZIMMERMANN (*Meded. 'S Lands Plantentuin, 1904, No. 67, pp. 105, pls. 4, figs. 54*).—In this report a number of diseases and physiological conditions of coffee and other plants are discussed.

Considerable attention is given to an account of a red pith disease caused by the attacks of *Pentatoma plebeja.* This insect attacks the leaves and other parts of various varieties of coffee as well as other plants. The method of making punctures in the plant tissues was carefully studied with the result that the lesions caused by these punctures are described in detail. The cell structures of the plants die in the immediate neighborhood of the puncture and lead to the formation of red spots in the leaves and pith. The common name of the disease is derived from this fact.

A general account is given of the fungi which occur in and on coffee plants with brief notes on their importance and means of combating them. The more important species mentioned in the account are *Hemileia vastatrix*, *Glœosporium coffeanum*, *Cercospora coffeicola*, etc. Under certain conditions the flowers of the coffee plant fail to develop normally. These conditions were investigated by the author and notes are given on the causes and means of preventing this trouble. An account is also presented of the variations in form of the fruit of *Coffea liberica.* The author also discusses briefly the injuries done to *Erythrina lithosperma* by nematode worms, and the eradication of *Lecanium viride* by various insecticides, such as mixtures of soap, lime, tobacco, copper sulphate, kerosene, corrosive sublimate, etc.

The "mosquito blight" of tea, II, H. H. MANN (*Calcutta: Indian Tea Assoc., 1904, pp. 20, pls. 8*).—This pamphlet contains a report of the continuation of the

author's work in combating mosquito blight of tea which is caused by *Helopeltis theivora.* It appears from the author's investigation that this insect lays its eggs chiefly during the early part of the day. During the latter part of March the larval insects are much more numerous than the adults. Statistical data are given showing the relative proportion of male and female adults and larvæ.

A number of experiments were carried out with insecticides, during which it was found that isolated plats of tea could be practically freed from mosquito blight by catching the insects and spraying with kerosene emulsion. A single application of kerosene delayed the appearance of mosquito blight for about six weeks. In order to obtain complete success from the use of this method it is recommended that the whole affected area should be thoroughly treated.

The pine sawfly (*Bd. Agr. and Fisheries* [*London*], *Leaflet 103, pp. 4, fig. 1*).—Notes are given on the habits and life history of *Lophyrus pini.* Brief mention is made of the natural enemies of this insect. The pest may be shaken from infested young trees and destroyed or the larvæ may be crushed.

The Mediterranean flour moth, F. L. WASHBURN (*Spec. Rpt. State Ent. Minnesota 1904, Feb., pp. 31, pl. 1, figs. 20*).—The Mediterranean flour moth is said to have appeared in large numbers in St. Paul and vicinity quite recently. Descriptions are given of the insect in its various stages and notes are presented on the usual means by which the pest gains entrance to mills and granaries.

Apparently the chief source of infestation is to be found in old sacks returned to the mill and secondhand machinery from infested mills. Such material should be thoroughly treated before being received in an uninfested mill. The best material for fumigation is carbon bisulphid, and this substance should be used in disinfecting old sacks. Cylindrical metal spouts have been devised which have smooth surfaces within and thus prevent insects from accumulating in grooves and depositing their eggs in such locations. Notes are given on belt brushes for cleaning wooden elevators. It has been found that the insects may be destroyed by exposing the spouts, elevator legs, and machinery to low temperatures in winter for a few days. This freezing period must be followed by a period during which the parts exposed are again heated, otherwise the effects of freezing upon the insects are not very marked.

Other experiments were carried on during which it was found that the moths could fly to considerable distances, but that they could not escape through a wire mosquito netting. Eggs exposed to the vapor of bisulphid of carbon for a few hours fail to hatch. Good results have been obtained from spraying bisulphid of carbon into infested machinery, spouts, etc. Notes are also given on a number of other insects affecting stored grain, among which are granary weevil, Angoumois grain moth, Indian meal moth, meal snout moth, cadelle, etc.

Insects injurious to wheat and other stored grains, G. LEONARDI (*Bol. R. Scuola Superiore Agr. Portici, 2. ser., 1903, No. 7, pp. 12, figs. 8*).—Notes are given on the habits and life history of a number of the common granary insects, with especial reference to the means of combatting them. The author places the greatest reliance in the thorough use of carbon bisulphid.

A preliminary list of Kansas spiders, T. H. SCHEFFER (*Industrialist, 30* (*1904*), *No. 24, pp. 371–386, figs. 7*).—During the author's study of this group of animals it was found that about 100 species occur in Kansas. These species are listed with notes on their habits, life history, and economic relations.

The garden spider and other insects, R. W. SHUFELDT (*Amer. Inventor, 12* (*1904*), *No. 9, pp. 195, 196, figs. 5*).—Notes on the habits and life history of the garden spider, saddle-back caterpillar, grass hoppers, etc.

Galls and insects producing them, M. T. COOK (*Ohio Nat., 4* (*1904*), *No. 6, pp. 115–147, figs. 7*).—In this portion of the author's monograph on galls, attention is called to galls on flowers and fruits as produced by moths, gall mites, and Lepidoptera. Notes are also given on root galls and on the histology of galls produced by

various groups of insects. The author discusses the mouthparts and egg-laying apparatus of various insects in relation to the galls produced on the plants which they infest. A discussion is also given on the morphology of leaf galls and stem galls.

In search for parasites, G. COMPERE (*Jour. Dept. Agr. West. Australia, 8 (1903), Nos. 2, pp. 132–145; 6, pp. 518–524*).—The author relates the results of his observations and researches in various parts of the world while engaged in the collection of beneficial insect parasites.

The mechanism of the movement of insects' wings, L. BULL (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 9, pp. 590–592, figs. 2*).—Brief notes are given on the study of this problem with special reference to the mechanics of insect flight, and the operation and structure of the wings.

Metamorphosis of the Trichoptera, G. ULMER (*Abhandl. Naturw. Ver. Hamburg, 18 (1903), pp. 154, pls. 4, figs. 13*).—A detailed biological account is presented concerning the eggs, larvæ, pupæ, and adults of various representatives of this order of insects, together with notes on the structure of the cases in which the larvæ live. The feeding habits and other biological relations of this group of insects are discussed.

Experimental study of hydrocyanic-acid gas as an insecticide, F. LOPEZ (*Com. Parasit. Agr. [Mexico], Circ. 5, pp. 9*).—In this circular the author recounts his experience in the use of hydrocyanic-acid gas in destroying insects, rats, mice, and other pests in houses. This work was undertaken in connection with the disinfection of houses after the occurrence of contagious diseases. It was found necessary to destroy insects and other pests as well as pathogenic bacteria and hydrocyanic-acid gas gave the best results in this work. Brief notes are also given on the use of this gas in the disinfection of sleeping cars.

Spray mixtures and spray machinery, S. A. BEACH, V. A. CLARK, and O. M. TAYLOR (*New York State Sta. Bul. 243, pp. 315–373, pls. 15*).—The purpose of this bulletin is to present a digest and review of the experiments which have thus far been made at various experiment stations and elsewhere in determining the best insecticide remedies and the best methods for applying them. Detailed directions are given for the preparation of all of the common and important fungicides and insecticides, together with notes on spraying machinery of all kinds. An index appended to the bulletin makes accessible the various details of information.

Practical guide for the study of mosquitoes, EDMOND and ÉTIENNE SERGENT (*Guide pratique pour l'étude des moustiques. Paris: Masson & Co. [1903] pp. 176, figs. 40*).—An historical discussion is given of the general problems relating to the extermination of mosquitoes and the agency of these insects in transmitting various diseases. The authors discuss also in a concise manner the method of examining mosquitoes, their classification, morphology, biology, and means of exterminating them. The blood parasites found in mosquitoes are also briefly noted.

A practical study of malaria, J. W. W. STEPHENS and S. R. CHRISTOPHERS (*London: Longmans, Green & Co., 1903, pp. 378+XXXV, figs. 93*).—A biological and economic account of mosquitoes is presented on pp. 57–257. The anatomy, habits, and life history of various species are discussed with special reference to the relation of these insects to the origin and spread of malaria and to means of combating the pests. In an appendix to the volume the authors present a brief systematic account of blood-sucking flies of various families, together with notes on fleas and related insects.

The warfare against mosquitoes, E. SERGENT (*La lutte contre les moustiques. Paris: J. Rueff, 1903, pp. 96, figs. 27*).—The literature relating to methods for exterminating mosquitoes is discussed in a critical manner, with references to a bibliographical list of 110 titles. Attention is called to the intimate connection between the prevalence of mosquitoes and the ineffectiveness of farm labor as a result of diseases carried by mosquitoes. The usual methods of extermination, including the use of kerosene and drainage, are outlined and strongly recommended.

Proceedings of the first general convention to consider the questions involved in mosquito extermination (*Brooklyn. National Mosquito Extermination Society, 1904, pp. 84, pls. 6, figs. 9*).—The present volume contains an account of the proceedings of a meeting of the National Mosquito Extermination Society held at the rooms of the Board of Trade, New York City, December 16, 1903. At this meeting a considerable number of papers were presented dealing with various aspects of the question of mosquito extermination. Among these papers we may mention the following: Remarks on Extermination Work at Morristown, N. J., by J. Chaflin; Extermination and Exclusion of Mosquitoes from our Public Institutions, by P. H. Bailhache; Government Anti-Mosquito Work, by J. C. Perry; Transmission of Malaria by Mosquitoes, by W. N. Berkeley; Anti-Mosquito Work in Havana, by W. C. Gorgas; Mosquito Engineering, by H. C. Weeks, etc.

Beekeeping for small farmers, W. B. CARR (*Jour. Bd. Agr. and Fisheries [London], 10 (1904), No. 4, pp. 468–475*).—The author discusses the economic aspects of beekeeping and presents notes on the most important bee plants in various parts of Great Britain. Practical directions are also given as a guide to the amateur in selecting a location for an apiary and in caring for the bees.

Studies on the races of bees, E. RUFFY (*Bul. Soc. Romande Apicult., 1 (1904), No. 1, pp. 4–6*).—A brief account of the comparative merits of races of bees.

Bees in walls and attics, DELÉPINE (*Jour. Agr. Prat., n. ser., 7 (1904), No. 16, p. 519*).—Attention is called to the frequency with which swarms of bees become established in the walls or unoccupied rooms of dwellings. Suggestions are made regarding the means of getting rid of such swarms where they prove to be a nuisance and also of utilizing the honey.

Memoir on the future of sericulture, L. DE L'ARBOUSSET (*Bul. Agr. Algérie et Tunisie, 9 (1903), No. 23, pp. 527–530*).—Statistics are presented for the purpose of indicating the gradual development and spread of the silk raising industry. The author formulated a resolution which was adopted by the International Congress of Agriculture at Rome to the effect that silk raising be recommended for further extension throughout the southern portion of Europe, especially along the Mediterranean Sea.

The silk-growing season of 1904, G. MCCARTHY (*Silk, 2 (1904), No. 2, pp. 11*).—A brief account is given of the work thus far accomplished in the recent revival of interest in silk growing in this country, together with notes on the prospects of the silk industry for the season of 1904.

The influence of low temperature during the incubation of silkworm eggs, J. BOLLE (*Ztschr. Landw. Versuchsw. Oesterr., 7 (1904), No. 3, pp. 173–179*).—The occasion of the investigations reported in this paper was the severe frost which occurred in parts of Austria in April, 1903.

Experiments were carried out during which it was found that temperature variations of 10° C. during the first part of the egg stage were without serious results when of only short duration (48 hours or less). The same may be said of temperature changes of not more than 5° C. for periods of 24 hours during the last part of the egg stage. Pronounced lowering of the temperature for 48 hours or more may have the effect of delaying the emergence of the larvæ, but produces no other consequence of a serious nature. The continuation of low temperature for long periods, however, may caũse outbreaks of flacherie.

During the feeding experiments carried on by the author it was found that no serious results were produced by feeding once a day rather than the usual 4 or 5 times. When the caterpillars were fed only every other day they became very susceptible to flacherie. A study of the fungi in the bodies of dead silk moths disclosed the fact that *Botrytis bassiana* was the common fungus present in moths affected with muscardine. Artificial infection was brought about in about the same proportion and with the same certainty whether the mycelium or spores of this fungus were

used. Fumigation with formalin fumes was found to be an effective method of controlling muscardine.

Investigations on flacherie, S. SAWAMURA (*Bul. Col. Agr., Tokyo, Imp. Univ., 5 (1903), No. 4, pp. 403–448*).—An elaborate series of bacteriological studies was carried on by the author for the purpose of determining the connection of different bacterial organisms with flacherie of silkworms. A number of organisms were found in studying this disease and detailed notes are given on their behavior on different nutrient media.

From the study of diseases of silkworms in connection with inoculation experiments it was found that flacherie is caused by the growth of bacteria in the intestinal juices of silkworms. Various kinds of micrococci were found in such location, together with *Bacillus megatherium* and coli bacillus. *B. megatherium* and one species of micrococcus, *Sarcina lutea*, was found in the eggs of silkworms. About 10 species of micrococci were found on mulberry leaves, and it appears from the author's investigations that flacherie is caused by eating mulberry leaves contaminated with these bacterial organisms.

Under ordinary circumstances, healthy silkworms resist the action of the bacteria. When reared at high temperatures, however, or under unfavorable conditions the worms may become infected. The author believes that flacherie is not caused by any special form of bacteria.

Eleanor Ormerod, R. WALLACE (*London: John Murray, 1904, pp. XX+348, pls. 30, figs. 76*).—This volume is almost entirely occupied with an autobiography of Eleanor Ormerod and selections from her entomological and other correspondence, edited by Professor Wallace. The correspondence reprinted in this volume relates to various problems connected with a great variety of injurious insects.

Supplement to the entomologists' directory, H. SKINNER (*Philadelphia: Amer. Ent. Soc., 1904, pp. 28*).—Lists are given of entomologists whose addresses have been changed and also of additional names and of certain entomologists whose names are to be omitted from future additions of the directory.

FOODS—NUTRITION.

Eighth report on food products, A. L. WINTON ET AL. (*Connecticut State Sta. Rpt. 1903, pt. 2, pp. 107–198, figs. 26*).—The work carried on during the year under the provisions of the State pure-food law is briefly spoken of in the introduction by E. H. Jenkins. The station has collected for analysis 227 samples of food products, 30 samples were submitted by private individuals, and 882 by the State Dairy Commissioner, making a total of 1,139.

Chocolate and other products of the cocoa bean, A. L. Winton, E. M. Bailey, and M. Silverman (pp. 123–145).—Of the 40 samples of chocolate examined 11 were found to be adulterated, 7 were mixtures marked compound, and the remainder were not found to be adulterated. Four of the samples were chocolate or cocoa containing milk or casein. Analyses and other data are discussed at length.

Coffee, A. L. Winton (pp. 145–148).—Seventeen samples of whole and 29 of ground coffee were examined. In every case the whole coffee was found to be pure. Nine of the samples of ground coffee were found to be adulterated, chickory being present in all such cases. In addition to chickory some of the samples contained brown imitation coffee made from wheat flour middlings or pellets made of pea hulls and other ingredients.

Lard, A. L. Winton and A. W. Ogden (pp. 149–155).—Of the 134 samples examined during the year 4 were sold as compound lard. Analyses showed that 48 per cent of the remainder were actually mixtures containing large amounts of cotton-seed oil "and consequently were grossly adulterated."

Food products examined for the dairy commissioner in the twelve months ending July 31, 1903 (pp. 156, 157).—The 882 samples examined included butter, molasses, and vinegar. Of these, 98 samples were found to be adulterated or below the required standard.

The composition of Acheen and Lampong black pepper, A. L. Winton and E. M. Bailey (pp. 158–164).—Analyses of Acheen and Lampong black pepper were made with a view to determining the amount of ash which should be allowed as a maximum in a standard of purity.

The anatomy and microscopic identification of the fruits of darnel and chess, A. L. Winton (pp. 165–174).—The anatomical structure of darnel (*Lolium temulentum*) and chess (*Bromus secalinus*) seeds, which are of common occurrence in wheat screenings, are described and methods of identification proposed which depend upon histological characteristics.

The anatomy of certain oil seeds with especial reference to the microscopic examination of cattle foods, A. L. Winton (pp. 175–198).—The materials studied included hemp seed, upland cotton seed, sesame seed, madia seed or common tar weed (*Madia sativa*), niger seed (*Guizotia abyssinica*), poppy seed, and their products. On the basis of microscopical studies, methods are proposed for the identification of a number of seeds important for the oil they produce and the residue or cake from the oil press, which is used as cattle food or in some cases for human consumption.

Report on work in food laboratory, H. E. BARNARD (*New Hampshire Sanitary Bul., 2 (1904), No. 3, pp. 37–52*).—Data regarding the examination of the various food products and condiments are reported. Of the 290 samples examined 139 were found to be adulterated or to vary from the legal standard. The manufacture and composition of fruit jams, jellies, marmalades, etc., are discussed. Wood alcohol and the harmful effects which attend its consumption are also spoken of.

Adulteration of food (*Ottawa, Canada: S. E. Dawson, 1904, pp. 123*).—Brief statements are made regarding the nature and extent of the work of the official analysts, and the following bulletins of the inland revenue department, which have been previously noted, are reprinted as appendixes: No. 82, Unfermented Grape Juice (E. S. R., 14, p. 894), No. 83, Lime Juice and Catsup (E. S. R., 14, p. 894), No. 84, Cereal Breakfast Foods (E. S. R., 14, p. 892), No. 85, Canned Meats (E. S. R., 15, p. 284), No. 86, Fertilizers, 1903 (E. S. R., 15, p. 349), No. 87, Canned Vegetables (E. S. R., 15, p. 285), and No. 88, Paris Green (E. S. R., 15, p. 279).

Anatomy of the fruits of darnel and chess, A. L. WINTON (*Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 6, pp. 321–327, figs. 8*).—Noted elsewhere from another publication (see above).

Anatomy of hemp seed, A. L. WINTON (*Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 7, pp. 385–388, figs. 5*).—Noted elsewhere from another publication (see above).

Cereal foods, E. GUDEMAN (*Jour. Amer. Chem. Soc., 26 (1904), No. 3, pp. 321–324*).—On the basis of an examination of a large number of cereal foods, including analyses and digestion experiments, some general conclusions are reached. The amount of soluble material in raw cereals before digestion, according to the author, varied from 2 to 8 per cent, in prepared cereals, i. e., cooked or roasted, from 4 to 23 per cent, and in malted cereals, from 4 to 60 per cent. It is stated that raw cereals should be cooked for at least an hour in order to render them satisfactory as articles of diet.

"It was found that the raw cereals, if sufficiently cooked, were as quickly digested as the best malted cereals, more quickly than the prepared cereals and a large majority of the so-called malted cereals. . . .

"It was found that the only advantage the prepared and malted cereals have over the raw cereals is that they come to the consumer ready for immediate consumption, and the preliminary preparation of boiling for one hour or so is not required. The claim that the prepared cereals are predigested food applied only to the malted

cereals and only so far as part of the starch has been converted. . . . The differences in the time of digestion, with saliva and pancreatin, between a well-boiled raw cereal and a fully malted prepared cereal is so small that the same can be ignored when determining the relative nutritive ratio and factor of digestibility."

Cereal foods, A. BEYTHIEN, H. HEMPEL, and P. BOHRISCH (*Ber. Chem. Untersuch. Dresden, 1902, pp. 15–17; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, pp. 300, 301*).—Among the products analyzed were American cereal breakfast foods.

Farinaceous foods, B. C. ASTEN (*New Zealand Dept. Agr. Rpt. 1903, pp. 21, 22*).—Analyses of flaked oats, flour, and wheat are reported.

The abnormal fermentations of bread, F. C. HARRISON (*British Food Jour., 5 (1903), No. 59, pp. 240–242*).—Sticky bread and other forms of abnormal bread fermentations are described.

Lakton bread, M. MANSFELD (*Ber. Unters. Anstalt. Allg. Oesterr. Apoth. Ver., 1902–3, p. 4; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, p. 301*).—Analyses are reported of 2 samples of so-called "Lakton" bread, made from almonds and recommended for diabetes.

Composition of several sorts of bakers' goods, K. FARNSTEINER ET AL. (*Ber. Hyg. Inst. Hamburg, 1900–1902, pp. 51–53; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, p. 300*).—Analyses of graham bread, pumpernickel, conglutin bread, etc., are reported.

The baking industry from a hygienic standpoint in relation to the trade and to consumers, R. EMMERICH (*Deut. Vierteljschr. Oeffentl. Gesundheitspfe., 35 (1903), pp. 172–199; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, pp. 299, 300*).—Existing conditions and the importance of hygienic measures in bakeries, and related topics are discussed.

Comparative milling and baking experiments with foreign and domestic wheats, P. BEHREND and E. KLAIBER (*Fühling's Landw. Ztg., 53 (1904), Nos. 2, pp. 41–51; 3, pp. 73–85; 4, pp. 121–129*).—A number of samples of home-grown and imported wheat were studied with a view to learning their relative value for bread making. None of the bread made was especially poor. In the authors' opinion there is no direct relation between the volume of bread produced and the protein content of the flour.

The catalytic properties of grain and flour, N. WENDER and D. LEWIN (*Oesterr. Chem. Ztg., 7 (1904), No. 8, pp. 173–175*).—The catalases in different cereal grains, whole and ground, and in bean meal were studied in connection with a critical discussion of the theories regarding the action of such bodies.

Thirty-five cc. of hydrogen peroxid was added to 100 gm. of flour mixed with 200 cc. of water and allowed to stand an hour at 20° C. The amount of oxygen liberated varied from 8 cc. in the case of wheat starch to 392 cc. in maize meal 1 year old. Similar tests were made with the different milling products of wheat, the amount of oxygen varying from 64 cc. with wheat flour No. 0 to 246 cc. with wheat flour No. 7½. According to the author, it is evident that the flour ground from the outer portion of the wheat grain is richer in catalases than the inner portion. The author also concludes that the catalytic power is inversely proportional to the fineness of the flour and states that this fact will be taken advantage of in studies on a method of judging the quality of flour.

The composition of hard wheat and hard-wheat gluten, E. FLEURENT (*Ann. Chim. Analyt., 8 (1903), No. 2, pp. 43–45*).—Noted from another publication (E. S. R., 14, p. 378).

Vetches in cereal grains and in human foods, A. SCALA (*Staz. Sper. Agr. Ital., 36 (1903), pp. 695–716; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, pp. 297, 298*).—The value of hydrochloric acid, alcohol, ether, chloroform, and sulphurous acid for removing the bitter principle from vetch seed was tested, the most

satisfactory results being obtained with the sulphurous acid. The author believes that on account of its high nutritive qualities, properly prepared vetch flour would be of value in the diet of the Italian poor. Methods of detecting ground legumes in flour were tested.

Experiments on losses in cooking meat, 1900–1903, H. S. Grindley and T. Mojonnier (*U. S. Dept. Agr., Office of Experiment Stations Bul. 141, pp. 95*).—Continuing their investigations on the changes brought about in meat by cooking (E. S. R., 13, p. 772), the authors report the results of 87 experiments with beef and pork, the methods of cooking being boiling, panbroiling, sautéing, and roasting.

The results of the investigations indicate that the chief loss in weight during the boiling, sautéing, and panbroiling of meats is due to water removed by the heat of cooking; in roasting, to the removal of both water and fat. The losses of nutritive material in the panbroiling of meats are very small as compared with those observed in boiling, roasting, and sautéing.

When beef was cooked in water 3.25 to 12.67 per cent of the nitrogenous matter, 0.60 to 37.40 per cent of the fat, and 20.04 to 67.39 per cent of the mineral matter of the original uncooked meat were found in the broth. The nutritive material thus removed is designated a loss, but is not an actual loss if the broth is utilized for soup or in other ways. When meat was sautéed 2.15 per cent of the nitrogenous matter and 3.07 per cent of the ash occurring in the uncooked meat were taken up on an average by the fat in which the meat was cooked, while the cooked meat contained 2.3 times more fat than before cooking. When the meats were roasted 0.25 to 4.55 per cent of the nitrogenous matter, 4.53 to 57.49 per cent of the fat, and 2.47 to 27.18 per cent of the mineral matter present in the uncooked meat were found in the drippings.

Beef which has been used for the preparation of beef tea or broth has lost comparatively little in nutritive value, though much of the flavoring material has been removed.

In the boiling of meats, the fatter kinds and cuts, other things being the same, lost less water, nitrogenous and mineral matter, but more fat than the leaner kinds and cuts. In sautéing, panbroiling, and roasting meat the losses increased in proportion to the degree of cooking. In other words, the longer the time and the higher the temperature of cooking, other things being the same, the greater the losses resulting. As a rule the larger the piece of meat boiled or sautéed, the smaller the relative losses.

The experiments indicate plainly that different cuts of the same kind of meat behave very differently as regards the amount and nature of the losses which they undergo when cooked in hot water. Thorough investigation confirms the conclusion that when meat is cooked in water at 80 to 85° C., placing the meat in hot or cold water at the start has little effect on the amount of material found in the broth.

The ripening of meat, M. Müller (*Ztschr. Fleisch u. Milchhyg., 14 (1904), No. 7, pp. 217–221*).—The ripening of meat is discussed and is due, it is maintained, to autolysis being facilitated by hanging in cold storage.

Judging the degree of putrefaction in meat by means of its succinic-acid content, H. Wolff (*Beitr. Chem. Physiol. u. Pathol., 4, p. 254; abs. in Hyg. Rundschau, 14 (1904), No. 6, pp. 291, 292*).—According to the author large amounts of succinic acid indicate that meat is badly spoiled.

Studies of animal gelatinoids, III, W. S. Sadikoff (*Ztschr. Physiol. Chem., 41 (1904), No. 1–2, pp. 15–19*).—A progress report of investigations on the behavior of purified commercial gelatin, tracheal gluten, and other gelatinoids when treated with salt solutions.

The composition of several new meat preservatives, R. Racine (*Ztschr. Oeffentl. Chem., 9 (1903), pp. 163, 164; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, pp. 318, 319*).—A number of preservatives are described and analytical data reported.

Composition of a number of preservatives, K. Farnsteiner et al. (*Ber. Hyg. Inst. Hamburg, 1900–1902, pp. 18, 19; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, p. 318*).—The composition of a number of commercial preservatives is reported.

The occurrence of leaf lard showing high iodin absorption, W. D. Richardson (*Jour. Amer. Chem. Soc., 26 (1904), No. 4, pp. 372–374*).—In a discussion of the standards recommended for leaf lard by the committee appointed by the Secretary of Agriculture, the author reports determinations of the constants of a number of samples, calling especial attention to the high iodin absorption number of lard from mast-fed pigs. Carcasses of such animals, it is stated, may be easily identified "owing to the fact that even at the freezing point, their fat does not harden, while, if the leaf or back fat of such an animal be placed in room temperature, the oil runs freely from the tissue."

The data reported, in the author's opinion, would indicate "that the limit of 60 [of the proposed standard] is ample, indeed somewhat excessive, for the iodin number of leaf fat from the kind of hog most frequently marketed. The fact remains, however, that we may have samples of leaf lard ranging in iodin value all the way from 50 to 85, and all genuine. That the majority of hogs shipped to our various stock yards will yield a comparatively hard fat indicates simply that such a hog is more easily marketable (more in demand) than the other kind."

The aroma of margarins, P. Pick (*Chem. Rev. Fett u. Harz-Ind., 10 (1903), pp. 175–178; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 7, pp. 415, 416*).—The causes of unpleasant flavor in different sorts of margarin are spoken of, and various methods of improving the flavor are discussed.

Honey, 1903, T. Macfarlane (*Lab. Inland Rev. Dept. Ottawa, Canada, 1903, Bul. 90, pp. 15*).—Of the 99 samples of honey examined 81 were regarded as genuine, 5 as doubtful, and the remainder adulterated. The analytical methods are briefly discussed. A further examination of 13 samples of honey showing right-handed rotation was made by Miss E. Davidson.

Heated honey, K. Farnsteiner et al. (*Ber. Hyg. Inst. Hamburg, 1900–1902, p. 70; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 5, p. 310*).—The changes brought about by the pasteurization of sour honey were studied.

Edible bulbs, J. H. Lagemann (*Jour. Columbus Hort. Soc. 19 (1904), No. 1, pp. 9, 10*).—A note on the use of various bulbs as food.

The coloring matter of red grapes, II, L. Sostegni (*Gaz. Chim. Ital., 32 (1902), II, pp. 17–19; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 6, p. 347*).—Coloring matters were isolated, which, in the author's opinion, were tannin derivatives of protocatechuic acid.

Some cellulosic constituents of orange peel, H. Stanley (*Chem. News, 87 (1903), No. 2267, pp. 220, 221*).—Elementary analyses of the outer and inner layer of orange peel are reported, as well as determinations of furfurol and cellulose in the peel, the effect of acids, alkaline hydrolysis, and the dyeing properties of the cellulose present.

The permissibility of treating cocoa with alkalis, the so-called Holland process, M. Mansfeld (*Oesterr. Chem. Ztg., 7 (1904), No. 8, pp. 175–177*).—On the basis of analytical data, the need of changes in the provisions of the proposed *Codex alimentarius austriacus* for the analysis of cocoa beans and cocoa products is pointed out.

The antiseptic qualities of coffee, W. H. Crane and A. Friedlander (*Amer. Med., 6 (1903), No. 10, pp. 403–407*).—With the object of determining the antiseptic properties of coffee, a number of experiments were carried on. It was found that ground coffee well mixed with the yolks and whites of eggs and with chopped beef prevented decomposition. Coffee infusion exposed to the air became covered with mold on the surface, but never turbid through bacteria. A 10 per cent infusion pre-

vented the growth among other micro-organisms of typhoid and anthrax bacilli, *Bacillus coli communis*, etc. The coffee constituent to which the observed germicidal properties were due was not ascertained.

Distilled liquors, A. McGill (*Lab. Inland Rev. Dept. Ottawa, Canada, 1903, Bul. 92, pp. 17*).—In this investigation of distilled liquors sold in Canada, 216 samples were examined. Those most tampered with were whisky, both rye and malt, and gin. No deleterious substances were found in any of the samples, and the principal adulterant was water.

Cider, T. Macfarlane (*Lab. Inland Rev. Dept. Ottawa, Canada, 1904, Bul. 94, pp. 3*).—In a study of commercial cider 41 samples were examined. The specific gravity at 15.5° C. varied from 1.0025 with 9.54 per cent alcohol by volume to 1.0688 with only 1.13 per cent. In the case of 17 samples the amount of alcohol by volume was less than 1 per cent and the specific gravity varied from 1.0368 to 1.0627. Two samples of fresh apple juice after filtration had a specific gravity, respectively, of 1.0546 and 1.0573 at 15.5° C.

"Having in view these variations it would seem necessary to obtain, at the place of production, undoubtedly genuine samples of fresh and pure apple juice before drawing any conclusions regarding the samples described in the tables as to their containing added water or sugar." Fourteen of the samples examined contained small quantities of salicylic acid.

Cider vinegar and suggested standards of purity, A. E. Leach and H. C. Lythgoe (*Jour. Amer. Chem. Soc., 26 (1904), No. 4, pp. 375–382*).—Full analyses are reported of a number of samples of vinegar with a view to securing data for formulating methods for the detection of adulteration. According to the authors it is rarely necessary to make a complete analysis to determine whether or not an alleged vinegar is spurious.

"Aside from the determination of acidity and total solids, by far the most important tests consist in the polarization and in the calcium chlorid and lead acetate tests for malic acid. It is rare that spurious vinegar will fail of detection by at least one of these tests. Only in doubtful cases is it necessary to go farther. It is well, however, to be able in some cases to confirm one's judgment by added proof, and where litigation is involved a complete analysis may be helpful."

Ground spices, T. Macfarlane (*Lab. Inland Rev. Dept. Ottawa, Canada, 1904, Bul. 95, pp. 25*).—Of the 188 samples of ground spices examined 88 or 46.8 per cent were regarded as genuine and the remainder doubtful or adulterated. In a note by A. McGill analyses of several samples of ground ginger are reported, the method followed being described.

The composition of some new condiments, J. Graff (*Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 7, pp. 389–392*).—Meat extracts, yeast extracts, i. e., so-called vegetable bouillons, and some miscellaneous goods, such as concentrated soups or soup extracts, are described and analyses reported.

Flavoring extracts, A. McGill (*Lab. Inland Rev. Dept. Ottawa, Canada, 1903, Bul. 89, pp. 16*).—With a view to the detection of adulteration analyses were made of commercial lemon, vanilla, peppermint, raspberry, and other flavoring extracts. The different kinds of extract are briefly discussed.

The dietetic value of patented foods, W. D. Halliburton (*New York Med. Jour. and Philadelphia Med. Jour., 79 (1904), No. 4, pp. 145–147*).—In an address delivered before the American Chemical Society at New York, the author discussed the dietetic value of patent foods, giving special attention to meat extracts, infant foods, and similar goods. The common error of judging foods solely by their composition, the need of instruction in what constitutes true food value, and other related topics were spoken of.

Instruction in judging the nutritive value of the diet of private and public institutions, Lichtenfelt (*Anleitung zur Begutachtung des Nährwertes der Kost Pri-*

vater und der in Öffentlichen Anstalten. Bonn: Friedrich Cohen, 1903, pp. 26; rev. in Hyg. Rundschau, 14 (1904), No. 6, pp. 283, 284).—Data regarding the composition of food are given, which it is believed will prove useful in calculating the nutritive value of diets.

Practical dietetics with reference to diet in disease, ALIDA F. PATTEE (*Somerville, Mass.: Author, 1903, pp. 100; rev. in Home Sci. Mag., 20 (1904), No. 4, p. 199).*—On the basis of experience in teaching cookery in hospitals, the author has prepared this volume of recipes designed for class-room or household use.

Feeding school children in Germany, B. H. WARNER, Jr. (*Dept. Com. and Labor, Mo. Consular Rpts., 75 (1904), No. 284, pp. 426, 427).*—In a number of German cities the poorer children are fed in part at municipal expense. The methods followed are briefly described.

Diet suggestions for the Transvaal, F. BOLTON (*Transvaal Agr. Jour., 2 (1904), No. 6, pp. 209, 210).*—In the author's opinion meat should be eaten more sparingly than in colder climates. The importance of leguminous vegetables, cheese, and wheat as sources of protein is spoken of; the need of consuming large amounts of water is recognized; and other hints are given regarding a diet suitable for tropical conditions.

Practical cooking manual, C. H. SENN (*London: Universal Cookery and Food Assoc., 1903, pp. 168; rev. in Home Sci. Mag., 20 (1904), No. 4, p. 199).*—Directions are given for the preparation of simple dishes suited to the needs of families with a moderate income.

United States food standards (*Jour. Bd. Agr. and Fisheries [London], 11 (1904), No. 1, pp. 31–34).*—The food standards recently adopted in the United States are discussed with special reference to British farmers and consumers.

Chemistry of human foods and condiments. II, Foods and condiments, their preparation, composition, and properties, J. KÖNIG (*Chemie der Menschlichen Nahrungs- und Genussmittel. II, Die Menschlichen Nahrungs- und Genussmittel, ihre Herstellung, Zusammensetzung und Beschaffenheit. Berlin: Julius Springer, 1904, 4. ed., pp. XXVI + 1557, figs. 44).*—This very comprehensive volume, which constitutes a digest of available information, deals with the composition of foods and condiments, digestibility, theories of nutrition, animal foods and condiments, vegetable foods and condiments, alcoholic beverages, water, air, and the preparation of food. There are also many tables and a detailed index. In every case the topics are very thoroughly discussed, the volume being encyclopedic in its nature and constituting a very valuable reference book for all interested in the subject of nutrition. The present edition has been thoroughly revised and rewritten to include the results of investigations which have accumulated since the last edition was published.

Economy expense book, G. B. WOOLSON (*New Haven, Conn.: George B. Woolson & Co., 1904, pp. 100; rev. in Boston Cooking-School Mag., 8 (1904), No. 9, p. XVI).*—A housekeeper's account book designed to simplify the record of household and other expenses.

Energy value and the useful physiological effect of foods, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 7 (1904), No. 16, pp. 509, 510).*—A résumé of some of M. Rubner's investigations.

Original research regarding human perspiration, etc., J. H. HOELSCHER (*New York Med. Jour. and Philadelphia Med. Jour., 79 (1904), No. 7, pp. 296–300).*—Human perspiration was studied under varying conditions, sweating being induced by hot-air baths and the perspiration collected by enveloping the subjects in sterile gauze covered with oilcloth. Most of the experiments and the conclusions drawn from them have to do with the effects of drugs and similar topics. The following are of more general interest:

As regards the elimination of normal and abnormal substances the skin is not to be compared with the kidneys. One thousand cc. of perspiration contained about 11.5

gm. of solids made up of equal amounts of inorganic and organic material, the urea content being about 0.6 gm., and the nitrogen content 0.47 gm. "A case of chronic constipation and indicanuria did not disclose the presence of indol or skatol in the sweat."

On the morphological changes in the blood after muscular exercise, P. B. Hawk (*Amer. Jour. Physiol., 10 (1904), No. 7, pp. 384–400*).—The experiments which were made with student athletes have to do with the effects of muscular work.

Sanitary precautions in food, A. S. Atkinson (*What-To-Eat, 16 (1904), No. 5, pp. 171, 172*).—The possibility of transmitting disease by eating vegetables exposed for sale where they can be contaminated with street dust is pointed out. The author also notes the importance of washing fruits and vegetables which are eaten raw, in water of known purity.

Food and drink in relation to disease; feeding in relation to the health of the young, J. Niven (*London: Sherratt & Hughes; rev. in British Med. Jour., 1904, No. 2255, pp. 674–676*).—The importance of proper nourishment for children is pointed out and suggestions made for systematic improvement under existing conditions.

Other sources of typhoid infection than through the medium of drinking water, and how to guard against them, S. Harris (*Sanitarian, 52 (1904), No. 413, pp. 310–322*).—Milk, ice, oysters, vegetables—especially those commonly eaten raw—grown on land fertilized with night soil, dust, and flies are discussed as sources of typhoid infection, in addition to those commonly recognized. To avoid the possibility of infection the author believes that vegetables, if eaten raw, should be thoroughly washed in water of known purity, and in boiling water where it will not destroy their flavor. Oysters that are suspected of being infected should never be eaten raw. Flies are regarded as especially dangerous and the need of protecting food from them is pointed out.

ANIMAL PRODUCTION.

The importance of pentosans in feeding stuffs, especially those of rye straw, A. von R. Rudzinski (*Ztschr. Physiol. Chem., 40 (1904), No. 5–6, pp. 317–390, fig. 1*).—From experiments reported in detail the following conclusions were drawn: The formation of pentosans in rye straw is not dependent upon the fertilizers used. They are not evenly distributed in the head, but are found most abundantly in the rachis. Chaff has a considerably higher pentosan content than straw, while the root closely resembles the head in respect to the amount of this constituent present.

As shown by experiments with sheep, the coefficient of digestibility of rye-straw pentosans is 46.825 per cent, a value which is regarded as quite near the minimum. The pentosans in the head and in the chaff were apparently a little less digestible than those in the straw, the coefficient of digestibility being 39.89 per cent. The head and the chaff, notwithstanding the large proportion of nutrients which they contain, do not have the same nutritive value as straw.

Modifying straw by the Lehmann method, i. e., heating the chopped material with a dilute sodium-hydroxid solution for 6 hours under a pressure of 6 atmospheres, increased the digestibility of pentosans to 70.20 per cent and that of the crude fiber to 61.49 per cent. The author points out, however, that straw thus treated is not a satisfactory feeding stuff under all circumstances.

Feeding 6.29 lbs. starch and 1.57 lbs. sugar per 1,000 lbs. live weight diminishes the digestibility of pentosans of rye straw to 12.56 per cent and the digestibility of crude fiber to 9.09 per cent. The pentosans, therefore, are apparently more easily digested than the crude fiber.

Concentrated feeds, J. B. Lindsey et al. (*Massachusetts Sta. Bul. 93, pp. 51*).—The Massachusetts law regulating the sale of concentrated commercial feeds, which was approved March 2, 1903, is quoted. In accordance with its provisions analyses

were made of a number of samples of cotton-seed meal, linseed meal, gluten meal, gluten feed, dried distillers' grains, malt sprouts, wheat by-products, dairy feeds, oat middlings, and rye feed.

The comparative value of different feeding stuffs is briefly discussed; several typical mixtures for dairy animals are suggested, and four rations quoted, which are actually fed by dairymen in Massachusetts.

Commercial feeding stuffs, H. J. WHEELER ET AL. (*Rhode Island Sta. Bul. 98, pp. 63–78*).—In accordance with the State feeding-stuff law, analyses are reported of a number of samples of gluten meals and feed, distillers' grains, barley sprouts, wheat feeds including mixed feeds, proprietary feeds, hominy and chop feeds, provender, corn meal, peanut bran, beef scraps, and bone and meat meal.

"The lots of hominy and provender were quite generally poor, yet . . . this in many cases, particularly as concerns the provenders, was due to the inferior quality of certain of the cereals that were grown in 1902. The poor quality of the 'mixed feeds' was shown to have been due in most cases to gross adulteration with corncob, and possibly other materials of little feeding value."

Licensed commercial feeding stuffs, F. W. WOLL (*Wisconsin Sta. Bul. 109, pp. 3, 4, 6*).—A list is given of 44 brands of commercial feeding stuffs licensed for sale in the State, with the guaranteed composition of each. The State feeding-stuff law is quoted.

Condimental feeds, L. WEIL (*Pharm. Ztg., 48 (1903), pp. 606, 607; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 7 (1904), No. 3, pp. 190, 191*).—The condimental feeds examined were made up of glauber salts, chalk, gentian powder, anis, and other common drugs with the addition of concentrated feeds in some cases.

The use of molasses as a feeding material, E. CUROT, trans. by J. A. MUNN (*Ballière, Tindall & Cox; rev. in Mark Lane Express, 88 (1903), No. 3746, pp. 22*).—A summary of information regarding the feeding value of molasses.

A locally manufactured cattle food (*Agr. Gaz. New South Wales, 14 (1903), No. 7, p. 655*).—An analysis is reported of Maizena cattle food.

The adulteration of feeding stuffs; rice husks and coffee bean husks (*British Food Jour., 6 (1904), No. 63, pp. 55, 56*).—A note on the use of rice husks and coffee-bean husks as adulterants of feeding stuffs in Great Britain.

Results of some recent agricultural experiments, D. A. GILCHRIST (*Newcastle-on-Tyne, [1902], pp. 26*).—Recent English experiments with feeding stuffs and fertilizers are briefly summarized.

Concerning the so-called metallic compounds of proteids in relation to the theory of chemical equilibrium, G. GALEOTTI (*Ztschr. Physiol. Chem., 40 (1904), No. 5–6, pp. 492–549, figs. 9*).—Experiments are reported and discussed.

On the percentage of fat in different types of muscle, J. B. LEATHES (*Jour. Physiol., 31 (1904), No. 1, Proc. Physiol. Soc., 1904, pp. II, III*).—The amount of insoluble fatty acids present as fats, soaps, etc., in different types of muscular tissue (rabbit and cat) was determined. The dried and powdered muscular tissue was extracted twice according to Rosenfeld's method and the combined chloroform and alcohol extracts saponified with alcoholic potash.

The soaps dissolved in a large volume of water were precipitated with sulphuric acid and heated until a sharp separation took place. The precipitated fatty acids were filtered while hot, washed with a large amount of water, dried on a filter in vacuo, and extracted with petroleum ether, the extracts being filtered, dried, and weighed in the usual way. The smallest amount of fat was found in the semimembranosus; the largest amount on an average in the heart. In one case with a rabbit the largest amount was found in the soleus.

On the adaptation of the pancreas, F. A. BAINBRIDGE (*British Med. Jour., 1904, No. 2257, pp. 778–781*).—Experiments were carried on with pancreatic juice obtained from dogs and cats, some of which had special reference to the influence of

secretin on the action of the pancreas. The results obtained showed that this body stimulates the pancreas to secrete a juice containing all the enzyms present in the gland at the moment. "The amount and nature of the ferments, which are present in and secreted by the pancreas at any moment depend not on the action of secretin, but on the previous diet of the animal, and are quite independent of secretin.

"The existence of a chemical mechanism for the adaptation of the pancreas is merely a natural corollary to the chemical mechanism of normal pancreatic secretion. . . . But the mechanism, though in each case chemical, is not of exactly the same nature; the stimulus of secretin calls forth an immediate response on the part of the pancreas, whereas the specific stimulus of the food stuff has a slower, but more prolonged effect.

"Hence, secretin evokes the secretion by the pancreas of all the different enzyms present in the pancreas at the time; and the actual composition of the juice as regards its ferments for any given meal depends mainly on the previous diet of the animal, and little if at all on the nature of that particular meal, except in so far as the nature of the food determines the amount of hydrochloric acid secreted by the stomach.

"The influence of diet in modifying the nature and amount of the enzyms secreted by the pancreas has some bearing on the time of appearance of the ferments after birth. Apparently lactase is not present in the pancreas at birth, although it makes its appearance certainly within 10 days, and in all probability earlier."

The peptone-splitting ferments of the pancreas and intestine, H. M. VERNON (*Jour. Physiol.*, *30* (*1903*), *No. 3–4*, *pp. 330–369*, *dgms. 9*).—The questions studied include the rate of development of the biuret reaction, the law of action of peptone-splitting ferments, the differentiation of trypsin and pancreatic erepsin, the action of peptone-splitting ferments on native proteids and related topics. Among the author's deductions are the following:

"The peptone-splitting power of ferments can be estimated colorimetrically by means of the biuret test. If, for instance, twice as great a volume of the partially digested peptone solution as of the undigested peptone is needed to give the same tint with alkaline copper sulphate when observed in a colorimeter, then 50 per cent of the peptone must have been split up by ferment action. It was found that the biuret reaction took an appreciable time to develop its maximum tint. . . .

"It was found that the time required to split up any given percentage of the peptone varied inversely as the quantity of ferment. . . . Of the peptone splitting effected by pancreatic extracts the larger part is due to pancreatic erepsin, a ferment entirely distinct from trypsin. Thus extracts which have little or no fibrin-digesting power, owing to the existence of the trypsin in the zymogen form, have a considerable peptone-splitting action. When the trypsin has become liberated from the trypsinogen the extract may have twice as rapid an initial action on peptone, but the amount of peptone splitting ultimately accomplished by it is always smaller than that by the zymogen extract. This is presumably due to the free trypsin destroying the erepsin. Neither pancreatic nor intestinal erepsin exists in a soluble zymogen form. The peptone-splitting and fibrin-digesting powers of kept pancreatic extracts vary independently, trypsin being more stable in glycerin extracts and pancreatic erepsin in alcoholic. . . .

"Pancreatic erepsin is much more readily precipitable by alcohol than trypsin [and is] . . . a different ferment from intestinal erepsin. . . . The action both of intestinal and of pancreatic extracts is accelerated by increasing alkalinity up to 0.4 to 1.2 per cent Na_2CO_3, but the intestinal ferment—in contradistinction to the pancreatic—is at the same time more and more rapidly destroyed. . . .

"In confirmation of Cohnheim, it was found that extracts of intestinal mucous membrane had little or no action on fibrin, and very little on egg-white and serum proteids. Even pancreatic extracts had a much slower hydrolyzing action on native proteids than upon Witte-peptone."

The relationship of blood supply to secretion, with special reference to the pancreas, O. May (*Jour. Physiol., 30 (1904), No. 5–6, pp. 400–413, figs. 9*).—Experiments with dogs and cats, which are reported in detail, led to the conclusion that there is no direct relationship between the rate of secretion of pancreatic juice and the extent of the blood supply of the pancreas. Secretion was found to continue for some time after complete cessation of the pancreatic circulation.

The proteolytic activities of the pancreatic juice, W. M. Bayliss and E. H. Starling (*Jour. Physiol., 30 (1903), No. 1, pp. 61–83*).—Noted from another publication (E. S. R., 15, p. 798).

Concerning tryptic digestion, H. R. Weiss (*Ztschr. Physiol. Chem., 40 (1904), No. 5–6, pp. 480–491*).—The effect of a number of salts and other substances upon tryptic digestion was studied. Alkali salts of the halogen acids exercised only a slight effect upon tryptic digestion, the effect of sodium chlorid being the most marked. Sodium oxalate diminished the digestibility more than sodium chlorid. The sulphates also exercised a greater effect than the chlorids. Borax was without effect, while sodium phosphate had a favorable effect.

Investigations on the proteolytic enzyms of the spleen of the ox, S. G. Hedin (*Jour. Physiol., 30 (1903), No. 2, pp. 155–175*).—According to the author's investigations the spleen of the ox includes 2 proteolytic enzyms an α-protease, acting only or principally in an alkaline medium and a β-protease, acting only or mainly in an acid medium. Both enzyms were obtained combined and uncombined with nuclein substances. In the former case they were not soluble in weak acetic acid. Ox serum was found to contain antibodies of the α-protease, but not of the β-protease.

On the presence of the proteolytic enzym in the normal serum of the ox, S. G. Hedin (*Jour. Physiol., 30 (1903), No. 2, pp. 195–201*).—The serum of the ox was found to contain a weak proteolytic enzym, active in an alkaline medium. The properties of this enzym were studied.

Concerning the relation between molecular weight and physiological action in the case of the higher fatty acids. I, Myristic and lauric acid, L. F. Meyer (*Ztschr. Physiol. Chem., 40 (1904), No. 5–6, pp. 550–564*).—As was to be expected from theoretical considerations the fatty acids could not entirely replace fats. In experiments with a dog fatty acids with a lower molecular weight than palmetic, stearic, and oleic acid prevented the cleavage of protein to some extent. Judged by the author's results, myristic and lauric acid are to be considered as nutrients.

The heat of combustion and physiological value of nutrients. IV, Composition and energy value of meat feces, J. Frentzel and M. Schreuer (*Arch. Anat. u. Physiol., Physiol. Abt., 1903, pp. 460–479; abs. in Chem. Centbl., 1904, I, No. 3, pp. 199, 200*).—The elementary composition and energy value of feces were studied in experiments in which dogs were fed meat.

Breeding of live stock in Belgium (*Jour. Bd. Agr. and Fisheries [London], 11 (1904), No. 1, pp. 21–25*).—A brief summary, based on a recent publication of the Belgium Department of Agriculture.

Feeding farm animals (*Iowa Agr., 4 (1904), No. 5, pp. 189–196*).—A summary and discussion of feeding stuffs, rations, and feeding standards.

East Friesian animal husbandry and herds, H. Gross and A. Ellerbroek (*Das Ostfriesische Zuchtgebiet und seine Zuchten. Leipzig: Richard C. Schmidt & Co., 1903, pp. IV+87, figs. 29*).—The feeding, care, and management of East Friesian cattle, horses, and sheep are discussed.

Zootechny: Cattle, P. Diffloth (*Zootechnie: Bovidés. Paris: J. B. Baillière & Sons, 1904, pp. VIII+450, pls. 40, figs. 67*).—The general principles of cattle breeding, cattle raising for milk production and for meat, races of cattle, and other topics are treated of in this volume, which constitutes a handbook of available information on the subject. It is included in the series entitled *Encyclopédie Agricole.*

Fattening of cattle (*Mark Lane Express, 90 (1904), No. 3784, Sup., pp. V, VI*).—The nutritive value of rations is discussed with special reference to that fed the Earl of Rosebery's champion reserve heifer in the carcass competition in the Smithfield Show in 1902. Market requirements and other problems in cattle feeding are also briefly spoken of.

Winter fattening of cattle, J. Wilson (*Jour. Dept. Agr. and Tech. Instr. Ireland, 4 (1903), No. 1, pp. 3–21*).—Recent experiments are summarized and discussed with special reference to cattle under local conditions.

Use of potatoes for cattle food, T. Jamieson (*Agr. Research Assoc. [Scotland] Rpt. 1903, pp. 39, 40*).—On the basis of chemical composition the relative value of potatoes and turnips for cattle feeding is discussed, and brief reference made to the successful use of potatoes by local feeders.

The external conformation of German cattle, A. Lydtin (*Arb. Deut. Landw. Gesell., 1904, No. 90, pp. 141*).—The results of a large number of measurements of cattle and other data are reported, with a view to the establishment of standards for form, size, and weight of different breeds.

Systems of judging cattle by a scale of points and the system recommended by the German Agricultural Society, A. Lydtin (*Arb. Deut. Landw. Gesell., 1904, No. 87, pp. VIII+64, figs. 2*).—Different systems of judging cattle are described. That recommended by the German Agricultural Society is believed to be satisfactory.

Carcass demonstration (*Iowa Agr., 4 (1904), No. 4, pp. 151–154, figs. 2*).—A brief account of a carcass demonstration at the Iowa State College which included 9 steers. All but 1 of these had been used in a test of the relative merits of beef breeds *v.* dairy breeds.

The Asiatic buffalo, H. T. Pease (*Agr. Jour. Cape Good Hope, 24 (1904), No. 3, pp. 367, 368*).—A summary of information regarding the Indian buffalo (*Bos bubalus*), with special reference to its value as a draft and dairy animal for the Cape of Good Hope.

An experiment in mutton production, J. H. Burdick (*Illinois Agr., 6 (1902), pp. 42–46*).—With 4 lots of 4 lambs each the relative value of shelled corn with and without gluten meal, shelled corn and oats, and whole oats was studied, clover hay being fed in addition to the grain. In the 9 weeks covered by the test the greatest gain, 0.52 lb. per head per day, was made by the lambs fed corn and gluten meal 2:1, and the smallest gain, 0.39 lb., by those fed whole oats.

"The result of this experiment favors the use of shelled corn and clover hay for the fattening of lambs, as these feeds produce a first quality of mutton with a high percentage of dressed weight."

Notes on the Angora goat, C. D. Woods (*Maine Sta. Bul. 98, pp. 193–198, figs. 4*).—For the last 2 or 3 years the station has kept a small flock of Angora goats and has studied their adaptability to local conditions and their value for clearing underbrush. It was found to be almost impossible to secure pure-bred goats at a moderate price, so a high-grade buck and grade does were purchased. They were hardy and thrifty, requiring during the winter the same care as sheep.

During the summer they required no extra feed if given an ample range of young woodland or brushy pasture which should contain a shed as a shelter from storms. They were wintered on 750 lbs. of hay per head. The goats were regarded as effective for clearing underbrush in woodland covered with birch or evergreen. In the author's opinion, they would doubtless kill other varieties excepting the very large trees. They also cleared bushes and other waste growth from pastures, such feeds being eaten in preference to grasses. Ordinary fencing would not hold the goats, but a fine mesh-wire fence of such height that they could not rest their fore feet upon it was found to be satisfactory even for small areas. As shown by a test, the flesh had a flavor between lamb and venison.

Angora goats in Australia, R. N. BLAXLAND (*Agr. Gaz. New South Wales, 14 (1903), No. 10, pp. 1028–1035, figs. 12*).—The importance of the goat industry is discussed and a brief historical account of Angora-goat raising in Australia is given, as well as statements regarding its condition at the present time.

Angora goat breeding (*Jour. Dept. Agr. West. Australia, 8 (1903), No. 3, pp. 256–258*).—A brief account of the Australian Angora-goat industry.

Pork production in Illinois, D. S. DALBEY (*Illinois Agr., 6 (1902), pp. 74–80*).—In a discussion of the value of different crops for pork production, a test made by C. A. Rowe of the feeding value of soy beans is briefly reported. On September 11, a lot of 132 pigs, weighing on an average 77.1 lbs. each, was pastured on 4.79 acres of ripe soy beans. In the 4 weeks of the test the lot was fed 108.65 bu. of corn in addition to the soy beans and made an average daily gain of 1.25 lbs. per head. Assuming that 10 lbs. of pork were produced from 1 bu. of corn consumed, it was calculated that the amount of pork produced by the soy beans alone was 647 lbs. per acre.

Feeds supplementary to corn for fattening hogs, E. B. FORBES (*Mo. Bul. Missouri State Bd. Agr., 3 (1904), No. 10, pp. 41–48*).—In an address delivered before a meeting of the Improved Live Stock Breeders' Association, the author summarized and discussed experimental data, the most of which was obtained at the experiment stations.

On the value of distillery dried grains as a food for work horses, C. S. PLUMB (*Indiana Sta. Bul. 97, pp. 37–42*).—The two tests were undertaken to learn the value for horses of Fourex dried distillers' grains as compared with oats. For the first 4 and the last 3 weeks of the first test, 2 of the horses were fed the distillers' grains and 2 were fed oats. For the intermediate period of 4 weeks the rations were reversed. In every case not far from 90 to 95 lbs. of hay per head per week was eaten in addition to concentrated feed.

Marked differences were noted in the quantity of distillers' grains eaten, the average amount in the case of 2 of the horses being 6.64 lbs. per head per week as compared with 31.61 lbs. per head in the case of the other two. The amount of oats ranged from 75.84 lbs. to 94.1 lbs. per head per week. In all cases it was found necessary to accustom the horses to the distillers' grains by adding them in increasing amounts to the oat ration. The average weight of 3 of the horses was slightly greater on oats than on distillers' grains, while with the remaining animal the reverse was true.

In the second test, which was made under practically the same conditions except that some corn was added to the ration, the amount of distillers' grains eaten per head per week ranged from 6.87 lbs. to 54.7 lbs. and the amount of oats from 33.1 lbs. to 68.4 lbs. During the 6 weeks of the test all the animals practically maintained their weight. The author notes that they did not relish the dried distillers' grains and that the amount eaten would not have sufficed for the performance of their ordinary work unless other and more palatable feeds had been supplied.

In brief, the conclusion is reached that the distillers' grains tested are not a palatable horse feed, although judged by chemical composition they possess a high feeding value. The investigation "simply illustrates the special importance of palatability as a factor in the adoption of food stuffs for use in common practice.

The zebrula v. the mule, R. GUENTHER (*U. S. Consular Rpts., 73 (1903), No. 277, pp. 350, 351*).—A brief account of experiments carried on in Germany and elsewhere on crossing zebras and horses.

Poultry division, D. D. HYDE (*New Zealand Dept. Agr. Rpt., 1903, pp. 81–93, pl. 1, fig. 1*).—Data are given regarding the flocks at the different poultry stations, the number of eggs laid by different flocks, poultry exports, and related topics.

Practical poultry raising, C. de Lamarche (*Le poulailler pratique. Paris: Henri Gautier [1904], pp. 106, ill.; rev. in Jour. Agr. Prat., n. ser., 7 (1904), No. 16, p. 525*).—A general treatise on poultry raising.

Poultry and eggs in Denmark, R. R. Frazier (*Dept. Com. and Labor, Mo. Consular Rpts., 75 (1904), No. 284, pp. 405–410*).—A summary of information regarding the kind of poultry raised, cooperative associations for egg marketing, preservation of eggs, and related topics.

Eggs and poultry in England, F. W. Mahin (*Dept. Com. and Labor, Mo. Consular Rpts., 75 (1904), No. 284, pp. 404, 405*).—A summary of data regarding the British poultry and egg trade from a financial standpoint.

Table fowls (*Jour. Jamaica Agr. Soc., 8 (1904), No. 2, pp. 61–63*).—The suitability of a number of breeds and crosses of chickens for table birds is discussed, and the Old English Game-Minorca cross is recommended as especially satisfactory for local conditions.

Guinea fowls (*Queensland Agr. Jour., 14 (1904), No. 2, p. 108*).—A short summary of data on guinea fowls. Under local conditions they are not regarded as profitable.

Quailology, H. W. Kerr (*Little Sioux, Iowa: Taxiderm Co., 1903, pp. 63, pls. 16, figs. 2*).—This publication deals with the domestication, propagation, care, and treatment of wild quail in confinement. On the basis of personal experience the author discusses incubation, the feeding and care of the young, and related topics. The different varieties of quail are described at considerable length, and letters and other data from quail raisers are quoted.

Ostrich farming with irrigation, F. Frank (*Agr. Jour. Cape Good Hope, 23 (1903) No. 4, pp. 436–439*).—The feeding, care, and management of breeding birds and young ostriches are discussed. Alfalfa is considered an important feed for both old and young birds.

DAIRY FARMING—DAIRYING.

Forage and soiling experiments, 1902, G. C. Watson and T. I. Mairs (*Pennsylvania Sta. Bul. 65, pp. 12*).—The following forage crops were grown during the season: (1) Clover and timothy, (2) flat peas, (3) Canada field peas and oats, (4) rape, (5) soy beans, (6) sorghum, (7) sorghum and cowpeas, (8) cowpeas, and (9) corn. Notes are given on the culture and growth of each of these crops. The following table shows the dates of planting and harvesting, the yield per acre, and the nitrogen content of the different crops:

Data for succession of forage crops.

Crop.	Date planted.	Date harvested.	Yield per acre. Green.	Yield per acre. Dry.	Nitrogen content of dry matter.
			Pounds.	*Pounds.*	*Per cent.*
Clover and timothy	....	June 15–23	6,872	2,319	1.80
Flat peas	....	June 25–July 1	15.588	3,565	3.23
Canada field peas and oats (early sowing)	Apr. 23	July 2–12	17,314	2,405	2.28
Canada field peas and oats (late sowing)	May 12	July 13–21	18,190	2,928	2.22
Rape	May 5	July 24–26	24,960	3,136	1.98
Soy beans	May 12	July 29–Aug. 4	9,934	2,016	2.22
Sorghum	May 13	Aug. 10–19	27,279	4,337	1.33
Sorghum and cowpeas	May 28	Aug. 20–31	29,563	5,519	1.18
Cowpeas	May 28	Sept. 4–11	18,095	4,071	1.50
Corn	June 21	Sept. 14–23	....	....	1.11

The forage crops were fed to 3 cows. The data for the individual cows are given in the following table:

Yield and fat content of milk of three cows fed different forage crops.

Crops.	Length of feeding period.	Cow Lucy.		Cow Letha.		Cow Cena's Favorite.	
		Daily yield of milk.	Fat content of milk.	Daily yield of milk.	Fat content of milk.	Daily yield of milk.	Fat content of milk.
	Days.	*Pounds.*	*Per ct.*	*Pounds.*	*Per ct.*	*Pounds.*	*Per ct.*
Clover and timothy	9	32.18	5.4	33.31	4.9	36.14	4.8
Flat peas	7	32.01	5.4	33.73	4.8	33.96	4.9
Canada field peas and oats (early sowing)	11	29.77	5.3	31.10	4.7	30.73	4.7
Canada field peas and oats (late sowing)	8	30.55	5.1	31.26	4.5	30.94	4.5
Rape	3	26.75	5.2	29.37	4.9	30.70	4.5
Soy beans	7	24.09	4.6	29.66	4.3	28.86	4.4
Sorghum	10	21.34	4.5	26.48	4.3	26.25	4.6
Sorghum and cowpeas	12	19.90	4.6	24.85	4.3	24.71	4.5
Cowpeas	8	22.10	5.2	27.35	4.7	27.42	4.7
Corn	9	20.74	....	25.28	....	25.65	....

The decrease in the milk production of the 3 cows for the entire period of 101 days was, respectively, 35.55, 24.11, and 29.03 per cent; while during the same time the average decrease in the milk production of 10 other cows of the station herd was 37.5 per cent.

Milk investigations at Garforth, 1903, C. CROWTHER (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 16 (1904), pp. 268–325, dgms. 6*).—This is in continuation of work reported by Ingle (E. S. R., 14, p. 1113), the object of which was to determine the chief factors influencing the yield and quality of milk. The present investigations were made with 18 cows and lasted 52 days, the object being to determine if the variations in yield and quality of milk due to milking at unequal intervals could be lessened by the method of feeding.

The cows were divided into 4 groups. Group 1 was fed a grain ration consisting of 2 lbs. of undecorticated cotton-seed cake, 2 lbs. of decorticated cotton-seed meal, and 1 lb. of wheat meal, divided equally between the morning and evening feeding. Group 2 was fed 1 lb. of undecorticated cotton-seed cake and 1 lb. of corn meal in the morning, and 1 lb. of cotton-seed cake and 2 lbs. of corn meal in the evening. Group 3 was fed grain only in the morning, the ration consisting of 2 lbs. of undecorticated cotton-seed cake and 3 lbs. of corn meal. Group 4 was fed grain only in the evening, the ration being the same as for group 3. All the cows were fed the same as group 1 for several weeks previous to the experiment.

The results are presented in detail and discussed at considerable length. It was found that changing from a narrow to a wide nutritive ratio increased the yield of milk but decreased the fat content, the change being more pronounced in the morning's than in the evening's milk; and also that feeding all the grain ration in the morning tended to increase the fat content of the morning's milk, which latter result confirms the conclusion previously drawn by Ingle. Feeding all the grain in the evening also tended to increase the fat content of the morning's milk, but had apparently little or no effect on the evening's milk. These changes persisted for a number of weeks after the conclusion of the experiment proper.

While milking at equal intervals is believed to be the best method of preventing the fat content of the morning's milk from falling below the legal standard of 3 per cent, and should be adopted wherever possible, the results nevertheless show that the fat content of the morning's milk may be increased by feeding a liberal supply of highly nitrogenous feeding stuffs in the morning. During the summer months the average fat content of the morning's milk of the herd under investigation was on

most days below 3 per cent. It is noted that similar results have been obtained with other herds in different parts of the country.

Data are given on the effects of sexual excitement on the yield and quality of milk and observations upon the influence of weather conditions on milk production are also reported and discussed. It is stated that a change from an equable to either a decidedly low or a decidedly high temperature tends in the majority of cases to decrease the fat content of the milk.

Milk records, J. SPEIR (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 16 (1904), pp. 170–229, figs. 3*).—The Highland and Agricultural Society, in cooperation with local associations, conducted tests of 11 herds in Ayrshire, 11 in Dumfriesshire, and 12 in Wigtownshire. The principal object of the work was to compare the productive capacity of the individual cows in each herd rather than to compare one herd with another. In all, 1,342 cows belonging, with one or two exceptions, to the Ayrshire breed were tested. The records, which cover a period of 6 months, are reported in detail in tabular form.

During the 6 months the best cow produced 731 gal. of milk containing 4.02 per cent of fat. The 90 most profitable cows produced on an average 545 gal. of milk containing 3.84 per cent of fat, and the 90 least profitable cows, 318 gal. of milk containing 3.5 per cent of fat. The cows were classified as small, medium, and large. The small cows averaged 420 gal. of milk containing 3.62 per cent of fat, the medium cows 441 gal. containing 3.69 per cent of fat, and the large cows 464 gal. containing 3.53 per cent of fat.

The average production of 903 cows grouped according to age was as follows: Thirty cows 2 years of age, 362 gal. of milk containing 3.83 per cent of fat; 147 cows 3 years of age, 377 gal. of milk containing 3.87 per cent of fat; 164 cows 4 years of age, 403 gal. of milk containing 3.76 per cent of fat; 137 cows 5 years of age, 421 gal. of milk containing 3.66 per cent of fat; 110 cows 6 years of age, 438 gal. of milk containing 3.63 per cent of fat; 88 cows 7 years of age, 465 gal. of milk containing 3.63 per cent of fat; 80 cows 8 years of age, 468 gal. of milk containing 3.69 per cent of fat; 50 cows 9 years of age, 461 gal. of milk containing 3.63 per cent of fat; 36 cows 10 years of age, 457 gal. of milk containing 3.64 per cent of fat; 28 cows 11 years of age, 464 gal. of milk containing 3.60 per cent of fat; 16 cows 12 years of age, 493 gal. of milk containing 3.48 per cent of fat; 10 cows 13 years of age, 428 gal. of milk containing 3.42 per cent of fat; 3 cows 14 years of age, 375 gal. of milk containing 3.56 per cent of fat; 3 cows 15 years of age, 406 gal. of milk containing 3.39 per cent of fat; and 1 cow 18 years of age, 471 gal. of milk containing 3.74 per cent of fat.

In a large number of cases where the intervals between milkings were equal, the fat content of the evening's milk averaged slightly higher than that of the morning's milk, though the difference was small and considered almost within the limit of experimental error.

Official tests of dairy cows, 1902–3, F. W. WOLL (*Wisconsin Sta. Bul. 107, pp. 43, figs. 21*).—This bulletin contains a brief account of the testing of dairy cows by the station since 1886, a description of the method of making official dairy tests which have been conducted since 1894, a comparison of different systems of testing cows, rules regarding the conduct of official tests, and detailed data for tests of over 200 cows representing Holstein, Guernsey, Jersey, and Red Polled breeds. Illustrations are given of many of the best cows tested during the year.

The average production of the Holstein cows in 7 days was as follows: Cows 5 years old and over (65 tests with 55 cows), 420.4 lbs. of milk and 14.507 lbs. of fat; cows 4 years old (23 tests with 20 cows), 400 lbs. of milk and 13.941 lbs. of fat; cows 3 years old (32 tests with 29 cows), 369.7 lbs. of milk and 12.621 lbs. of fat; cows 2 years old (39 tests with 36 cows), 279.8 lbs. of milk and 9.697 lbs. of fat; and cows below 2 years of age (12 tests with 11 cows), 252.5 lbs. of milk and 8.403 lbs. of fat.

During the year comparisons were made of the results obtained by the system of

monthly 1-day tests conducted by the station, and the results obtained by the breeder himself on the basis of monthly tests of composite samples. The average fat production of 10 Jersey cows as determined by the different methods was 434.9 and 430.5 lbs. and the average fat production of 7 Guernsey cows was 337.1 and 343.9 lbs., the latter figures in each instance being the results obtained by the station. The results are believed to give strong support to the system of monthly 1-day tests.

The influence of food on milk, A. B. GRAHAM (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 16 (1904), pp. 43–62*).—A detailed account is given of 3 feeding experiments, the primary object of which was to determine the influence of the amount of water consumed upon the quality of the milk produced. In the author's opinion the quality of milk is largely influenced by the amount of water consumed, and the results of the experiments are believed to confirm this view.

A brief summary is given of some of the literature on this subject, and determinations of the acidity of milk immediately after milking and after aeration and cooling are reported.

The influence of corn cockle on milk production, J. HANSEN (*Landw. Jahrb., 32 (1903), No. 5–6, pp. 899–927*).—Two series of experiments with cows are reported. Feeding stuffs containing 40 to 50 per cent of corn cockle were eaten by cows without any injurious effects. On the whole, corn cockle exerted a more favorable than unfavorable influence upon the total yield of milk, and also on the yield of fat and solids-not-fat. On the other hand, corn cockle exerted a very unfavorable influence upon the quality of butter, and is therefore of doubtful value as a food for cows.

Investigations on the poisonous properties of corn cockle, O. HAGEMANN (*Landw. Jahrb., 32 (1903), No. 5–6, pp. 929–948*).—The results of several experiments with cows, sheep, pigs, and goats indicated that the feeding of corn cockle in the amounts ordinarily found in feeding stuffs exerted no poisonous influence upon domestic animals. The feeding of large quantities to cows, however, exerted an unfavorable influence upon the quality of the butter.

Action of formaldehyde on milk, A. TRILLAT (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 11, pp. 720–722*).—Comparative tests were made of the digestibility in pepsin solutions of (1) casein from milk treated with formaldehyde in varying amounts (1:5000 to 1:20000) and curdled with rennet, (2) casein obtained from freshly curdled milk and suspended in aqueous solutions of formaldehyde of the strength mentioned, and (3) casein obtained from the same source but not subjected to the influence of formaldehyde.

The digestibility of the untreated casein was 5 to 6 per cent greater than that in the first series of experiments, and 30 per cent greater than that in the second series. Previous to the coagulation of the milk formaldehyde was recovered in practically the amounts added, showing no fixation of the antiseptic. Owing to the action of formaldehyde on the gastric mucous membrane, it is believed that its addition to milk should be prohibited.

Milk, T. MACFARLANE (*Lab. Inland Rev. Dept. Ottawa, Canada, Bul. 93, pp. 15*).—This gives the results of the examination of 227 samples of milk collected during the months of November and December, 1903, of which 159 samples were found genuine or unadulterated.

The milk supply of large towns, F. W. HARRIS (*British Food Jour., 6 (1904), No. 62, pp. 26–30*).—A general discussion of this subject with special reference to the milk supply of Glasgow, analytical data being given.

Studies and observations on milk in the region of Padua, G. ROSSI (*Staz. Sper. Agr. Ital., 36 (1903), No. 10–12, pp. 893–925*).—The author presents a descriptive account of the conditions observed in dairies in the vicinity of Padua and gives the results of a large number of analyses of milk samples.

Sanitary milk—its future, R. A. PEARSON (*Cornell Countryman, 1 (1904), No. 6, pp. 168–170, fig. 1*).—Notes are given on the production of sanitary milk and on the outlook for this branch of the dairy industry.

Preservation of milk by hydrogen peroxid, A. RENARD (*Abs. in Jour. Soc. Chem. Ind., 23 (1904), No. 2, p. 74*).—Observations are given on the rate of decomposition of hydrogen peroxid in milk. A quantity not exceeding 2 per cent of a 12-volume solution was completely decomposed in from 6 to 8 hours. With the addition of 5 per cent of a 12-volume solution the decomposition was not complete after several days.

While a small quantity of hydrogen peroxid does not sterilize the milk, the keeping qualities are much improved. The milk preserved with 1, 2, and 3 per cent of a 12-volume solution remained sweet for 24, 26, and 32 hours, respectively, at 20° C., while milk not preserved soured in 13 hours. It is considered best to add the hydrogen peroxid immediately after milking and keep the milk in a cool place for 6 to 8 hours until the hydrogen peroxid is completely decomposed.

The presence of a lipase in milk, C. GILLET (*Jour. Physiol. et Path. Gén., 1903, No. 3; abs. in Rev. Gén. Lait, 3 (1903), No. 4, pp. 89, 90*).—The investigations were made with human milk obtained with every aseptic precaution. Only exceptionally was the milk sterile. *Staphylococcus pyogenes albus* was almost constantly present and *S. pyogenes aureus* occasionally found. Both sterile and contaminated milk caused a decomposition of monobutyrin. This action was not increased by the development of bacteria in the milk, but was destroyed by a high degree of acidity.

Pure cultures of the bacteria found in the milk were not able to decompose the glycerid. The activity of the ferment was diminished but not prevented by the addition of sodium fluorid or chloroform. The ferment was not destroyed by the coagulation of the milk. It resisted temperatures to 60–65° C., and was found to have no action on other glycerids than monobutyrin, and ought therefore to be designated merely a monobutyrinase rather than a lipase. The monobutyrinase was found also in the milk of the cow, ass, and goat.

It is believed that a number of enzyms exist in milk, anaerobic oxydase, monobutyrinase, and amylase being mentioned. It is considered that no satisfactory explanation concerning the physiological rôle of these ferments has yet been offered.

The oxidizing ferment in milk, L. M. SPOLVERINI (*Rev. Hyg. et Méd. Infantiles, 3 (1904), No. 2, pp. 113–155*).—The author discusses oxidizing ferments in general and reports extended investigations on the oxidizing ferment in the milk of the cow and goat, and in human milk. A distinction is made between the direct oxidizing ferments, or the oxydases which have the power of utilizing directly atmospheric oxygen, and the indirect oxidizing ferments, or anaerobic oxydases which are incapable of oxidizing substances in the presence of atmospheric oxygen alone, but which require an intermediate substance rich in oxygen, as for instance, hydrogen peroxid. Some of the conclusions drawn from the results as a whole are noted below.

Under normal conditions anaerobic oxydase is constantly present in considerable quantities in the milk of cows and goats, in which the ferment is found uniformly diffused throughout the milk serum and is not in combination with cellular elements.

Human colostral milk always produces a noticeable oxidizing action, due to the presence of organized elements in the milk. While the amount of the anaerobic oxydase in human milk varied considerably in the 57 cases under observation, its complete absence was very rare. In human milk containing colostral corpuscles the oxydase was believed to exist mainly within the organized elements, while in other milk it was found to be diffused throughout the serum.

The anærobic oxydase of the milk of cows and goats was believed to be a product of normal elimination. This was thought to be only exceptionally the case in human milk. By modifying the food of a goat, as by feeding the oxidizing ferment, the amount of the oxydase in the milk and in the urine was made to increase or decrease. The characteristic reaction of anærobic oxydase was thought to be due to two special ferments, one decomposing the hydrogen peroxid, and the other fixing the oxygen.

The ferments of milk: An experimental and critical study, H. VAN DE VELDE and J. DE LANDSHEERE (*Ann. Soc. Medico-Chirurg. Anvers, 1903; abs. in Rev. Gén. Lait, 3 (1903), No. 5, pp. 111, 112*).—Conclusions of Spolverini that soluble ferments in certain foods consumed by goats and cows pass into the milk were tested with cows fed germinating barley rich in amylase. No amylase was found in the milk, and the results of Spolverini are attributed to the presence of bacteria.

Contribution to the knowledge of spontaneous coagulation of milk, UTZ (*Centbl. Bakt. u. Par., 2. Abt., 11 (1904), Nos. 20–22, pp. 600–631; 24–25, pp. 733–739*).—The results of investigations led to the following conclusions: The acid formed in the spontaneous coagulation of milk is either dextrolactic acid or inactive lactic acid, or a mixture of the two forms. The variations in the nature of the lactic acid formed has not as yet been satisfactorily explained.

The temperature at which the fermentation takes place influences the period of coagulation, but is without decisive influence on the kind of lactic acid formed. *Bacterium acidi lactici* forming dextrolactic acid, and *B. acidi lævolactici* forming levolactic acid, are the principal organisms concerned in the spontaneous coagulation of milk, the first mentioned being by far the most common. The organism forming dextrolactic acid isolated by the author is believed to be identical with the organism described by Hueppe, Günther and Thierfelder, Leichmann, and Clauss and Kozai; and the organism forming levolactic acid identical with the bacillus of Clauss and Kozai, and probably also with the *B. acidi lævolactici* of Schardinger.

Bacteria in the teats of the cow, goat, and sheep, O. UHLMANN (*Thesis, Jena, 1903; abs. in Rev. Gén. Lait, 3 (1904), No. 7, pp. 163, 164*).—Thirty-five teats of cows, goats, and sheep were hardened in alcohol, sectioned serially, and stained with thionin. Over 800 sections were studied. Milk was never present in the capillary ducts except in very small quantities, and was often entirely absent. Bacteria, on the contrary, were present in every section, occasionally as many as a hundred, but generally only in small numbers. Micrococci predominated. The bacteria were less numerous in the teats of goats and sheep than in those of cows.

The dairy law and its results, J. B. LINDSEY, N. J. HUNTING, and E. B. HOLLAND (*Massachusetts Sta. Spec. Bul., July, 1903, pp. 14, fig. 1*).—The text of the dairy law in Massachusetts is given, the results of inspection of glassware and Babcock machines are reported, and notes are given on making the Babcock test.

Creamery butter making, J. MICHELS (*Lansing, Mich.: Author, 1904, pp. 271, pl. 1, figs. 74*).—This is designed as a handbook to be used by the student in conjunction with lectures on butter making, as well as by the butter maker who can not attend a dairy school, and seems well suited to this purpose. "Special emphasis has been laid upon starters, pasteurized butter making, methods of creamery construction, and creamery mechanics, subjects which have usually been treated only in a very elementary way in similar publications that have appeared heretofore." Historical matter and references are in the main omitted. A glossary is appended.

The use of liquid cultures of milk ferments in the souring of cream, G. FASCETTI (*Staz. Sper. Agr. Ital., 36 (1903), No. 10–12, pp. 997–1003*).—As a result of experiments carried out by the author along this line it was found that the use of milk ferments was of considerable advantage. The time required for churning was somewhat reduced, thus making a saving of labor. The flavor of the butter was improved in some cases.

The interdependence of the physical and chemical criteria in the analysis of butter fat, T. E. THORPE (*Jour. Chem. Soc. [London], 85 (1904), No. 496, pp. 248–256, dgms. 6*).—Determinations were made of various analytical constants on samples of butter of known origin and made from milk obtained under varying conditions. In all, 357 samples were analyzed. This article comments briefly on

the methods of analysis and the results obtained, and summarizes the data in the table given below:

Constants of butter fat.

Number of samples.	Reichert-Wollny number.	Specific gravity at 37.8° C.	Saponification number.	Refractometer number at 45° C.	Soluble acids as butyric.	Insoluble acids.	Mean molecular weight of insoluble acids.
					Per cent.	*Per cent.*	
7	22.5	0.9101	255.4	42.0	4.3	90.1	266.9
17	23.5	.9104	253.4	41.5	4.5	89.7	265.5
15	24.5	.9108	251.3	41.5	4.7	89.4	265.0
27	25.5	.9110	251.1	41.3	4.8	89.3	264.2
37	26.5	.9113	248.9	41.0	4.9	88.9	261.9
51	27.5	.9114	247.4	40.6	5.2	88.7	261.7
78	28.8	.9118	245.7	40.1	5.4	88.4	260.9
56	29.5	.9120	244.0	40.1	5.6	88.3	259.6
41	30.5	.9123	242.4	39.9	5.8	87.9	260.1
18	31.3	.9125	241.5	39.7	5.7	87.9	258.0
10	32.6	.9130	241.2	39.4	6.0	87.7	257.8

In general the specific gravity increased with the Reichert number, and the saponification and refractometer numbers decreased. A low proportion of volatile acid was associated with a high percentage of oleic acid. Twenty samples showed an average Reichert number of 24.2 and an iodin number of 40, and 30 samples an average Reichert number of 30.8 and an iodin number of 32.4.

Sodium fluorid for the preservation of butter, F. JEAN (*Ind. Agr. Prog.* [*Valenciennes*], *1903, No. 293; abs. in Rev. Gén. Lait, 3* (*1903*), *No. 4, p. 91*).—While condemning the use of antiseptics in food products the author would make an exception of sodium fluorid as a means of preserving butter, arguing that when properly used for this purpose the daily consumption of 60 gm. of butter would mean the ingestion of 6 mg. of the fluorid, an amount considered entirely unoffensive, and which would moreover be rendered inert by the lime in the food and digestive secretions.

Chemical changes in the souring of milk and their relations to cottage cheese, L. L. VAN SLYKE and E. B. HART (*New York State Sta. Bul. 245, pp. 36*).—The authors have studied the formation of casein monolactate and casein dilactate in the ordinary souring of milk, and have considered the results obtained in their relation to the manufacture and digestibility of cottage or Dutch cheese.

To study the relation existing between the disappearance of milk sugar and the formation of lactic acid, with the subsequent formation of casein monolactate and casein dilactate, fresh separator skim milk, with and without pasteurization and the addition of a starter, was kept at room temperatures and examined at frequent intervals. In all cases the milk sugar was found to decrease rapidly during the first 32 hours, after which the change was slow, ceasing entirely at the end of 72 to 96 hours. On an average 11 per cent of the milk sugar disappeared in 8 hours, 21 per cent in 24 hours, 25.5 per cent in 32 hours, 26 per cent in 48 hours, 27 per cent in 72 hours, and 27.6 per cent in 96 hours.

The maximum amount of acid calculated as lactic, was about 0.9 per cent, which was equivalent to only about 62 per cent of the milk sugar that disappeared. The equation $C_{12}H_{22}O_{11}+H_2O=4C_3H_6O_3$, while expressing the most prominent chemical action which occurs, is therefore not believed to give anything like a complete or accurate statement of the entire chemical action. Under the conditions of the experiment the milk coagulated in from 24 to 29½ hours, the acid content of the milk at the time of coagulation varying from 0.6 to 0.7 per cent. At the beginning of coagulation the amount of casein in the form of monolactate was 13 to 14 per cent, and in the form of dilactate, 86 to 87 per cent. Later the monolactate was

practically all converted into the dilactate. In one experiment the casein monolactate in milk before coagulation was visible amounted to 65 per cent of the casein. No dilactate was then present.

In studying cottage cheese attention was paid to the relative amounts of monolactate and dilactate present, the conditions most favorable for the manufacture of such cheese, the manufacture of cottage cheese with artificial acids, the question of the occurrence of a ripening process such as takes place in Cheddar cheese, and the digestibility of cottage cheese in pepsin solutions. The experimental work is reported in detail, and is summarized in essentially the form given below.

"*Yield and composition of cottage cheese.*—The yield of cheese from 20.5 lbs. of milk varied from 3.56 to 4.63 lbs. under the conditions tried. The moisture in cheese varied from below 70 to over 80 per cent. The variation in moisture accounts largely for the variation in yield. The amount of moisture in cheese is dependent upon the temperature used in curdling the milk and in heating the curd to expel moisture and also on the length of time the curd is heated. Cottage cheese of the best texture should contain 70 to 75 per cent of moisture. Best success was attained when milk was soured and curdled not much above 70° F. (21° C.) and the subsequent heating was not carried above 90° F. (32° C.). Milk sugar in the cheese varied from 3.28 to 4.08 per cent, which is equivalent to 10 to 16 per cent of the sugar originally present in the milk. Of the sugar in the milk 23 to 27 per cent was decomposed in the souring. Nitrogen in cheese is mostly in the form of casein dilactate, equivalent to 2 to 2.5 per cent of nitrogen.

"*Manufacture of cottage cheese by direct addition of an artificial acid to milk.*—Milk was coagulated by addition of lactic acid and hydrochloric acid and the curd made into cottage cheese. Satisfactory results in every respect were secured. For example, hydrochloric acid (sp. gr. 1.20), diluted with 10 times its volume of water, was added to milk in the proportion of 8 ounces for 100 lbs. of milk at 75° F. (24° C.) and stirred vigorously. The curd separated at once in flocculent form and was strained from the whey without further heating. Any absence of sour-milk flavor can be supplied by mixing with the cheese some ripened cream. Cheese made in this way contains more milk sugar and more nitrogen than cheese made by the ordinary method of souring milk.

"*Slight change of insoluble into soluble nitrogen compounds in cottage cheese.*—Cottage cheeses were made by ordinary souring method from whole milk and from pasteurized and unpasteurized skim milk, with and without rennet, and were examined at intervals to ascertain to what extent insoluble nitrogen compounds change into soluble ones, as in the case of Cheddar cheese. Such proteolytic changes as occurred in 2 to 3 weeks were insignificant.

"*Artificial digestion of some compounds of casein and paracasein contained in cottage cheese.*—According to popular belief, fresh cottage cheese is more readily digested than Cheddar cheese. To test this by laboratory methods, we have subjected to pepsin digestion, without hydrochloric acid and with hydrochloric acid in varying proportions, fresh cottage and Cheddar cheese, in which we had one or more of the following substances: Paracasein, paracasein monolactate in Cheddar cheese, paracasein dilactate, casein monolactate, casein dilactate (cottage cheese) prepared by normal souring of milk and also by direct addition of lactic acid to milk, and casein dihydrochlorid. In the absence of acid, paracasein fails to be digested by pepsin, while paracasein monolactate (the chief nitrogen compound of fresh Cheddar cheese), paracasein dilactate, casein monolactate and casein dilactate (cottage cheese) are partially digested. Paracasein monolactate and casein monolactate, in the absence of acid, are digested more than are paracasein dilactate and casein dilactate. In the presence of 0.4 per cent of hydrochloric acid, paracasein dilactate is digested by pepsin more than is paracasein monolactate. Paracasein monolactate and dilactate and casein monolactate and dilactate and casein dihydrochlorid digest more readily and

completely in the presence of free hydrochloric acid than in its absence. Casein dilactate and casein dihydrochlorid do not differ in the rapidity and extent to which they are converted into soluble compounds by pepsin. The addition of acid after the beginning of the digestion increases the amount of proteid digested, whether we use cottage cheese or Cheddar cheese. Cottage cheese made from whole milk digests more rapidly than that from skim milk, owing to the loose texture of the former. Fat in such cases does not impede digestion. The rapidity of digestion is dependent in part upon the fineness of division of the material to be digested. Cottage cheese as ordinarily consumed is in a state of finer division than Cheddar cheese. Cottage cheese may be properly regarded as more readily digestible than new Cheddar cheese for two reasons: First, the casein dilactate, the chief constituent of cottage cheese, is more digestible by pepsin in the presence of free hydrochloric acid than is paracasein monolactate, the principal nitrogenous constituent of Cheddar cheese; second, cottage cheese is in such a mechanical condition that it admits of easier attack by digestive agents than does new Cheddar cheese."

The details of the methods which were found most practical in the manufacture of cottage cheese are also summarized. The commercial value of cottage cheese depends primarily upon its flavor, which, it is stated, should be of mildly soured or properly ripened cream, and upon its texture, which should be smooth and free from harshness.

The manufacture of cheese with pasteurized milk, G. FASCETTI (*Staz. Sper. Agr. Ital., 36 (1903), No. 10–12, pp. 1004–1008*).—From the experiments reported in this paper it is concluded that the use of pasteurizd milk in the manufacture of cheese makes it necessary to allow more time for ripening than is required when untreated milk is used. The use of fluid extract of a half-ripe cheese of the same sort exercises a marked influence on pasteurized milk and makes it possible to obtain excellent products. When pasteurized milk is used a somewhat larger quantity of cheese is obtained per 100 parts of milk.

A comparison of the bacterial content of cheese cured at different temperatures, F. C. HARRISON and W. T. CONNELL (*Centbl. Bakt. u. Par., 2. Abt., 11 (1904), No. 20–22, pp. 637–657*).—This has been noted from another source (E. S. R., 15, p. 717).

Report of a conference of dairy instructors and experts at the Department of Agriculture, Ottawa, November 4, 5, and 6, 1903 (*Ottawa: Govt. Printing Bureau, 1904, pp. 128*).—Among the subjects discussed at this conference were the cooperation of dairy farmers, export trade in dairy products, the preservation and safe transportation of dairy products, common defects in butter and cheese, the syndicate system in Ontario and syndicate inspectors, milk testing, aeration and cooling of milk for cheese making, sanitation of cheese factories and creameries, pasteurization in butter making, and the cold curing of cheese. In an appendix are given suggestions for the prevention of mold on butter and directions for the determination of acidity in milk.

VETERINARY SCIENCE AND PRACTICE.

Modern theories of immunity and vaccination, L. PFEIFFER (*Ztschr. Hyg. u. Infectionskrank., 43 (1903), No. 3, pp. 426–462, figs. 11*).—A description is given of the various bodies which have been assumed to be present in the serum in accounting for infection, vaccination, and immunity. Notes are given on bacterial immunity and immunity against Protozoa.

The intracellular toxins of certain micro-organisms, A. MACFADYEN and S. ROWLAND (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1904), No. 4, pp. 415, 420*).—Brief notes are given on the nature and methods of demonstrating the intracellular toxins of *Staphylococcus pyogenes aureus*, *Bacillus enteritidis*, and the tubercle bacillus.

The influence of certain bacteria on the coagulation of the blood, L. Loeb (*Jour. Med. Research, 10 (1903), No. 3, pp. 407–419*).—Most of the experiments reported in this paper were made in vitro, the plasma of goose blood being subjected to various organisms, including coli bacillus, tubercle bacillus, etc. In a series of small sterilized porcelain dishes 3 to 18 drops of a bouillon culture of the organisms to be tested were mixed with 3 cc. of diluted plasma of goose blood. It was found that the results thus obtained were approximately constant. *Staphylococcus pyogenes aureus* was found to possess the greatest coagulating power, while very little such power was observed in tubercle bacillus.

The principles and conditions of the control of epizootics, W. Nagorsky (*Fortschr. Vet. Hyg., 1 (1904), Nos. 10, pp. 277–280; 11, pp. 301–306, dgms. 4*).—A historical account is given of the theories upon which repressive measures against various animal plagues have been based. In this discussion especial attention is given to the more important infectious diseases, such as anthrax and rinderpest.

General views on the etiology of infectious diseases; hygiene and serum researches; tuberculosis, F. Hueppe (*London: Baillière, Tindall & Cox, 1904, pp. 39*).—These three subjects were discussed by the author during the presentation of the Harben lectures at King's College, London, 1903. In the first lecture a general account was given of the problems of immunity and susceptibility to disease from the standpoint of modern theories and investigations. In the second lecture the author discussed the results obtained by experiments with various investigators in the treatment and prevention of infectious diseases by means of serum inoculations. The various complex bodies of immune and normal sera were described in detail.

In a discussion of tuberculosis the author called attention to the great importance of this disease in human and veterinary pathology and discussed the means by which the disease can be controlled in man and also the methods by which intertransmission may be prevented.

A study of infection through the navel, Kabitz (*Ztschr. Thiermed., 7 (1903), No. 3–4, pp. 251–274, figs. 4*).—The importance of infection of young animals through the umbilical cord is briefly discussed. The author found that infection by this means could take place as the result of the attack of streptococci, staphylococci, coli bacilli, etc. Various forms of nephritis are caused by infection through the navel. Notes are also given on the importance of this source of infection in meat inspection and on the desirability of making a thorough examination of the umbilical cord in the inspection of meat.

Annual report of the imperial bacteriologist for the year 1902–3, A. Lingard (*Calcutta: Supt. Govt. Printing, India, 1902, pp. 23*).—A report is made on the experiments which have thus far been carried out by the author in the control of rinderpest, anthrax, dourine, hemorrhagic septicemia, Texas fever, etc.

It was found that the mucoid material in the bile of cattle and buffalo is a nucleo-proteid, which rapidly increases in quantity after the animals are injected with virulent rinderpest blood. In cattle inoculated simultaneously with protective serum and virulent blood the nucleo-proteid begins to increase on the day after inoculation. The same substance may be precipitated from the bile of animals affected with rinderpest. An active immunity to the disease begins to be developed on the fifth day after injection with virulent bile, but a passive immunity is manifested immediately after inoculation.

Detailed notes are given on methods of preparing protective serum and the results obtained from its use. During the year covered by the report 87,791 doses were issued, and as a general rule excellent results were obtained from its use.

Live-stock sanitation in Arkansas, R. R. Dinwiddie (*Arkansas Sta. Bul. 82, pp. 97–106*).—Copies are given of Arkansas laws relating to the protection of horses, mules, jacks, and jennets against contagious diseases, and a discussion is presented regarding Federal regulations on shipment of cattle from Arkansas and the laws of

Oklahoma, Kansas, Missouri, and Indian Territory which affect the shipment of cattle from and into Arkansas.

Report of inspectors of stock for the year ended March 31, 1903, T. A. FRASER ET AL. (*New Zealand Dept. Agr. Rpt. 1903, pp. 94–189*).—Detailed reports are presented for various inspectors in different parts of New Zealand regarding the condition of grazing lands and pastures and the prevalence of diseases in different farm animals. Notes are also given on slaughterhouse inspection, the destruction of injurious mammals and birds, the inspection of milk in dairies, and other related topics.

Veterinary, sanitary, and zootechnical problems of the Steppes, A. I. KASATKIN (*Arch. Vet. Nauk, St. Petersburg, 33 (1903), Nos. 11, pp. 1160–1200; 12, pp. 1326–1357*).—Notes are given on the most important diseases which prevail among domestic animals in the regions of the Russian Steppes, and also on the various problems of breeding and care of these animals.

Interstate veterinary conference (*Agr. Jour. Cape Good Hope, 24 (1904), No. 1, pp. 81–90*).—A conference was held November 4–6, 1903, at Bloemfontein, at which representatives of all the British South African States, German South West Africa, and Portuguese East Africa were present, for the purpose of discussing measures calculated to suppress animal diseases in South Africa.

D. Hutcheon spoke on the subject of pleuro-pneumonia and rinderpest. In the discussion regarding these diseases Koch stated his opinion as being that immunity against rinderpest was best accomplished by the use of pure serum. Other speakers agreed with Koch, but Flintoff referred to satisfactory experience which he had had in Orange River Colony in the use of bile. Dr. Koch also presented an account of the African Coast fever. In the discussion of this trouble A. Theiler argued that this disease would probably be confined to the areas in which ordinary Texas fever is at present found. A resolution was adopted to the effect that the different governments of South Africa be requested to collect information and conduct experiments with regard to the possibility of exterminating ticks.

The subject of sheep scab was also discussed by Woollatt, Hutcheon, Tooke, and others. Hutcheon defended the use of the lime-sulphur dip, which he stated possessed an efficacy superior to that of most dips.

The imperial law concerning food animals and meat inspection of June 3, 1900, with related decrees of the Federal Council (*Das Reichsgesetz Betreffend die Schlachtvieh- und Fleischbeschau. Berlin: Carl Heymann, 1903, pp. 381*).—A copy of the text of the German imperial meat inspection law is given, together with various decrees of the Federal Council by which the different sections of the law were put in force and recent decisions of Prussian authorities regarding the execution of the law in the control of meat traffic and animal diseases.

Necrosis as the result of Bacillus necrophorus, H. A. VERMEULEN (*Tijdschr. Veeartsenijk. Maandblad, 30 (1902), No. 3, pp. 102–111*).—The literature of this subject is briefly discussed. The author presents detailed clinical notes on a number of cases which came under his observation. In 1 case in a cow the liver was extensively affected with the process of necrosis, while all other organs were found to be in a normal condition. Notes are also given on the occurrence of *Bacillus necrophorus* in cases of quittor and a brief account is given of the biology of the necrosis bacillus.

Gangrenous broncho-pneumonia caused by the awns of grasses, DUBOIS (*Rev. Vét. Toulouse, 28 (1903), No. 9, pp. 542–545*).—In a number of cases of broncho-pneumonia which were characterized as gangrenous and evidently developed from small foci the author found that the means of infection was furnished by punctures produced by the awns of *Hordeum murinum*.

Hair balls in sheep, J. A. VOELCKER (*Analyst, 28 (1903), No. 330, p. 263, figs. 2*).—From 1 to 50 hair balls were found in the first stomach of lambs and in some cases caused death. A microscopical examination showed that these balls were aggregations of the soft downy hairs which are found mainly on the florets.

The action of the poisonous principle of Equisetum hyemale, MATZ and LUDEWIG (*Ztschr. Veterinärk., 15 (1903), No. 2, pp. 49–54*).—The authors' experiments showed that the poisonous principle of Equisetum was apparently neither an alkaloid nor glucosid, but was aconitic acid. This acid, obtained free, caused the death of guinea pigs to which it was fed, and was also shown to be poisonous for horses.

Tuberculosis; its nature, distribution, cause, and prevention, W. SCHUMBURG (*Die Tuberkulose, ihr Wesen, ihre Verbreitung, Ursache, Verhütung und Heilung. Leipzig: B. G. Teubner, 1903, pp. 139, pl. 1, figs. 8*).—A general account is given of the nature of tuberculosis, its various clinical forms in man and animals, the distribution of the disease, and the means of infection. Particular attention is given to sanitary regulation of tuberculous human patients, the control of tuberculosis among cattle, and the proper treatment of tuberculous meat and milk.

The passage of tubercle bacilli through the normal intestinal wall, M. P. RAVENEL (*Jour. Med. Research, 10 (1903), No. 3, pp. 460–462*).—The author selected healthy dogs and fed them upon an emulsion of equal parts of melted butter and warm water containing numerous tubercle bacilli. The dogs were killed 3½ or 4 hours after feeding, and the chyle was collected for examination. The mesenteric glands were also examined. No lesion was observed in any case in the alimentary tract. Tubercle bacilli, however, were found in the chyle or mesenteric glands of all 10 dogs upon which experiments were made.

As a result of these experiments the author concludes that, at least under certain conditions, tubercle bacilli may readily pass through the normal intestinal wall and infect the animal without causing any lesion in the alimentary tract.

Cerebral tuberculosis in heifers, C. BESNOIT (*Rev. Vét. Toulouse, 28 (1903), No. 8, pp. 465–472*).—Detailed notes are given on the symptoms and pathological anatomy of a case of tuberculosis in a heifer in which the meninges of the brain and other cerebral structures were affected.

The immunization of young cattle against tuberculosis, THOMASSEN (*Rec. Méd. Vét., 8. ser., 10 (1903), No. 1, pp. 5–19*).—The literature of this subject is briefly reviewed, with special reference to the experiments of von Behring. In the author's experiments a number of young cattle were used and were inoculated intravenously with tubercle bacilli of human origin. Detailed notes are given on a series of 5 experiments. From these experiments the author concludes that cattle endure intravenous inoculations of human tubercle bacilli in doses of 30 mg. The first inoculation does not produce any reaction until after 10 to 15 days, while the second and third injections produce an elevation of temperature within 24 hours. The author is not disposed to draw definite conclusions from his experiments regarding the practical value of this method of immunization.

Protective vaccination for tuberculosis, M. SCHLEGEL (*Berlin. Tierärztl. Wchnschr., 1903, No. 49, pp. 745–750*).—A test was made of the efficacy of von Behring's method in immunizing cattle against tuberculosis (E. S. R., 14, p. 393). Two immunized cattle were obtained from the Marburg Institute and the results obtained from inoculation of these cattle were compared with the effects of inoculation of 3 control cattle. In the first experiment the immunized cattle and 1 control animal were used and it was found by tuberculin injections that the 2 immunized cattle were still affected by tuberculosis. All 3 animals were inoculated with virulent material obtained from the lymphatic glands of a tuberculous beef animal. Inoculations of guinea pigs with this material showed that the tubercle bacilli were exceedingly virulent. During the first 3 weeks after inoculation no reaction was shown in any of the animals. After that time, however, in the control animal a considerable elevation of temperature and other symptoms of infection were observed. A tuberculin test made 9 weeks after inoculation produced a decided reaction in all 3 animals.

These 3 animals were then subjected to a second inoculation with virulent material and the results were compared with the effect of similar inoculation in 2 healthy

control cattle. The material used for inoculation was exceedingly virulent. Only the slightest febrile reaction was observed in the immunized animals and 1 of the control animals. In the other 2 control animals a considerable rise of temperature was noted. Detailed notes are given on other symptoms which were observed during the course of the experiment. All 5 animals were killed and carefully examined. The results of these post-mortem examinations showed that all of the animals were affected to some extent with tuberculosis.

The author believes that it is impossible to state, on the basis of experiments thus far carried out, whether von Behring's method can be applied without harmful results in all cases or not. The immunized animals, however, showed an almost complete resisting power toward injections with virulent material, and the author concludes that this method must be considered as of great value and promise in the control of tuberculosis in cattle.

The cure of tuberculosis as the keystone of the problem of combating bovine tuberculosis, E. Hauptmann (*Ztschr. Thiermed., 7 (1903), Nos. 3-4, pp. 161-200; 5-6, pp. 321-357*).—In the author's opinion the unity of human and bovine tuberculosis must be assumed as a demonstrated fact. Attention is therefore called to the great importance for animal industry of securing any method of treatment which can be relied upon to cure the disease in man and animals.

A critical historical review is presented on the literature of this subject in connection with a bibliography of 302 titles. In this discussion the opinions of various investigators regarding the possibility of curing tuberculosis in man or animals are quoted, and notes are given on the formulas which have been recommended in the preparation of medicines to be used for this purpose. While various preparations of silver have yielded encouraging results, the author considered that iodin was more promising, and in the use of various forms of this drug finally experimented with a preparation recently put upon the market under the name Iodipin. This remedy may be used in the treatment of tuberculosis in cattle, either by hypodermic injections or by way of the mouth.

The author made experiments on cattle during which Iodipin was repeatedly injected under the skin. No irritation, inflammation, or infiltration was observed. The drug remains sterile and there is therefore no necessity of sterilizing the inside of hypodermic syringes after treating experimental animals. Numerous experiments were also made during which cattle were fed varying quantities of Iodipin. In the first experiment a tuberculin reaction was obtained in animals which had been treated with Iodipin, but the tuberculous foci gave evidence of being gradually walled in by connective tissue and of becoming less virulent. It was found by further experiments in the subcutaneous use of Iodipin that this drug could be administered to cattle in daily doses of 50 gm. without producing any injurious effects upon the experimental animals. The largest dose which was administered was 600 gm., and this had no bad effects upon the animal. In 4 tuberculous animals subjected to repeated doses of Iodipin no tuberculin reaction was obtained when they were tested later, and an examination of the animals indicated that they were apparently cured.

This method of treating tuberculosis in cattle is compared with the methods proposed by Bang, von Behring, Ostertag, and others, and the advantages and disadvantages of the various methods are discussed in considerable detail. The author believes that his method possesses many advantages over all other methods, and is to be preferred in combating tuberculosis in cattle. The author suggests that his method be tested on a large scale for the purpose of determining its practicability.

Tuberculin tests in western Norway, C. Lekknes (*Norsk. Vet. Tidsskr., 16 (1904), No. 1, pp. 1-7*).—A brief account is given of the tuberculin tests which have been made during recent years in western Norway, with notes on the prevalence of tuberculosis as indicated by these tests.

The utilization of the meat of tuberculous animals in Germany, Kopp (*Rec.

Gén. Méd. Vét., *2 (1903), No. 22, pp. 513–518*).—The laws and regulations of Germany relating to this matter are briefly discussed, and the regulations are compared with those which exist in France with regard to the disposal of tuberculous meat. It is urged that greater attention should be given to this matter in order that a greater uniformity of treatment may be brought about, and also in order that dangerous meat may more certainly be excluded from the market.

A specific enteritis in cattle apparently of a tuberculous nature, H. MARKUS (*Tijdschr. Veeartsenijk. Maandblad, 30 (1903), No. 5, pp. 195–206*).—Detailed clinical notes are given on an enteritis observed in cattle. In cases of this disease a diffuse chronic infiltration was observed in the alimentary canal, involving mucous and submucous layers. The mesenteric lymph glands were also affected in a manner apparently identical with tuberculosis of these structures.

Disease of cattle in the Molteno District (*Agr. Jour. Cape Good Hope, 24 (1904), No. 2, pp. 163–165*).—A preliminary investigation was made regarding the nature and cause of a disease of cattle in the Molteno District of South Africa. The disease affects cattle of all ages, but chiefly old cows. It does not appear to be due to an active plant poison, but some evidence was obtained which indicates the possibility of a slow-acting plant poison. According to this hypothesis the disease would be related to the cirrhosis of the liver which is supposed to be caused by eating *Senecio jacobæa*.

An investigation of calf diarrhea, E. JOEST (*Ztschr. Thiermed., 7 (1903), No. 5–6, pp. 377–413*).—The observations and experiments reported in this paper were confined to the Province of Pomerania. A large number of calves were obtained for examination, all of which were submitted with the statement that they were affected with diarrhea. Among these calves a bacteriological examination showed that 20 were affected with diarrhea, 1 with polyarthritis, 1 with hemorrhagic enteritis, and 1 with catarrhal pneumonia.

An examination of the lesions in cases of calf diphtheria showed that the most essential pathological characteristics of this disease are catarrhal inflammatory phenomena in the stomach and alimentary tract, inflammatory swelling of the corresponding lymph glands, parenchymatous degeneration of the liver, kidneys, and heart, and hemorrhages in the serous membranes. A bacterial organism was found in the small and large intestines, spleen, and blood. This organism was grown in pure cultures on various media, and inoculation experiments were made upon guinea pigs, mice, rabbits, and calves. The results of these experiments are presented in detail.

It was found that the development of calf diarrhea could be to some extent prevented by allowing the calf to have the fresh cow's milk immediately after birth. It was shown, however, that the disease could develop in calves within a period of from 12 to 15 hours without any infection having taken place through the alimentary tract; in such cases the infection took place through the umbilical cord. A comparison of the bacterial cultures convinced the author that the bacteria of calf diphtheria described by Jensen, the virulent coli bacilli of Poels, and the organism isolated by the author are all one and the same species. This organism is also identical in all essential particulars with the common coli bacillus, its one distinguishing character being its greater virulence for calves. The author therefore proposes the name coli bacillus of calf dysentery for this organism.

Immunizing experiments with rabbits showed that it is a simple matter, by means of increasing doses of this organism, to obtain a strongly agglutinating serum. Experiments with this protective serum, however, showed that it is effective only against bacilli belonging to the same race, while against organisms coming from any other culture it is almost entirely inactive. In preparing a protective serum, therefore, the author recommends that a large number of cultures of coli bacilli should be mixed so as to obtain a polyvalent serum.

Spotted kidney in calves, its histological nature, J. BASSET (*Rev. Gén. Méd. Vét., 2 (1903), No. 23, pp. 582–588, figs. 2*).—The histological pathology of this disease is described in detail. As a result of this study the author reaches the conclusion that spotted kidney of calves is characterized by inflammatory lesions of an acute nature, which may terminate in suppuration or in the development of a chronic condition. The etiology of the disease is not understood.

Contagious pleuro-pneumonia, CONSTANT and MESNARD (*Rec. Méd. Vét., 8. ser., 10 (1903), Nos. 13, pp. 436–444; 17, pp. 569–573*).—The authors present in a tabular form the prevalence and fatality of pleuro-pneumonia in various parts of France and also give an account of inoculation experiments which were undertaken for the purpose of determining the period of incubation and other important matters concerning this disease.

A test was made of a method of preventive inoculation from which considerable success was had, although a number of the animals thus treated died without the ordinary lesions of the disease in the lungs. The authors conclude from their experiments that the accidents which follow the use of preventive inoculation are observed chiefly in animals in a state of latent infection. It is believed that the results obtained throw new light upon the importance of latent infection in general. Pure cultures of a known virulence may be used in inoculating healthy animals and animals in a state of latent infection, and the results thus obtained may be readily compared.

The authors believe that preventive inoculation may reveal the fact of latent infection in animals thus treated, and that this inoculation appears to bring about a localization of the virus in vaccinated animals. The duration of immunity produced by the first inoculation is at least 10½ months.

Parturient paresis, F. W. VAN DULM (*Tijdschr. Veeartsenijk. Maandblad, 30 (1902), No. 3, pp. 111, 112*).—According to the author's experience the most effective treatment consists in increasing the pressure within the mammary gland. This may be done by injections of potassium iodid or other fluid, or by insufflation of air.

The recurrence of parturient paresis, A. J. WINKEL (*Tijdschr. Veeartsenijk. Maandblad, 30 (1903), No. 6, pp. 256–258*).—A brief account is given of the occurrence of parturient paresis in a cow which had recovered from an attack of the disease a short time before and about 3 days after parturition.

The etiology and treatment of parturient paresis, CAILLIBAUD (*Rev. Vét. Toulouse, 28 (1903), No. 7, pp. 420–428*).—The author attempts to reach a reasonable hypothesis regarding the nature of this disease. The Schmidt treatment was used by him for 2 years with excellent results. Warm applications to the udder and friction along the vertebral column were also found to exercise a beneficial influence. From the fact that the injection of liquid or air into the udder produces good results in the cure of this disease, the author concludes that parturient paresis is due to toxins set free in the udder as the result of increased metabolism. The pressure of the liquid or air in the udder is believed to check the physiological processes and consequently reduce the amount of toxin.

Clinical notes on parturient paresis, E. NAUDINAT, Jr. (*Rev. Vét. Toulouse, 28 (1903), No. 5, pp. 262–267*).—In some cases of this disease the author applied friction together with treatment with mustard in the lumbar region, while stimulants were administered by way of the mouth. The best results were obtained from the use of Schmidt's method followed by the insufflation of air into the udder. In the use of this combined treatment the author produced complete cure in 95 per cent of cases.

The use of air in treating parturient paresis, EGGMANN (*Schweiz. Arch. Tierh., 45 (1903), No. 1–2, pp. 52–55*).—In the author's experience the results obtained in treating this disease by means of infusions of potassium iodid were not very satisfactory. Much better results were had from the use of air.

Treatment of parturient paresis with oxygen, KNÜSEL (*Schweiz. Arch. Tierh., 45 (1903), No. 1–2, pp. 56–59, figs. 3*).—Descriptions are given of a number of forms of apparatus which in the author's experiments have been found convenient for use in carrying oxygen and administering it in cases of parturient paresis. Considerable difficulty is naturally experienced in transporting sufficient oxygen for use in country practice. Excellent results have been obtained from the application of this method.

Treatment of parturient paresis during the past five years, J. SCHMIDT (*Rev. Vét. Toulouse, 28 (1903), No. 1, pp. 1–16*).—The author describes his method of treatment of this disease and the theory upon which it was based. Good results were obtained by this method, but recently a double treatment has been preferred consisting of first an injection of iodid of potash, later of insufflation of air.

According to the author's experiments the results from this treatment are manifest within ¼ hour, especially in cases where coma was present before the treatment was begun. Among 51 cows treated by this method, 48 have recovered after application in from 1 to 16 hours, the average period required for recovery being 5 hours.

Differential diagnosis of parturient paresis and apoplectic purpureal septicemia, E. H. B. GRAVENHORST (*Tijdschr. Veeartsenijk. Maandblad, 30 (1902), No. 2, pp. 81–84*).—Frequently the symptoms of these two diseases are so similar as to lead to confusion. As a rule, however, the temperature in septicemia does not show a tendency to become subnormal as in cases of parturient paresis.

The bacteria concerned in mammitis of cows and goats, P. STEIGER (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1903), No. 3, pp. 326–341; 35 (1904), Nos. 4, pp. 467–484; 5, pp. 574–593*).—An elaborate study was made of acute and chronic forms of mammitis in cows and goats. Most of the material came from cows. The literature of this subject is discussed in connection with a short bibliography. Notes are given on the various forms assumed during the development of mammitis, and the organisms obtained from the milk of infected animals were identified and cultivated on a nutrient media.

Among the organisms found in these cases mention may be made of *Staphylococcus mastitidis*, *Galactococcus fulvus*, *Streptococcus mastitidis*, coli bacillus, and *Bacillus ærogenes*. The last two named organisms resemble each other very closely, biologically and morphologically, and their peculiar characters are therefore described in detail. Many cases of mammitis were found to be caused by mixed infection in which several organisms participated.

With regard to the origin of infection in cases of mammitis considerable difference of opinion has prevailed, and experiments were undertaken by the author for the purpose of obtaining evidence concerning this point. Negative results were obtained in all cases from rubbing bouillon cultures of coli bacillus upon the teats of healthy cows. Neither the mammary gland nor the milk secretion was altered in any way. The author concludes, therefore, that this is not the usual method of infection. The theoretical possibility of infection by means of the lymphatic system is conceded, but it is urged that this can not be the usual means of infection. Apparently the most probable method of infection in this disease is through the blood system.

An enzootic occurrence of acute streptococcic mammitis, P. DUBOIS (*Rev. Vét. Toulouse, 28 (1903), No. 13, pp. 789–796*).—The author calls attention to the importance of this disease on account of its great infectiousness, the number of animals affected, and the lack of satisfactory treatment. An especially acute outbreak occurred and was investigated by the author, with the result that *Streptococcus conglomeratus* was found to be the pathogenic organism of the disease. The outbreak spread rapidly in spite of the most severe measures of disinfection. Notes are given on the behavior of the organism on various culture media.

Operative treatment of anomalies of the teats, HUG (*Schweiz. Arch. Tierh., 45 (1903), No. 5, pp. 224–237, fig. 1*).—The author describes the various practical

methods which have been devised for enlarging the opening in teats which are pathologically altered, and in the treatment of various other anomalies of these organs.

The study of parasitic diseases of the blood, especially malaria in cattle and man, E. JACKSCHATH (*Berlin. Tierärztl. Wchnschr., 1903, No. 50, pp. 769–776*).—The author reviews in a critical manner some of the more important contributions to a study of Texas fever in cattle and malaria in man. The life history of the blood parasite of Texas fever is described in considerable detail with special reference to the theoretical explanation of immunity toward this disease. The author concludes that natural or acquired immunity toward Texas fever is due to the presence of asexual degenerated forms of the blood parasite.

The piroplasmoses of cattle, E. DSCHUNKOWSKY and J. LUHS (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1904), No. 4, pp. 486–492, pls. 3*).—According to the authors, piroplasmosis in Russia appears under 3 forms, the first of which is observed in northern Russia, the second in Ciscaucasia, and the third in Transcaucasia. The form which occurs in Transcaucasia is called tropic piroplasmosis, and is characterized by the development of extensive hemorrhages in all organs of the body. The blood parasites observed in cases of this disease occur in the form of cocci, rings, and bacilli. Immunization experiments have not given satisfactory results, and the agency of ticks in the distribution of the disease has not been definitely proved.

Piroplasmosis of the donkey, T. H. DALE (*Transvaal Agr. Jour., 2 (1904), No. 6, pp. 187–195*).—This disease occurred in a serious outbreak in Lydenburg. The period of incubation was not definitely determined, but the symptoms were similar to those in equine malaria.

Inoculation experiments with virulent blood from donkeys caused no reaction or serious disturbance in dogs, rabbits, mules, or donkeys. These experiments indicate that the disease is not easily transmitted in this manner until after the blood parasite has undergone a series of metamorphoses. The disease yields readily to medicinal treatment, and prognosis is therefore considered favorable unless the animal has suffered for some time before treatment is begun. In the first stages of the disease ammonium carbonate in 2-gm. doses is recommended, followed by arsenic in doses of 3 gr. in 1 gm. of sulphur after the fever abates.

The cultivation of Trypanosoma brucei, F. G. NOVY and W. F. MCNEAL (*Jour. Amer. Med. Assoc., 41 (1903), No. 21, pp. 1266–1268*).—The results of the experiments made by the authors in devising suitable means for cultivating the parasitic organism of nagana are briefly described. *T. brucei* as found in the blood of infected animals is exceedingly virulent, and intraperitoneal injection of virulent cultures is sufficient to kill mice and rats in 7 or 8 days. Experiments in immunizing laboratory animals against nagana have not thus far yielded final results. Apparently a slight protection was afforded by vaccination. Attention is called to the differences between *T. brucei* and *T. lewisi*.

A trypanosoma disease of North Africa, RENNES (*Rec. Méd. Vét., 8. ser., 10 (1903), No. 18, pp. 424–430*).—During the first months of the year the author observed a disease among horses which was apparently due to infection with a Trypanosoma. The blood parasite appears to differ from that of dourine. The symptoms and course of the disease are described in detail. Considerable fever is present and acute nervous symptoms are noted together with hematuria. The organism is described and notes are given on its morphology. In the author's experiments it was found to be pathogenic for the gray mouse, the jerboa, and the dog.

African coast fever, R. KOCH (*Agr. Jour. and Min. Rec. [Natal], 6 (1903), No. 20, pp. 734–742*).—This is the author's third report concerning his investigations on African coast fever. It has been found that a mild infection may be produced by repeated injections of blood from sick or recovered animals. The severity of infection thus produced is not increased by repeated passages through various animals.

In the author's investigations 3 distinct lines of experiments were undertaken for the purpose of devising immunizing and curative methods. A number of animals were subjected to inoculation with the blood of sick or recovered animals. It was found that as good results were obtained from the use of the blood of recovered animals as with blood taken from animals during the progress of the disease. During these experiments many cases of undoubted immunity were established.

In a second series of experiments healthy and sick animals were treated with doses of serum obtained from immunized animals. This serum exercised a remarkable effect upon the blood parasites, causing them to shrink and disappear. The serum treatment, however, while possessing this great advantage, is subject to one serious disadvantage, viz, that the serum exercises a pronounced hemolytic effect upon the blood of diseased cattle. An injection of 50 cc. of serum in a sick animal is sufficient to cause death by hemolysis. Considerable success was had in using the serum method on healthy animals for the purpose of preventing the development of the disease.

In a third series of experiments a test was made to determine the existence of natural immunity in various races of cattle. It was found that zebus and half-bred zebu cattle had no natural immunity toward African coast fever; on the other hand, cattle coming from German East Africa appeared to be perfectly immune. As a general result of the author's investigations inoculation with the blood of recovered animals is recommended as the most effective and most feasible means of controlling this disease.

A contribution to the diagnosis of heart water in cattle, A. Theiler (*Transvaal Agr. Jour., 2 (1904), No. 6, pp. 163–173, pl. 1*).—The symptoms of heart water in sheep and goats are described in detail, together with an account of the post-mortem lesions of this disease, its geographical distribution, and occurrence in cattle. Experiments indicate that the incubation period in cases of tick infection is longer than in cases of injection with virulent blood. The disease may be transmitted by inoculating the virulent blood of sheep and goats into cattle. Under natural conditions the disease is carried by bont ticks in a nymphal or adult condition.

The Texas cattle fever: How science is winning a long fight, C. S. Potts (*Amer. Mo. Rev. of Reviews, 29 (1904), No. 168, pp. 49–55, figs. 11*).—A brief historical account is given of the traffic in Texas cattle, which were driven over the trail from the South into Kansas and Missouri during the period from 1867 to 1887. Notes are also given on the quarantine line, the nature and transmission of Texas fever, the method of inoculation with the blood of recovered animals, and the benefits of this discovery to the stock interests of the South.

The cattle tick and the quarantine restrictions, T. Butler (*Bul. North Carolina State Bd. Agr., 24 (1903), No. 10, pp. 30–37*).—The author presents a general description of the quarantine line and the restriction of federal quarantine upon the cattle of North Carolina. It is argued that, while these restrictions are necessary, they cause considerable loss to animal industry in the State. Detailed recommendations are given regarding methods of destroying the cattle ticks.

The classification and nomenclature of diseases known under the name actinomycosis, J. Lignières and G. Spitz (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1903), No. 3, pp. 294–308; 35 (1904), No. 4, pp. 452–458*).—In an extended study of actinomycosis it was found desirable to classify the organisms found in cases of this disease into 3 groups, viz., *Actinomyces bovis*, *Streptothrix israeli*, and Actinobacillus. The behavior of these organisms on various culture media is described in detail and notes are given on the results of inoculation experiments in laboratory animals and a study of the virulence of the different organisms.

The authors conclude that actinomycosis can no longer be considered as a simple disease due to 1 organism, but that some classification must be adopted based on the morphological, cultural, and pathogenic properties of the micro-organisms which cause the various forms of the disease.

A study of dourine, J. ROUGET (*Rec. Méd. Vét., 8. ser., 10 (1903), No. 3, pp. 81–90*).—This article consists largely of a critical review of the results thus far obtained in a study of the symptoms, pathological anatomy, and etiology of this disease.

The treatment of dourine by cacodylates, E. MARCHAL (*Rec. Méd. Vét., 8. ser., 10 (1903), No. 7, pp. 230–232*).—The author describes a number of experiments made in treating dourine by the salts of cacodylic acid. In the first experiments of the author, cacodylate of iron was used in subcutaneous injections. Lesions were produced in the skin, however, and later this remedy was abandoned and cacodylate of soda was used in its place. The latter remedy was injected subcutaneously in daily doses of 1 gm. Notes are given on 6 cases in which this remedy was used, and excellent results were obtained in all except 1 case in which the treatment was not begun until 132 days after infection.

Blackleg and vaccination, N. S. MAYO and C. L. BARNES (*Kansas Sta. Bul. 122, pp. 163–178, figs. 6*).—In the authors' experience blackleg is apparently confined to cattle. Only 1 case was reported of its appearance in sheep and this was considered doubtful. Reports from 1,656 stock men indicate that the greatest losses from blackleg occur in May, June, September, and October. While blackleg is generally supposed to be transmissible by wound infection, the evidence thus far obtained does not seem to favor this theory. The authors' experiments and observations on this disease indicate that the greatest loss in cattle occurs between the ages of 6 to 18 months, and that fat calves are most susceptible. The average loss among unvaccinated calves is between 4 and 5 per cent, while after vaccination it is 0.4 per cent.

The minute structure of the anthrax bacillus, D. OTTOLENGHI (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1904), No. 5, pp. 546–553, figs. 3*).—The author studied the anthrax bacillus from material obtained by means of pure cultures and in the blood or exudations of infected animals. The organism was stained by various methods and subjected to different reagents for the purpose of differentiating its finer structures. These structures are described in detail. According to experiments carried out by the author it is possible to stain living anthrax bacilli with neutral red without destroying their germinating power.

The period of life of anthrax spores, A. VON SZÉKELEY (*Ztschr. Hyg. u. Infectionskrank., 44 (1903), No. 3, pp. 359–363*).—Notes are given on the results of an examination of anthrax cultures which had been kept in laboratories for long periods. It was found that in gelatin media which had been inoculated with the spores of anthrax bacilli and maintained at the temperature of a living room, exposed to diffuse light and under conditions which favor moderately rapid desiccation virulent spores were found after a period of 18½ years that were still capable of germinating and were virulent, at least for white mice. Under the same conditions the spores of the bacillus of malignant edema also retained their vitality for the same length of time. It was found also that the spores of these 2 species of bacilli could be maintained together in one culture for 18½ years without either species of organism being influenced to any noticeable degree.

Preliminary note on the resistance to heat of Bacillus anthracis, A. MALLOCK and A. M. DAVIES (*Proc. Roy. Soc. [London], 72 (1903), No. 486, pp. 493–499, fig. 1*).—The experiments reported in this paper were undertaken for the purpose of determining the degree of heat and period of exposure necessary for the destruction of anthrax bacilli and spores. A special apparatus was constructed for these experiments, and a detailed description of the apparatus is given. The anthrax bacilli used in these experiments were contained in infected water in sterilized glass tubes 3 in. long and ½ in. in diameter. Care was taken that spores were present in all cases.

During the experiments 113 tests were made, of which 95 were at temperatures above and 18 below 100° C. In the 95 experiments at temperatures above 100°, 14

cases occurred in which some growth took place after incubation of the tubes; in 12 of these 14 cases, however, the growth was contaminated. In the 18 experiments made at temperatures below 100° C., growth occurred in 5 cases, in only 1 of which a pure anthrax culture was found. The authors conclude from their experiments that the subjection of anthrax spores to a temperature of 100° or higher, even for the shortest possible period, is sufficient to insure their destruction.

The treatment of anthrax in cattle, M. STREBEL (*Schweiz. Arch. Tierh., 45 (1903), No. 3, pp. 105–113*).—The literature of this subject is briefly discussed and the usual prophylactic measures are described. While considerable success may be expected in the prevention of the disease by the adoption of strict antisepsis and the use of the vaccination method, little hope may be entertained of good results from the ordinary treatment of anthrax. Carbolic acid has been recommended for use in intravenous injections and was tried by the author without very satisfactory results. In 4 cases the exposure of the affected animals to a very low temperature appeared to have striking results in bringing about a cure.

Anthrax vaccination according to Sobernheim, KUNZE (*Berlin. Tierärztl. Wchnschr., 1903, No. 52, pp. 798, 799*).—Brief notes are given on successful results obtained from vaccinating cattle and horses against this disease.

Effect of anthrax vaccination on the severity of foot-and-mouth disease, DELHAYE (*Rec. Méd. Vét., 8. ser., 10 (1903), No. 10, pp. 235–237*).—Statistics are presented with reference to infection with foot-and-mouth disease in animals which have previously been vaccinated for the purpose of preventing anthrax. These statistics show that animals thus treated are unusually resistant to foot-and-mouth disease, and it is believed by the author and by Nocard, who joined in the discussion, that the anthrax vaccination apparently exercises a favorable influence in preventing the development of foot-and-mouth disease.

Transmission of foot-and-mouth disease from animals to man, A. CONTE (*Rev. Vét. Toulouse, 28 (1903), No. 5, pp. 249–262*).—This paper is based partly on replies to a circular letter of inquiry regarding the transmission of foot-and-mouth disease from animals to man, the means of transmission, the localities where the disease exists, number of cases observed, and duration of the disease. Incidentally observations were made on the difference in susceptibility of various domestic animals to this disease. It was concluded that as a rule man becomes infected with foot-and-mouth disease through drinking the milk of infected animals.

The transmission of foot-and-mouth disease to man, H. ROCHÉ (*Rev. Vét. Toulouse, 28 (1903), No. 4, pp. 185–194*).—Attention is called to the danger from drinking the milk of animals affected with this disease. It is argued that more attention should be devoted to the determination of the nature and forms of stomatitis in cattle.

Sheep poisoning at the Hawkesbury Agricultural College, H. W. POTTS (*Agr. Gaz. New South Wales, 14 (1903), No. 12, pp. 1212–1214, fig. 1*).—A number of sheep died suddenly with symptoms of poisoning. A post-mortem examination of these animals failed to reveal any constant set of lesions. The evidence obtained from a study of this outbreak indicated that *Sisyrinchium micranthum* was the cause of the poisoning.

Infectious broncho-pneumonia in lambs, G. MOUSSU (*Rec. Méd. Vét., 8. ser., 10 (1903), No. 3, pp. 90–95*).—A description is given of the symptoms, diagnosis, lesions, prognosis, and treatment of this disease. No remedy has been found which produces a certain cure. The best results are to be obtained by observing strict prophylactic measures, especially in avoiding the importation of diseased animals into healthy herds.

Preventive and curative serum for sheep pox, E. THIERRY (*Jour. Agr. Prat., n. ser., 7 (1904), No. 3, pp. 83–86*).—The results which have been obtained by various experimenters in preventing and curing this disease by serum therapy are briefly outlined. The author believes that the chief cause of accident in applying this treatment is carelessness in the matter of details.

The virulence of the fleece of sheep recovered from sheep pox and not washed, L. DUCLERT and A. CONTE (*Rev. Vét. Toulouse, 28 (1903), No. 6, pp. 335–339*).—On account of the marked infectiousness of this disease the author attempted to determine the period during which the virus may retain its virulence in the fleece of recovered sheep. It was found that within 58 days after inoculation or 46 days after a generalization of the disease the pustules had dried up entirely and were covered with brown scales. Experiments showed that native sheep which had been vaccinated were not likely to spread contagion after a lapse of 2 months from the time of inoculation.

A clinical study of variola in goats, A. CONTE (*Rev. Gén. Méd. Vét., 2 (1903), No. 24, pp. 635–639*).—Until within recent years this disease has been considered as identical with sheep pox. It has been shown, however, to be a specific disease. Goats are not susceptible to sheep pox. Variola in goats terminates with complete recovery in almost all cases. The pustules developed during the progress of this disease furnish a means of distinguishing between it and sheep pox. The disease does not spread as rapidly as sheep pox or foot-and-mouth disease, with which it might be confused. In preventing the disease it is recommended that attention be given to disinfection of premises and isolation of diseased goats.

Swine fever, S. STOCKMAN (*Transvaal Agr. Jour., 2 (1904), No. 6, pp. 213–219, pl. 1*).—The symptoms, etiology, diagnosis, and treatment of this disease are briefly discussed in connection with statistics relating to the prevalence of hog cholera in America.

Swine fever, W. C. QUINNELL (*Jour. Agr. and Ind. South Australia, 7 (1903), No. 5, pp. 308–311, figs. 4*).—Brief notes on the symptoms, post-mortem lesions, and means of eradication of this disease.

Combating swine erysipelas, J. J. WESTER (*Tijdschr. Veeartsenijk. Maandblad, 30 (1902), No. 2, pp. 49–63*).—Vaccination is said to be the most rapid and effective method for preventing the general and destructive spread of this disease. The author states that the danger from vaccination is so slight as to be largely characterized as imaginary. Vaccination is therefore recommended as a general method for preventing swine erysipelas.

Swine erysipelas and its treatment, BERTSCHY (*Schweiz. Arch. Tierh., 45 (1903), No. 3, pp. 115–119*).—Notes are given on the distribution and occurrence of this disease. In the Canton of Zurich in the year 1902, 2,242 hogs were vaccinated with the following results: In 2,141 animals no symptoms of the disease appeared; among the 101, however, which were already affected with swine erysipelas, 87 recovered while 14 had to be killed. The expense of the treatment was about 25 cts. per animal.

The work of sanitary police with regard to swine erysipelas, G. FERRANT (*Rev. Vét. Toulouse, 28 (1903), No. 2, pp. 84–87*).—Attention is called to the danger of starting an infection from the many hogs which are transported from place to place freely, although suffering from a latent infection of this disease. After a period of 10 days following treatment by an immunizing serum it is believed that animals are not likely to transmit infection.

The presence of the bacillus of swine erysipelas on the mucus membrane of healthy pigs, C. O. JENSEN (*Rev. Vét. Toulouse, 28 (1903), No. 9, pp. 533–538*).—The bacillus of this disease varies greatly and different individuals and races of pigs exhibit considerable difference in their susceptibility to the disease. The author calls attention to the almost normal and very frequent occurrence of this bacillus on the mucus membranes of healthy pigs.

Vaccination for hog cholera according to the method of Poels, H. ANKER (*Tijdschr. Veeartsenijk. Maandblad, 30 (1902), No. 2, pp. 63–80*).—The details of this method are briefly described and notes are presented on a number of experiments which were made in its application. The author concludes from his experiments

that a certain percentage of pigs vaccinated by the method of Poels may die of inoculation hog cholera, or may suffer from a chronic form of the disease as a result of vaccination. Great care is therefore recommended in the use of this method.

Observations on recovery from glanders, Mouilleron (*Rec. Méd. Vét., 8. ser., 10 (1903), No. 24, pp. 530–535*).—Clinical notes are presented on 4 cases of glanders in horses which ultimately recovered entirely. The horses were given mallein injections at intervals during periods of 3 to 4 years. Finally each horse was killed and subjected to a careful post-mortem examination and microscropic study. Material was also taken for use in the inoculation of male guinea pigs. Negative results were obtained from all these tests for the presence of the glanders bacillus.

Immunity toward contagious coryza, J. Schnürer (*Ztschr. Thiermed., 7 (1903), No. 3–4, pp. 286–307*).—The literature of this subject is critically discussed by the author. A number of cultures of the streptococci of contagious coryza were examined by the author, in all 13 cases in horses. This organism was found in an abscess of infected laryngeal lymph glands. Notes are given on the biology of this organism.

All cultures obtained by the author were found to be virulent for white mice. These animals died within 2 to 4 days after inoculation. Streptococci, however, were only slightly virulent for rabbits and guinea pigs. Experiments were made on white mice, rabbits, and 1 ass, for the purpose of testing the possibility of immunizing animals against this disease. During these experiments it was found that no substance was present in the serum of horses affected with spontaneous cases of contagious coryza or artificially immunized against this disease, which had any active influence in checking the progress of the disease in experimental animals.

Mal de caderas affecting horses, G. d'Utra (*Bol. Agr. São Paulo, 4. ser., 1903, No. 11, pp. 501–520*).—The literature relating to this subject is critically discussed. Notes are given on the ordinary clinical forms of mal de caderas, including the chronic and paralytic forms. The treatment of the disease is also briefly discussed and reference is made to the agency of insects in carrying the blood parasite.

Mal de caderas in South American horses, J. Lignières (*Rec. Méd. Vét., 8. ser., 10 (1903), Nos. 2, pp. 51–69; 4, pp. 109–134; 6, pp. 164–190, pls. 2*).—This disease is due to infection by *Trypanosoma elmassiani*. Notes are given on the morphology of the organism and its various developmental forms. Special attention is devoted to a discussion of agglutination of the blood parasite and its behavior toward antiseptics.

The vitality of the organism of mal de caderas differs greatly according to the medium in which it is grown. Agglutination takes place either in more or less irregular masses, or rarely in the form of a row of beads. In general agglutination occurs rapidly, but the phenomenon may disappear after a short period. The author made a number of experiments in inoculating animals with this organism and concludes that animals are susceptible to this disease in the following order: White mice, white rats, gray mice, gray rats, dogs, coati, horses, rabbits, cats, guinea pigs, sheep, cattle, pigs, etc. Notes are given on the development of the disease in these various animals and the differences between *T. elmassiani* and other species of this genus are described.

The relationship between surra and nagana according to an experiment of Nocard, Valée and Carré (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 16, pp. 624, 625*).—The authors present the details of an experiment carried out by Nocard during which it was shown that a cow immunized against nagana was as susceptible to surra as untreated animals. It was found that 3 months after the appearance of surra in this animal the blood contained the organism of surra and was very virulent for mice, as shown by inoculation experiments.

Erysipelas in horses, Osterwald (*Ztschr. Veterinärk., 15 (1903), No. 7, pp. 319–322*).—An outbreak of this disease occurred among a troop of cavalry horses and spread with considerable rapidity. Notes are given on a number of cases observed

in different years from 1888 to 1902. The symptoms are fever, reddening of the mucous membranes, discharges from the eyes, swelling of the eyelids, swelling of the legs and in the skin and other parts of the body. The disease attacks young horses more frequently. Success was had in treating the disease by proper attention to diet and by rubbing affected parts with spirits of camphor and antiseptic solutions.

The treatment of morbus maculosus with Ichthargan, LANGE (*Ztschr. Veterinärk.*, *15* (*1903*), *No. 3*, *pp. 117–119*).—For horses of medium size Ichthargan was found to produce good results when injected in doses of 3 gm. per day. Experiments showed, however, that this remedy does not exercise any effect upon the organism of morbus maculosus except in the circulating blood. It is recommended, therefore, that the treatment be repeated daily.

A skin eruption on the head of horses, SCHEFERLING (*Ztschr. Veterinärk.*, *15* (*1903*), *No. 7*, *pp. 322–326*, *fig. 1*).—This disease occurred in a number of horses and appeared to be confined entirely to the head. It began as a rule at the corners of the mouth and progressed backwards to the ears. Pustules were formed and the hair of affected parts was shed. The lymphatic glands of affected regions were also swollen and became distinctly visible. These symptoms could be controlled, however, by external treatment with potassium iodid. In some of the pustules *Staphylococcus pyogenes aureus* were found. Inoculation experiments with this organism, however, failed to reproduce the disease in any case. The true cause of the disease was believed to be a mite, *Cheyletus eruditus*, which was found in the skin and in the swollen lymphatic glands.

Lymphangitis, COLLARD (*Rec. Méd. Vét.*, *8. ser.*, *10* (*1903*), *No. 22*, *pp. 502–504*).—This disease, which is known in many parts of France and elsewhere under the name edema, appears suddenly and leads to the development of high fever in infected horses. The etiology of the disease appears to be obscure and so far as experiments have been made treatment is unsatisfactory.

Apoplectic hemorrhagic septicemia of new-born colts, C. DARMAGNAC (*Rec. Méd. Vét.*, *8. ser.*, *10* (*1903*), *No. 11*, *pp. 373–377*).—Detailed clinical notes are given on a number of cases of this disease. From a study of these cases the author comes to the conclusion that infection takes place through the umbilical vessels, and that the sudden development of the disease is due to the rapid spread of the toxin by means of the circulation. Good results have been obtained in controlling the disease from the application of thorough antisepsis to the umbilical cord, as recommended by Nocard in combating white scours.

The occurence of ticks on horses, D. JUNACK (*Ztschr. Veterinärk.*, *15* (*1903*), *No. 6*, *pp. 258, 259*).—Brief notes are given on the excessive infestation of horses by *Ixodes ricinus*. These ticks fasten themselves to the skin of horses in almost any location, and their occurrence in unusually large numbers caused the falling of the hair on infested areas and also other inflammatory processes in the skin.

Colics of the horse and their treatment, V. DROUIN (*Rec. Gén. Méd. Vét.*, *2* (*1903*), *No. 23*, *pp. 569–582*).—The various forms of colic which have been observed in the horse are classified according to their etiology and symptoms. Notes are given on the use of asafetida, opiates, Indian hemp, carbonate of ammonia, nux vomica, eserin, barium chlorid, and other drugs in the treatment of colics.

A pathology for forage poisoning, or the so-called epizootic cerebro-spinal meningitis of horses, D. J. MCCARTHY and M. P. RAVENEL (*Jour. Med. Research*, *10* (*1903*), *No. 2*, *pp. 243–249*, *pl. 1*).—In certain cases of so-called epizootic cerebro-spinal meningitis the cause was clearly traced to the feed which the horses had eaten. While feeding experiments conducted in connection with a spontaneous outbreak of this trouble showed that the disease was due to spoiled feeding materials, it was not possible to isolate any pathogenic organism which caused the trouble.

A careful post-mortem examination of animals affected with this disease revealed the presence of lesions in the anterior portion of the alimentary tract and also in

various parts of the nervous system, including the intervertebral and Gasserian ganglia, cerebral and cerebellar cortex, choroid plexuses, cerebral ventricles, and peripheral nerves of the larynx. Lesions in the intervertebral ganglia closely resemble those observed in cases of rabies as described by Van Gehuchten and Nélis. The disease may be distinguished from rabies, however, by the absence of the pericellular lesions in the medulla oblongata.

The authors conclude from their study of this disease that it is not a true meningitis, and propose the name forage poisoning as much more suitable. It appears that all epizootic outbreaks of the disease are due to some poisonous substance contained in the forage.

Rabies in the horse, FRANCKE (*Fortschr. Vet. Hyg., 1 (1904), No. 10, pp. 280–283*).—This subject is discussed in a general manner and detailed notes are given on a case of equine rabies which came under the author's attention. The symptoms and pathological anatomy are carefully described on account of the comparative rarity of this disease in horses.

Rabies, D. SIME (*Cambridge, Eng.: University Press, 1903, pp. XII+290*).—The purpose of the author in this volume is to present a general account of rabies in all its aspects. Special chapters are devoted to a discussion of the salivary glands, the medulla oblongata, symptoms of rabies, the occurrence of the disease in the sympathetic nervous system and other parts of the nervous system, incubation period, rabies virus, and the animals chiefly concerned in the spread of the disease.

Animals which are susceptible to rabies are classified into 2 groups, viz, intensifiers and attenuators. Herbivorous animals intensify the virulence of rabies virus, while carnivorous animals, particularly man, monkeys, and dogs, attenuate the virus. While the usual outbreaks of rabies are attributable to the existence of the disease in dogs, the author argues that the chief source of rabies is rabbits. Statistics indicate that the disease prevails most extensively in regions where rabbits are most numerous, and the countries where rabbits are unknown are shown to be also free from rabies. Australia, Tasmania, and New Zealand are cited in proof of this proposition, since rabbits were introduced there within comparatively recent times and since dogs have always been numerous in those islands.

The type of rabies in rabbits is not usually violent and the author thus accounts for the absence of epizootic outbreaks of rabies among these animals. The prevalence of rabies in dogs is attributed to the fact that dogs hunt and eat rabbits, and may thereby become infected by injuries to the mucous membranes of the mouth by broken bones of the rabbits.

The etiology of rabies, A. NEGRI (*Ztschr. Hyg. u. Infectionskrank., 44 (1903), No. 5, pp. 519–540*).—The author calls attention to his discovery of an organism belonging to the Protozoa and found in various parts of the nervous system of rabid animals. It is claimed that this organism occurs exclusively in the nerve cells of rabid animals and is the specific cause of rabies. The organism is described and notes are given on the lesions in the nervous system apparently due to the attacks of the organism.

During the author's investigations 75 animals suspected of being rabid were examined, and of these 52 proved to be suffering from rabies. In 50 of these 52 cases the protozoan organism was found by an examination of the hippocampus alone. The author concludes, therefore, that the identification of this organism may serve as a convenient and certain means of diagnosing rabies.

A study of the etiology of rabies, A. NEGRI (*Ztschr. Hyg. u. Infectionskrank., 43 (1903), No. 3, pp. 507–528, pls. 2*).—An organism belonging to the Protozoa was found by the author in various parts of the central nervous system, but especially in the hippocampus. This organism may be demonstrated most easily in dogs which have been experimentally infected with street virus by the subdural method. In the author's experience the best stain for differentiating this organism is methyl blue and eosin, according to the method of Mann.

The passage of rabies virus through filters, Remlinger (*Ann. Inst. Pasteur, 17 (1903), No. 12, pp. 834–849*).—A number of experiments were carried out in inoculating rabbits with rabies virus. While the subdural inoculation produces rabies, the subcutaneous inoculation immunizes the rabbit against the disease. Experiments were made in filtering virus, but on account of the fact that virus which had been passed through a Berkefeld filter was found to be still pathogenic, the conclusion is drawn that the rabies organism must be ultramicroscopic in size. From the fact, however, that the use of a centrifuge separates the virus into a peripheral inactive and central active portion, it is concluded that the cause of rabies is a definite organism and not a mere toxin.

Rabies virus obtained from spontaneous cases of the disease and fixed virus, Schüder (*Ztschr. Hyg. u. Infectionskrank., 42 (1903), No. 3, pp. 362–388*).—Experiments were carried on for the purpose of determining the cause of the difference between these 2 forms of the virus. During the author's experiments it was found that the course of spontaneous cases of rabies was from 2 to 5 days and seldom exceeded 6 days. The incubation period of spontaneous cases, however, varied greatly.

It is believed that the striking variation in the period of incubation in cases of spontaneous rabies is due largely to the different specific properties of the samples of virus obtained from spontaneous cases of the disease. Street virus can not be assumed to have a constant virulence, as is the case with the fixed or laboratory virus. Further experiments showed that the incubation period was almost the same in all cases where the experimental animals were inoculated with street virus obtained from the same source.

The author believes from his studies that the lesions in the central nervous system in cases of rabies are due to the toxins produced by the pathogenic organism and not to the organism itself.

Differential diagnosis of rabies by subdural inoculation of rabbits, A. N. Aleksyeev (*Uchen. Zapiski Kazan Vet. Inst., 20 (1903), No. 5–6, pp. 485–490*).—This method was tested in diagnosing rabies in suspected dogs brought to the laboratory.

The first experiments consisted in the inoculation of 1 rabbit with a portion of the medula oblongata and another rabbit with an emulsion of similar material. The first rabbit died 169 days after inoculation, while the second remained alive. Further experiments were made in inoculation of rabbits for the purpose of determining the incubation period of rabies produced by the use of street virus. The author concludes from his experiments that the variation in the incubation period in rabbits inoculated by the subdural method is due largely to the different susceptibility of different rabbits to street virus.

The histological diagnosis of rabies, Vallée (*Rec. Méd. Vét., 8. ser., 10 (1903), No. 4, pp. 93–97*).—According to the author's observations the special lesions in the cerebro-spinal and sympathetic ganglia as described by Van Gehuchten and Nélis are observed in the majority of cases. They were present in all of 42 dogs which died of rabies and in 25 out of 40 rabid dogs which were killed before the termination of the disease. The author concludes, therefore, that these histological lesions may be relied upon in the diagnosis of rabies in dead animals.

Fowl cholera (*Jour. Bd. Agr. and Fisheries [London], 10 (1903), No. 3, pp. 351–354*).—A short account of the symptoms and pathological anatomy of this disease. Recommendations are also made concerning disinfectant methods which are best suited for use in the prevention of this disease and in cleaning poultry houses after outbreaks of the disease have occurred.

The hemolysin of fowl cholera, D. Calamida (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1904), No. 5, pp. 618–621*).—The material used by the author was obtained from an infected fowl during an outbreak of the disease. For the purpose of obtaining hemolysin, cultures were made in bouillon prepared from peptonized meat. The

results of the author's experiments indicate that bouillon cultures of the bacillus of fowl cholera may produce a hemolysin which occurs in maximum quantity after the material has been maintained for 12 days at a temperature of 37° C. The hemolysin, while not especially resistant toward higher temperatures, appeared to withstand heat until subjected to a temperature of 70° C. for ½ hour. Hemolysin thus obtained has no toxic effect upon animals and its formation does not precede the agglutinations of the red blood corpuscles. Its hemolytic effect was greatest upon the red blood corpuscles of rabbits and less pronounced upon those of guinea pigs and fowls.

A new disease of poultry, E. THIERRY (*Jour. Agr. Prat., n. ser., 7 (1904), No. 5, pp. 150, 151*).—The author gives a brief description of fowl plague, with particular reference to the symptoms which differentiate this disease from fowl cholera. Notes are also presented on the distribution of the disease in various parts of Europe.

Spirillosis in geese, DUCLOUX (*Rec. Méd. Vét., 8. ser., 10 (1903), No. 16, pp. 360, 361*).—Notes are given on a disease of geese due to infection with *Spirochæte anserina*. The disease prevails most extensively in young geese and its course and development are very rapid. The symptoms are progressive weakness, diarrhea, and elevation of temperature. Death almost always occurs as the result of infection. The disease may also be transmitted to ducks.

The nonidentity of human and avian diphtheria, C. GUÉRIN (*Rec. Méd. Vét., 8. ser., 10 (1903), No. 1, pp. 20–28*).—The literature of this subject is briefly reviewed, with special reference to a determination of the nature of the organism which causes avian diphtheria. This organism is believed to belong to the genus Pasteurella, but to be distinct from the cause of human diphtheria.

Epidermophyton gallinæ, L. PALMANS (*Bul. Agr. [Brussels], 19 (1903), No. 6, pp. 1206–1208*).—This parasitic fungus, which has also been referred to the genus Lophophyton, is the cause of a skin disease of the head of fowls. It apparently does not attack other animals. The author found that it was a comparatively simple matter to cultivate this organism on various nutrient media, and notes are given on its behavior in artificial cultures. The disease may be successfully combated by treating the affected parts of fowls with solutions of various antiseptics.

AGRICULTURAL ENGINEERING.

The official proceedings of the Eleventh National Irrigation Congress, held at Ogden, Utah, September 15–18, 1903, edited by G. MCCLURG (*Proc. Nat. Irrig. Cong., 1903, pp. 472, figs. 49*).—This includes the organization, official call, constitution, a general review of the proceedings, and the minutes of the various sessions, including besides addresses of welcome, message from the President, reports of committees, resolutions, etc., the following addresses and papers: President's Address, by W. A. Clark; The Twin Ideas of Irrigation and the Conservation of Water for the Prevention of Floods, by J. R. Burton; Relation of Irrigation to Internal Trade and Commerce, by T. G. Haley; Colonization and Irrigation, by C. E. Wantland, J. M. Carson, J. H. Smith, C. C. Pardee, and F. Booth-Tucker; The Repeal of Some of Our Land Laws, by P. Gibson; Value and Importance of the Desert Land Law, by F. Mondell; The Utilization of the Public Grazing Lands of the United States, by W. M. Wooldridge; State Cooperation in National Irrigation, by F. Newlands; Irrigation Investigations made by the United States Department of Agriculture, by James Wilson; Irrigation as Shown at the World's Fair, by F. W. Taylor; The Victories of Peace, by G. H. Maxwell; The Influence of Irrigation on the American Ideal, by W. E. Smythe; Relation of National Irrigation to Local Problems, by F. E. Brooks; Alkali Reclamation, by T. H. Means; Forests and Water Supply, by F. H. Newell; Forestry, by G. Pinchot; Forest Reserves in Utah, by A. F. Potter; Irrigation in Utah, by A. F. Doremus; Irrigation Investigations of the United States Department of Agriculture, by W. H. Beal; The Irrigation Investigation of the Utah Experiment Station, by J. A. Widtsoe; The Value of the Study of

the Use of Water, by S. Fortier; The Planting of Trees on Prairie Lands where Irrigation is Impossible, by D. E. Willard; Pumping Water for Irrigation in Western Kansas, by J. G. Haney; Weather Bureau Cooperation in Reclamation Work, by F. H. Brandenburg; Irrigation Investigations in Nebraska, by O. V. P. Stout; Drainage Investigations in the Yakima Valley, Washington, by C. G. Elliott; Sugar Beet Culture in Utah, by H. H. Rolapp; Irrigation and Beet Sugar, by T. G. Palmer; The Sugar Beet, the Ideal Crop for Irrigated Areas, by H. W. Wiley; Horticulture under Irrigation, by J. A. Wright; Irrigation and Live Stock, by T. Shaw; Horticulture under Irrigation, by J. H. Richards; National Irrigation and Oriental Trade, by W. M. Bunker; Relation of the Eastern Farmer to National Irrigation, by C. B. Boothe; Fungus Diseases in Fruit Trees, by H. E. Dosch; Irrigation-Grown Barley, by H. Altenbrand; Forestry at Universal Expositions, by T. H. Bean; New Irrigation Construction on Snake River, Idaho, by J. D. Schuyler; Reclamation Work in Idaho, by D. W. Ross; The Salt River Reservoir, by A. P. Davis; Milk River Project, Montana, by C. C. Babb; Irrigation in Oregon, by J. T. Whistler; The Gunnison Tunnel, by A. L. Fellows; Development on the North Platte River in Wyoming, by J. E. Field; Correct Design and Stability of High Masonry Dams, by G. Y. Wisner; Electrical Transmission of Power for Pumping, by H. A. Storrs; Relation of Federal and State Laws to Irrigation, by M. Bien; State Progress in Irrigation, Wyoming, by C. T. Johnston; Wyoming's Use of Its Lands, by J. A. Breckons; Irrigation Progress in Nebraska, by A. Dobson; The Irrigation Laws of Nevada, by A. E. Chandler; Our Inheritance, by W. K. McAllister; Why and How State and Federal Government Should Cooperate for Irrigation, by F. H. Ray; This Year's High Tide of Immigration, by S. E. Moffett; Drainage and Irrigation, by H. H. Harrison; Utah Lake Reclamation Project, by G. L. Swendsen, and an address by F. T. DuBois.

Irrigation in humid districts, E. B. VOORHEES (*Cornell Countryman, 1 (1904), No. 2, pp. 39, 40*).—A brief discussion of the need and difficulty of securing proper irrigation in humid regions.

Report of the Indian Irrigation Commission, 1901–1903, C. SCOTT-MONCRIEFF ET AL. (*London: Eyre & Spottiswoode, 1903, pts. 1, pp. XIII+130, pl. 1; 2, pp. XXII+260, maps 2; 3, maps 6; 4, pp. 397*).—This report deals with the following subjects: Preliminary survey, limitations of irrigation, state irrigation works, scope for further extensions of state irrigation works, private irrigation works, loans for improvements, artesian wells, classification and financing of irrigation works, methods of charging for water, establishments, hydraulic and agricultural experiments, and famine relief works and programmes; the status of irrigation in Punjab, Bombay, Madras, Central Provinces, Bengal, United Provinces, Upper Burma and Baluchistan, and Native States; and selected evidence, statistics, maps, etc. (See also E. S. R., 15, p. 308.)

Studies on the irrigation of the Jauja, D. VALDIZÁN (*Estudios sobre la Irrigación de Jauja. Lima, Peru: Libreria de San Pedro, 1903, pp. 49, figs. 8, map 1*).—Plans and specifications for works for supplying the city and valley of Jauja with water for domestic and irrigation purposes.

Acquirement of water rights in the Arkansas Valley in Colorado, J. S. GREENE (*U. S. Dept. Agr., Office of Experiment Stations Bul. 140, pp. 83, pl. 1, fig. 1*).—This bulletin gives the results of investigations on the different kinds of water rights recognized in this region and the manner in which they affect the well-being of irrigators. It also describes physical conditions which affect the value of water rights. "The subject is presented in such a way as to be of aid to intending settlers in showing them some features of irrigation which should be looked into, and where needed information can be found. While these rights are considered primarily from the standpoint of the farmer, the interests of investors in irrigation works and of the public in the best use of the water supply are also kept in mind."

Preliminary report on the geology and water resources of Nebraska west

of the one hundred and third meridian, N. H. DARTON (*U. S. Geol. Survey Prof. Paper 17, pp. 69, pls. 43, figs. 23*).

Some observations on sewage farms in England (*Engineer. News, 51 (1904), No. 16, pp. 385–387*).

The trials of wind-pumping engines at Park Royal, 1903, F. S. COURTNEY and W. N. SHAW (*Jour. Roy. Agr. Soc. England, 64 (1903), pp. 174–220, figs. 17*).—Includes notes by the society's consulting engineer and report of the judge.

Miscellaneous implements exhibited at Park Royal, 1903, J. B. DUGDALE (*Jour. Roy. Agr. Soc. England, 64 (1903), pp. 221–241, figs. 17*).

MISCELLANEOUS.

Proceedings of the eighth annual meeting of the American Association of Farmers' Institute Workers, edited by W. H. BEAL and G. C. CREELMAN (*U. S. Dept. Agr., Office of Experiment Stations Bul. 138, pp. 119*).—This is a detailed account of the proceedings of the meeting held at Toronto, Ontario, June 23–26, 1903. A summarized account of this meeting has been given (E. S. R., 15, p. 101).

Special and short courses in agricultural colleges, D. J. CROSBY (*U. S. Dept. Agr., Office of Experiment Stations Bul. 139, pp. 59*).—This is a summary of information on the special and short courses in agriculture and related subjects offered at the land-grant colleges. Of the 63 agricultural colleges and schools receiving funds from the National Government 44 have organized such courses. These courses are designed to meet the requirements of those preparing to enter a regular agricultural course, those desiring instruction in agricultural subjects but not fully qualified for college work, those desiring instruction in some particular phase of agriculture, and teachers desiring to prepare themselves to give instruction in nature study and elementary agriculture. Brief statements are made concerning the date of opening, length, nature, admission requirements, and cost of attending these courses.

Finances, meteorology, index (*Maine Sta. Bul. 99, pp. 203–219 + VIII*).—This includes reprints of 4 newspaper bulletins on fertilizers for mangel-wurzels, forage crops to supplement summer pasture and winter hay, insecticides, and cotton-seed meal; meteorological observations noted elsewhere; a financial statement for the fiscal year ended June 30, 1903; the organization list of the station; and announcements relative to station work.

Annual Report of Nevada Station, 1903 (*Nevada Sta. Rpt. 1903, pp. 27*).—This consists of a report of the director on the work of the station during the year; a financial statement for the fiscal year ended June 30, 1903; and departmental reports.

Director's Report for 1903, W. H. JORDAN (*New York State Sta. Bul. 244, pp. 375–398*).—This is a rather extended review of the work of the New York State Station during the year. A financial statement is included, and a summary is given of the results of the inspection of fertilizers and feeding stuffs. Outlines are given of the work in the departments of animal husbandry, bacteriology, botany, chemistry, entomology, and horticulture; some of the results obtained being briefly summarized.

Twenty-second Annual Report of Ohio Station, 1903 (*Ohio Sta. Bul. 143, pp. XIX*).—This includes an announcement concerning the work of the station, the organization list, a report of the board of control, a financial statement for the fiscal year ended June 30, 1903, and a report of the director summarizing the work of the station during the year.

Press bulletins (*Ohio Sta. Bul. 143, pp. 145–153*).—Reprints of press bulletins on the following subjects: Caustic soda for Bordeaux mixture, the chinch-bug campaign, grape rot prevention, spraying for bitter rot of apples, loss of leaves by cherry-leaf spot and shot-hole fungus, tomato-leaf spot and muskmelon blight, a ten-year comparison of varieties of wheat, how to circumvent the Hessian fly, and fruit lists.

Report of the sugar experiment station in West Java, H. C. P. GEERLIGS (*Verslag Proefstat. Suikerriet, West Java, 1903, pp. 32, pls. 6*).—A condensed account

is given of the work of the station for the year 1903, with brief notes on the publications of the various investigators connected with the station.

Report on the agricultural fund of Cyprus, W. F. H. SMITH (*London: Darling & Son, 1903, pp. 29*).—In this pamphlet a statement is made regarding the industrial conditions of Cyprus with especial reference to agricultural improvements. Notes are also given on the statistics of agricultural production, including an account of the growing of various crops such as figs, cotton, grapes, etc., and notes on rainfall and soil conditions.

Progress in the manufacture of beet sugar during the last ten years, H. CLAASSEN (*Ztschr. Angew. Chem., 17 (1904), Nos. 13, pp. 385–389; 14, pp. 417–420*).

Note on the cotton-seed oil industry and the establishment of cotton-seed oil mill in India, J. MOLLISON (*Agr. Ledger, 1903, No. 9 (Veg. Prod. Ser., No. 75), pp. 215–232*).

[Agricultural conditions in Cape of Good Hope], E. A. NOBBS (*Report of Dr. Eric A. Nobbs, for the year 1903. Dept. Agr., Cape Good Hope, 1904, pp. 75*).—A general account, including statements regarding irrigation works and development in the Colony.

The organization and work of agricultural departments in Western Europe and the United States, A. SCHULTZ (*Byudzhetui organizatzyia i dyeyatelnost selskokhozyaistvennuikh vyedomstv zapadnoi Evropye i Syevero-Amerikanskikh Soedinennuikh Shtatakh, St. Petersburg, Dept. Agr., 1903, pp. 465.*)—The author presents a detailed account of the organization, work, equipment, and financial support of the Department of Agriculture in Sweden, Norway, Denmark, Great Britain, Belgium, France, Germany, Austria-Hungary, Italy, and the United States.

The settlement of Samoa, F. WOHLTMANN (*Pflanzung und Siedlung auf Samoa. Berlin: Kolonial-Wirtschaftliche Komitee, 1904, pp. V+164, pls. 20, figs. 9, maps. 4*).—This is a report on agricultural conditions in the Island.

Agriculture in primary schools (*New Zealand Dept. Agr. Rpt. 1903, pp. 419–422, pls. 3, dgm. 1*).—An account is given of the teaching of elementary agriculture in Mauriceville West School, with syllabus of the theoretical and practical work offered during the first and second years. A plan of the garden is given with a number of illustrations showing different phases of the work.

Progress in women's education in the British Empire (*London and New York: Longmans, Green & Co., 1898, pp. XXIV+370, charts 5, dgms. 2*).—This book is the report of the proceedings of the Education Section of the Victorian Era Exhibition in 1897, and is edited by the Countess of Warwick. It contains three series of papers and addresses on the following subjects: (1) Education of children; (2) some professions open to women; and (3) education in India and the colonies: University extension. Under "professions open to women" appear a number of papers on agricultural education for women in Great Britain and the colonies.

How to teach nature study, A. M. KELLOGG (*New York and Chicago: E. L. Kellogg & Co., pp. 55+VII, charts 6*).—This is the second number of a series of "How to Teach" Manuals. In it the author defines the term "nature study," gives its origin, object, etc., as well as detailed general and special methods for teaching this subject. The Massachusetts course of nature study covering nine years is fully described.

Science teaching and nature study (*Southampton: H. M. Gilbert & Son, pp. 48*).—This is the report of the proceedings of the nature study conference and exhibition held at the Hartley College, Southampton, in June, 1902. Educational institutions of all classes joined in sending contributions which made the exhibition a pronounced success.

At the conference the following papers were read: The Aim and Object of Nature Study, by R. Hedger Wallace; Beginning the Study of Science, by A. T. Simmons; The Teaching of Natural History on Humane Lines, by Mrs. Suckling; Example of

a Definite Plan for Nature Study in a Primary School, by T. G. Rooper, and Science Teaching and Nature Knowledge in Connection with the Perthshire Natural History Museum, by Henry Coates. A nature-study bibliography is appended.

The educational value of nature study, J. C. MEDD (*Cirencester: George H. Harmer, pp. 17*).—An address delivered by the author at the conference of the Private Schools' Association, at Harrogate, in June, 1903.

Ways of the six-footed, ANNA B. COMSTOCK (*Boston: Ginn & Co., 1903, pp. XII + 152, figs. 47*).—This is a collection of 10 nature-study stories dealing with crickets, bees, wasps, ants, leaf cutters, leaf rollers, butterflies, and 17-year locusts in a popular manner.

The nature student's note book, C. STEWARD and ALICE E. MITCHELL (*Westminster: Archibald Constable & Co., Ltd., pp. 152*).—Part 1 of this book consists of nature notes. Blank pages are inserted on which students may record regularly their own discoveries and observations. A list of books of reference for school gardening is also given, as well as a list of injurious insects and a summary of the wild birds protection acts, 1880–1896. Part 2 consists of tables for classification of plants, animals, and insects in full detail, with methods for using the tables.

NOTES.

Florida Station.—F. C. Reimer, assistant horticulturist and botanist at the station, has been appointed acting head of that department pending the appointment of a horticulturist and botanist. The Department is continuing its work in tomato breeding, started a year or two ago, with the object of securing varieties immune to tomato blight. Some promising results have already been secured.

Georgia College.—The chemical building (Terrill Hall), which is being erected at a cost of $30,000, on the foundation of the old one (Science Hall), which was destroyed by fire in November, 1903, will be one of the best constructed and equipped chemical laboratories in the South. Special provisions are being made for laboratories designed to meet the requirements of organic chemistry, physical chemistry, and electro-chemistry; and in addition to these special laboratories there will be a laboratory for beginners accommodating 120, a junior laboratory accommodating 36, a senior laboratory accommodating 18, a large pharmaceutical laboratory, two private laboratories, assay rooms, a large library room, two stock rooms, three museum rooms, four large lecture rooms, a balance room, a dark room, and a large fireproof vault. The building will be 75 by 133 ft., and three stories in height. The walls will be of brick, with a facing of red pressed brick, and all the floors will be supported by heavy steel girders. It is expected to be ready for occupancy by January 1, 1905.

Kansas College and Station.—The Kansas State Agricultural College has recently completed a new building to be used exclusively for dairy manufactures, the dairy machinery having been hitherto in Agricultural Hall. Prof. Oscar Erf, of the department of animal and dairy husbandry, has been given leave of absence in order to take charge of the scientific work in connection with the dairy exhibits and tests at the Louisiana Purchase Exposition. Professor Erf planned the creamery which is operated in connection with the exposition. Leslie F. Paull has resigned his position as assistant botanist in the college and station, to take a position in the Bureau of Plant Industry of this Department.

Missouri University and Station.—H. J. Waters has been given a further leave of absence for one year, for study and travel in Europe. Dr. J. W. Connaway has also been granted leave of absence for study abroad. In the absence of C. H. Eckles, who has gone abroad for a year or more, R. M. Washburn will be in charge of the dairy work. Dr. J. B. Tiffany, of Cornell University, has been appointed instructor in veterinary science, vice R. J. Foster, resigned. George M. Tucker, instructor of agronomy at the university and agronomist in the station, has resigned his position, and Merritt F. Miller, assistant professor of agronomy at the Ohio State University, has been elected to succeed him.

New Hampshire College and Station.—The completion of the new range of greenhouses was celebrated by a reception given by Prof. F. W. Rane May 20. The greenhouses were constructed with an appropriation of $7,000 made by the last legislature, and were first occupied by the department at the close of the winter term. They are steel structures, designed for both instruction and experimental work. The total

area under glass is 6,635 sq. ft. There are 7 distinct houses, besides a runway 10 by 44 ft., which is used for cutting benches on either side of the walk. Two of the houses have ground beds, similar to those found in the vegetable forcing structures about Boston, and the remainder have raised benches.

One house, 20 by 47½ ft., is used entirely as a greenhouse laboratory for instruction. This has a 3-ft. side bench built against the wall on either side, with a double row of students' workbenches 3 ft. 9 in. wide in the center, extending the entire length of the house and separated by a narrow passageway for the instructor. The students' benches are separated from the wall benches by a walk 2½ ft. wide. Each student has a space 5 ft. in length, from the side of which next to the walk a space 1 ft. by 18 in. is removed to give standing room for the student, thus keeping the walk behind him open. The wall bench behind each student is used for his potted plants, stock for cuttings, etc.

The greenhouses are connected with a potting house 20 by 30 ft., which has a basement used as a boiler room, and a finished room in the second story for the gardener. The main floor is provided with closets for tools, lockers for the students' working suits, a bench for making design work, etc. The range has a double system of heating, and each house is piped independently so that almost any range of temperature can be had which is desired for experimentation. Heat is supplied from the college heating plant, and there is a sectional steam boiler located in the basement of the potting house. The latter can be used in the spring and fall and at such other times as is desired. Each house has its own ventilating system and is lighted by electricity on separate switches.

Ohio University and Station.—The appropriation of $75,000 made by the legislature for the College of Agriculture of the University was vetoed by the governor. The following appropriations were made for the station for the current year: For expenses of the board of control, $800; publication of bulletins, $3,800; special work in entomology, botany, chemistry, and horticulture, $8,000; substations for field experiment, $7,000; general repairs, labor, and supplies, $7,500; special work in animal industry, $2,500; library equipment and care, $250; general construction, $2,000; purchase of test farm in southeastern Ohio, in part, $5,000; total, $36,850.

The test farm, the purchase of which is authorized by the last item of the budget, has been located in Meigs County, about 18 miles south of Athens. It contains 300 acres, and the purpose is to devote it to the study of such problems as especially concern the agriculture of the hilly counties of southern Ohio. It is expected that animal husbandry, orchard culture, and forestry will receive special attention. J. M. Van Hook, assistant plant pathologist of the Cornell Station, has accepted a similar position at this station. F. H. Ballou, of Newark, Ohio, has been appointed assistant horticulturist to the station, in charge of the orchards. Frank A. Welton, a this year's graduate of Buchtel College, Akron, Ohio, has been appointed assistant chemist to the station. J. L. Taggart, horticultural foreman, has resigned to take charge of a commercial orchard near New York.

A department of cooperative experiments has been organized in the station, to continue the cooperative work heretofore conducted by the Agricultural Student Union of Ohio, and L. H. Goddard has been appointed experimentalist. It is expected that the Student Union will maintain an organization holding an advisory relation to this department of the station and to the extension work of the College of Agriculture of the State University.

Pennsylvania Station.—A. K. Risser has resigned the position of assistant in agriculture in the station to accept an appointment in the Government Indian School at Lawrence, Kans. N. G. Miller, of the class of 1904, has been appointed as his successor.

Porto Rico Station.—F. D. Gardner, who has been in charge of the station since its organization, returned early in June and has assumed charge of the work in soil

management in the Bureau of Soils. Mr. Gardner was accompanied by O. W. Barrett, entomologist and botanist of the station, who will spend several weeks in visiting institutions of special interest in connection with his work. The station is constructing a small reservoir preparatory to making experiments in irrigation for special crops, including lowland rice. A bulletin on the propagation and marketing of oranges in Porto Rico is being published in both English and Spanish editions. This subject is attracting much attention in the island at present, and is one to which the station has given special attention. The growing of oranges on a commercial scale has commenced since the American occupation, and has not yet gone beyond the experimental stage. It is estimated that fully 6,000 acres of budded stock have been set out, and with the employment of suitable methods the outlook for successful and profitable orange growing in Porto Rico is thought to be very promising.

Rhode Island Station.—A. G. Lander, second assistant chemist, has resigned to accept a position in Providence, R. I.

South Carolina Station.—The veterinarian has undertaken to free the northern part of the State from cattle ticks, with a view to lowering the quarantine line.

Wyoming University and Station.—E. E. Slosson, for thirteen years professor of chemistry and chemist to the experiment station, who has been away most of the past year on leave of absence, has definitely severed his connection with the institution. He is at present located in New York as literary editor of the *Independent*.

New Greenhouses for the Department of Agriculture.—The location selected for the new Department building will require the tearing down of several ranges of greenhouses and frame structures used for potting and storage, and will ultimately necessitate the removal of the conservatories and all the greenhouses. An appropriation of $25,000 was made by the last Congress for constructing new houses and the removal of old ones to the new location which has been selected at the northwest corner of the Department grounds, adjoining Fourteenth and B streets NW. The site has been prepared by the removal of several large trees and the filling in of the lily pond. Eight new steel-frame greenhouses are now being constructed, and to these will be added three new ones of wood, the material for which is already on hand, and two comparatively new houses to be moved from their present location. A one-story brick building, about 275 feet in length, running along the north end of the greenhouses on B street, will serve as a potting house, carpenter shop, paint shop, and for storage of material, and will provide office rooms for those in charge of the greenhouse work. The new houses will be used largely for experimental work. They will take the place of those used for the physiological and pathological investigations, the seed and plant introduction work, the storage of plants for Congressional distribution, and the propagation of decorative plants. The new buildings will be ready early in September.

Recent Agricultural Progress.—This is the title of an address delivered by C. C. James, Deputy Minister of Agriculture for Ontario, before the Natural Science Association, and published in a recent issue of the *University of Toronto Monthly*. In this Professor James reviews the material and intellectual progress of agriculture in Ontario, and calls attention to the institutions for agricultural education and the benefits which are resulting from their work.

Referring to the agricultural college at Guelph, he says: "The first move made for improving Ontario agriculture was the establishing of the agriculture college in 1874. This was at the beginning of the period of depression, when the changed circumstances of the farmer were beginning to be severely felt. For many years the institution struggled against the harsh opposition of one political party and the half-hearted apologies of the other, and a certain disheartening indifference on the part of the farmers themselves. The work, however, was continued faithfully, though under the most discouraging conditions. In 1889 the attendance was 134, of whom 30 came from outside of Ontario. In each of the past two years the attendance has been

over 700. . . . There were, in 1889, two professors in the science department at $1,500 each, a professor of chemistry, and one professor for the following five subjects: Geology, botany, zoology, meteorology, and horticulture. Since then three fine laboratories have been erected and one rebuilt, and to-day ten members of the staff are required to cover the same work as the two of 1889. This is one illustration of the large place that scientific research and instruction have recently come to occupy in connection with agricultural work."

The farmers' institute system is described as an outgrowth of a university extension movement inaugurated in 1884, in order to bring the work of the college more directly to the farmer and to win his appreciation of it. Referring to the progress of these institutes, Professor James says: "Twenty years ago we discovered the farmer; five years ago we discovered that he had a wife; we are beginning to open our eyes to the fact that they have children. We have farmers' institutes, we have women's institutes. Where are the children's institutes? In the public schools. When we have worked out the rural public school course, and given the half-million children of farm homes all that can reasonably be given through public school work, we shall be making these children's institutes effective in their general upward movement. The rural public schools might and should be made the most important element in the permanent improvement of Ontario agriculture."

Professor James pays a high tribute to this Department, which he characterizes as "without doubt the largest and best equipped agricultural organization in existence. Its investigations are most varied, and the story of its working is more interesting than the latest work of fiction. It reaches out into all parts of the Continent, and its agents are to be found in all parts of the world. When housed in its new buildings, it will be the Mecca for all American students of the new agriculture."

National Diploma in Agriculture.—The annual examination for the national diploma in agriculture of Great Britain was held at Yorkshire College, Leeds, about the middle of May. Forty-six candidates were examined in the subjects comprised in part one (agricultural botany, mensuration and land surveying, general chemistry, geology, and agricultural entomology), and 25 candidates in part two (practical agriculture, agricultural bookkeeping, agricultural chemistry, agricultural engineering, and veterinary science). As a result of the examinations, 35 candidates passed part one and will be entitled to take the second part in 1905 or 1906; and 20 candidates passed part two, and are therefore entitled to receive the national diploma in agriculture. The candidates were from the various agricultural colleges throughout Great Britain. Of the 55 who passed part one or two, there was a total of 15 from Yorkshire College, 10 from Harris Institute at Preston, 6 from the West of Scotland Agricultural College, 6 from the Harper-Adams Agricultural College, 4 from the University College of Wales, 3 each from the Royal College of Science at Dublin, Durham College of Science at Newcastle-on-Tyne, and the Agricultural College at Holmes Chapel, and one each from the agricultural colleges at Uckfield and Aspartia, the South-Eastern Agricultural College at Wye, and the University at Aberdeen. Two women passed the examination in part one.

Association of Official Agricultural Chemists.—The annual meeting of this association will be held at St. Louis about September 20.

Miscellaneous.—The first annual commencement of the Dunn County School of Agriculture at Menomonie, Wisconsin, occurred May 27. The graduating class numbered 15, 5 of whom were girls. There were also 6 graduates of the short course.

C. L. Goodrich, in charge of the instruction in agriculture at Hampton Institute, has resigned his position and will sever his connection with the school at the close of the present year. He will be succeeded by E. A. Bishop, a graduate of the Massachusetts Agricultural College and for many years past in charge of the agricultural work at Talladega College, Talladega, Alabama.

At the recent jubilee of the University of Wisconsin, the degree of doctor of laws was conferred upon Hon. James Wilson, Secretary of Agriculture, and Dr. H. P. Armsby, director of the Pennsylvania Experiment Station. Secretary Wilson also received the same degree from Cornell College, at Mount Vernon, Iowa.

The honorary degree of doctor of engineering was conferred by Purdue University upon Elwood Mead, Chief of Irrigation Investigations in this Office and a graduate of the university.

Sir Henry Thompson, widely known for his work in dietetics, died at his home in London, April 18, 1904. He was born in Framingham, Suffolk, August 6, 1820, and was graduated in medicine with honors at the University College, London. He was the author of numerous papers on scientific and surgical topics, and two of his works on dietetics, Food and Feeding and Diet in Relation to Age and Activity, have gone through numerous editions and been widely read.

The agricultural and dairy building of the State Normal and Industrial School at Tallahassee, Fla., was destroyed by fire in April, together with most of the dairy equipment in the building. Plans are now being drawn for a more commodious and modern building to replace the one burned. Zachary T. Hubert, of Milledgeville, Ga., who graduates from the Massachusetts Agricultural College this year, has been elected professor of agriculture and science in the school.

The Board of Agricultural Studies at Cambridge University reports, according to a note in *Nature*, the continued progress of the department, which last term had 40 students. A number of field experiments have been instituted and are in progress on the university farm and in the adjoining counties, under the supervision of Professor Middleton and his staff.

According to a note in the *Daily Telegraph*, of Sydney, New South Wales, the establishment of a chair of agriculture at Sydney University is being advocated, and is under consideration by the minister of public instruction, the director of agriculture, and other prominent officials.

O

EXPERIMENT STATION RECORD.

Vol. XV. July, 1904. No. 11.

This number concludes the fifteenth volume of the Record, except the index. The index number will, as usual, constitute No. 12, and the work on this has been kept so well up with the current numbers that it will be issued quite promptly. Special effort has been made in this direction for several years past, for it is recognized that the permanent value of the Record depends largely on its indexes, and that it is a great advantage to those who file it permanently to have the index in their hands as soon as possible after the conclusion of a volume.

The general index, which has been so long promised, has at length been issued. This has been in press since last September, and has suffered several unavoidable delays due to the shortage of some of the type used, as well as the usual delays incident to reading the proof. The manuscript was so ponderous that it was necessary to leave many matters to be attended to in the proof. This final work was made more difficult by the inability to have the whole index in type at one time. This was impracticable from a typographical standpoint. The plates were stereotyped as fast as the proof was read, so that the final changes necessitated cutting the plates or resetting, and hence had to be limited to those absolutely necessary to accuracy.

A large amount of time was expended in the effort to group entries, so that a subject would be found complete by persons approaching it from somewhat different points of view. There are always two and frequently more entries for each item, and cross references are used wherever it was thought they would be an aid. The result is a volume of six hundred and seventy-one pages, which furnishes a complete index to the work of the experiment stations and of this Department since the Hatch Act went into effect, and since about 1893 to the more important investigations of a similar character in foreign countries.

The range of subjects revealed by casually running over the index is hardly less surprising than the number of entries included under some of the larger subjects. The longest of these, Milk (and Milk production), occupies nearly eleven double-column pages; Soils, nine and a half pages; Corn, eight; Wheat, seven; Cows, six; and Butter

and Cheese four pages each. It is estimated that there are not far from one hundred and twenty-five thousand entries, arranged under fully fifty thousand headings and subdivisions.

The first edition of a thousand copies hardly more than sufficed to supply the college and station libraries and the heads of departments in the stations. As far as possible the chief assistants were also included, but a large number of regular recipients of the Record had to be left to be supplied from a second edition. As the latter under the present laws can not exceed one thousand copies, owing to the size of the volume, those who are as yet unsupplied and who especially desire it should have their names listed, as the further distribution will be upon application only. Many, doubtless, will not care particularly for this index, as they lack complete files or do not preserve the volumes in bound form.

The index is obviously of little value except to those who have complete sets of the Record, and one effect of its issue will doubtless be to stimulate attempts to complete broken files. No duplicates of the earlier volumes are now in stock at the Department, and very few of the later volumes. Occasional numbers can sometimes be supplied to help in completing volumes, but our ability to do this is dependent upon duplicates or discarded files which are returned to us. The attention of those who have incomplete sets or duplicates which they do not care especially to preserve is called to the fact that there is a constant call for back numbers from libraries, institutions, scientific workers and writers, and the like, which it is desirable to meet, and that such files or duplicates would be highly appreciated. We will be glad to send franks for the forwarding of such back numbers at any time, and will place them where they will do the most good and have a permanent value.

Two recent departures in the editorial line are worthy of notice on account of their novel character and the enterprise which they evidence. While totaly unlike, they are both typical of the thought which is given by American stations to the publication of their work and of the various efforts which are made to appeal to the farmer.

The Wisconsin Station has varied the usual form of the annual report this year, as it did ten years ago on the completion of its first decade. The present report is the twentieth. It summarizes the work of the station in its various lines from 1893 to 1903, the summaries being in the form of separate articles, each treating of a particular phase of the work. How concisely these summaries are made may be judged from the fact that the report does not exceed its usual size. In addition to them, the director contributes a brief history of the college of agriculture and the experiment station, and a description of the new agricultural building.

The advantage of such summaries and of discussing the accumulated results in the light of later information will be readily apparent. It serves as a convenient means for farmers to get a clear grasp of the work and its present status; and it also relieves the demand upon the station for its earlier reports, which are rapidly becoming exhausted. It places its work permanently on record in convenient form for reference.

Not every station could afford the time for such a summary perhaps; but some such periodical summing up of the work will be necessary as a permanent record, particularly where a station has accumulated a large amount of work on a variety of subjects. It is often a good thing for a station itself to try to point out exactly the ground it has covered, and the stage it has reached in its investigations. It clarifies the ideas of the workers and helps them to get their bearing in their work. If this could be done in some lines of experiments that have been allowed to drift along in a time-honored way, without even a careful summing up of the yearly results, chiefly on account of the supposed value of their cumulative results, it is quite possible we should lose our reverence for them and evolve something more promising.

The requirement of an annual report is a wise one, as well for the station and its workers as for the general public. The decennial summary has many things to commend it, and will become the more important with the flight of time.

The second editorial venture to which it is desired to call attention is that of the agricultural college and experiment station of Tennessee which recently undertook the editorial management of a daily newspaper, Prof. Andrew M. Soule, the director, appearing in the rôle of editor of the *Knoxville Sentinel* for its issue of June 3d. The object was to attract attention to the work of the college and station, and the immediate occasion was the East Tennessee Farmers' Convention, which held its final session on that date.

Many of the papers presented at the convention were reproduced, and to these were added various articles relating to agricultural education, the work of the experiment station, and the application of the results in practice to improve Tennessee agriculture, written by members of the station staff. An article by Prof. C. S. Plumb, of Ohio State University, summarized the results of feeding trials with hogs, and one by M. A. Carleton, of this Department, discussed the improvement of winter cereals for the South.

The editorial page was essentially agricultural throughout. There were editorials on Agricultural Opportunities in Tennessee, The Farm Home, The Value of Good Roads, More Reading Farmers, Sweet Clover and Alfalfa Bacteria, and Trained Farm Foremen in

Demand. The usual short notes on this page gave bits of information upon agricultural topics, agricultural statistics, etc.

The management of the paper explains in a note that "in turning its columns over to the farmers for to-day the *Sentinel* thus recognizes the great importance of agriculture, surpassing that of all other factors in our industrial activities. The development of better methods of farming in our section will more than aught else promote our wealth and progress. Professor Soule has given his best efforts to this edition, and we believe it will be found to reflect great credit on him, and we trust also upon the *Sentinel*."

This undertaking is as interesting as it is novel, and the result is certainly most creditable.

We publish in this issue a description of the respiration calorimeter as adapted to use with animals. Editorial mention of this apparatus and its significance to investigation in animal nutrition has already been made (E. S. R., 15, p. 737). In view of the interest attaching to the apparatus both from its intrinsic importance and on account of its American origin, a popular description of its construction seemed desirable. Doctor Armsby consented to prepare such a description, the first of the kind which he has published; and to this he has added some remarks on the way in which the apparatus is employed in studying questions in animal nutrition, and the interpretation of the results with reference to the demand for nutrients and the use to which they are put by the animal organism. This will doubtless prove helpful to many who have not given special attention to the subject, and make more evident the important function of the apparatus.

THE RESPIRATION CALORIMETER AT THE PENNSYLVANIA EXPERIMENT STATION.

H. P. Armsby, Ph. D., LL. D.,

Director Pennsylvania Experiment Station.

Our present methods of investigating the problems of stock feeding are still very largely based upon the classic investigations of Henneberg and Stohmann at the Weende Experiment Station, covering approximately the years from 1858 to 1870. Beginning with investigations upon the digestibility of feeding stuffs and upon the maintenance requirements of farm animals, they subsequently took up more complex problems. A respiration apparatus modeled after that of Pettenkofer at Munich was constructed, and somewhat extensive respiration experiments with both cattle and sheep were conducted. No more carefully thought out, complete, and logical programme for investigations in animal nutrition is on record than that written by Henneberg in 1868 and published in 1870 as an introduction to his "Neue Beiträge."[a] This paper outlines the general features of the problem and will well repay careful perusal by every student of the subject.

Such investigations as Henneberg mapped out, however, are necessarily slow and expensive, particularly in the case of farm animals, and while the respiration apparatus found extensive use by the physiologists for smaller animals, investigators of feeding problems were largely content for many years with the simpler methods of digestion and metabolism experiments. It is only quite recently that the investigations of Kühn and Kellner at Moeckern and of Zuntz and Hagemann at Berlin have aroused new interest in these fundamental questions. In the United States the work of the experiment stations has almost of necessity been along lines similar to those pursued for many years abroad. While the investigations of our stations have done much to advance our knowledge of the subject of stock feeding, especially as related to questions of practice, they have at the same time made increasingly evident the need for more scientific study of

[a] Ueber das Ziel und die Methoden der auf den Landwirthschaftlichen Versuchsstationen auszuführenden thier-physiologischen Untersuchungen.

the fundamental physiological laws upon which a rational practice must necessarily be based.

In 1898, encouraged by the success which had attended the investigations with the Atwater-Rosa respiration calorimeter at Wesleyan University, the Pennsylvania Experiment Station and the Bureau of Animal Industry of the U. S. Department of Agriculture undertook in cooperation the construction and operation of a similar apparatus for studying the fundamental principles of the nutrition of farm animals (Pls. IV and V). It was determined to make the apparatus large enough for experiments with cattle, and in view of the costly and unique nature of the apparatus the erection of a special building for housing it was authorized by the trustees of the college.

Work upon the apparatus was begun in the fall of 1898. In addition to the numerous problems of construction involved in the considerable enlargement of the apparatus, other questions had to be solved. Thus, no cooperation could be had from the subject of the experiment, but everything relating to the conditions inside the apparatus must be adjustable by the observer without. Moreover, for experiments with cattle large amounts of bulky food and excreta had to be introduced into or removed from the apparatus. A further complication arose from the considerable production of combustible gases by ruminating animals, rendering it necessary to provide special means for their determination. As a result of all these difficulties, the construction proved slower and more expensive than was anticipated, extending over nearly three and one-half years. Preliminary tests were completed and the first actual experimental work begun early in the year 1902.

GENERAL PLAN.

The general plan of the apparatus is substantially that of the Atwater-Rosa apparatus; that is, it is a Pettenkofer respiration apparatus, the chamber of which serves also as a calorimeter. The original Middletown apparatus has been fully described in bulletins 63 and 136 of the Office of Experiment Stations, and the reader is referred to these publications for details on many points.

The respiration chamber of the Pennsylvania apparatus (figs. 11 and 12) is constructed of sheet copper, and measures 6 feet by 10 feet 4 inches and 8 feet high. A platform 21 inches above the base of the chamber carries the stall in which the animal stands. Beneath the rear portion of this stall is a small chamber of sheet copper about 34 by 67 inches, entirely shut off from the rest of the respiration chamber except for two holes through the platform, and having a separate air-tight door. Through one of the holes mentioned a rubber tube leads from the urine funnel to a receptacle of tinned copper; to the other hole is attached a large rubber duct covering the hind quarters of the

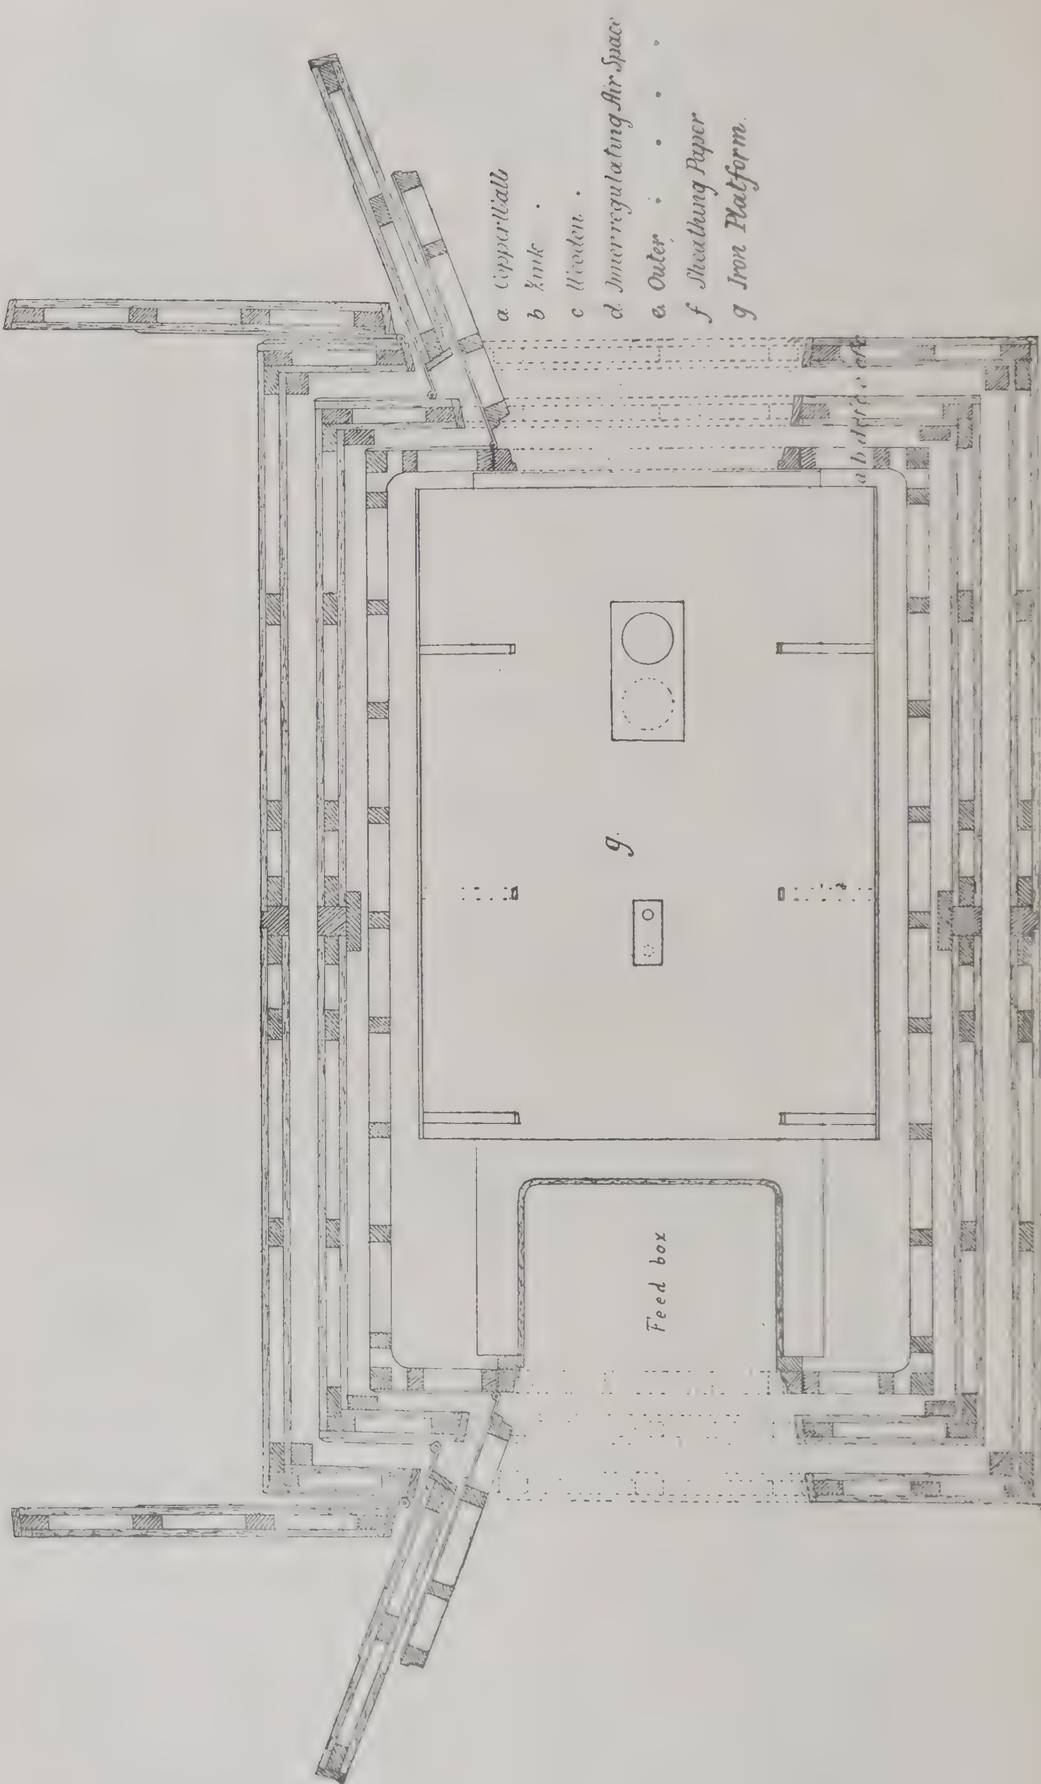

FIG. 12.—Horizontal cross section.

animal, and underneath it is placed a galvanized iron box, tightly pressed against the lower side of the platform, to receive the droppings of the animal. This small chamber, therefore, has only such air connection with the remainder of the chamber as is unavoidable through the openings around the two ducts, but is in thermal communication with it through its copper walls. The operation of opening the air-tight door, removing the excreta and replacing the receptacles occupies not more than a minute or two, and it is assumed that any error thus introduced is insignificant.

At the other end of the platform is the feed box. This is provided with an air-tight cover, which can be opened or closed by means of a lever operated from outside, and is also provided with an air-tight door. By lowering the cover the feed box can be entirely shut off from the chamber. The air-tight door can then be opened for the introduction of feed or the removal of residues, the door closed and the lid again lifted. The arrangement constitutes, in brief, an air lock and is substantially like that employed in the respiration apparatus of the Moeckern Experiment Station. The water supply is introduced into a small drinking basin at the side of the feed box by means of a pipe carried through the calorimeter wall, the water being weighed in and any excess removed by drawing the water in the pipe down to a fixed level.

The large door at the rear of the apparatus through which the animal enters and the two small doors giving access respectively to the feed box and excreta have heavy oak frames and are made tight by means of gaskets composed of rubber tubing, the doors being kept in place by means of pressure catches such as are frequently used on large refrigerators.

THE RESPIRATION APPARATUS.

Through the chamber above described a current of outdoor air is aspirated by means of a special pump (Pl. VI), the air first passing over the expansion coils of an ice machine where most of its moisture is deposited as frost. At the point of entry to the chamber samples are taken alternately by one or the other of two large aspirators of constant flow at the rate of 200 liters in 12 hours. In these samples moisture and carbon dioxid are determined by passing them through U tubes containing sulphuric acid and soda-lime.

The air leaving the respiration chamber passes first through four large copper cans, standing in wells in a brine bath which is cooled to about -20° C. by means of the ice machine. In these cans the larger share of the moisture of the outcoming air condenses as frost and is subsequently weighed.

From the copper cans the air passes to the meter pump, which serves both to maintain the air current and to measure and sample it.

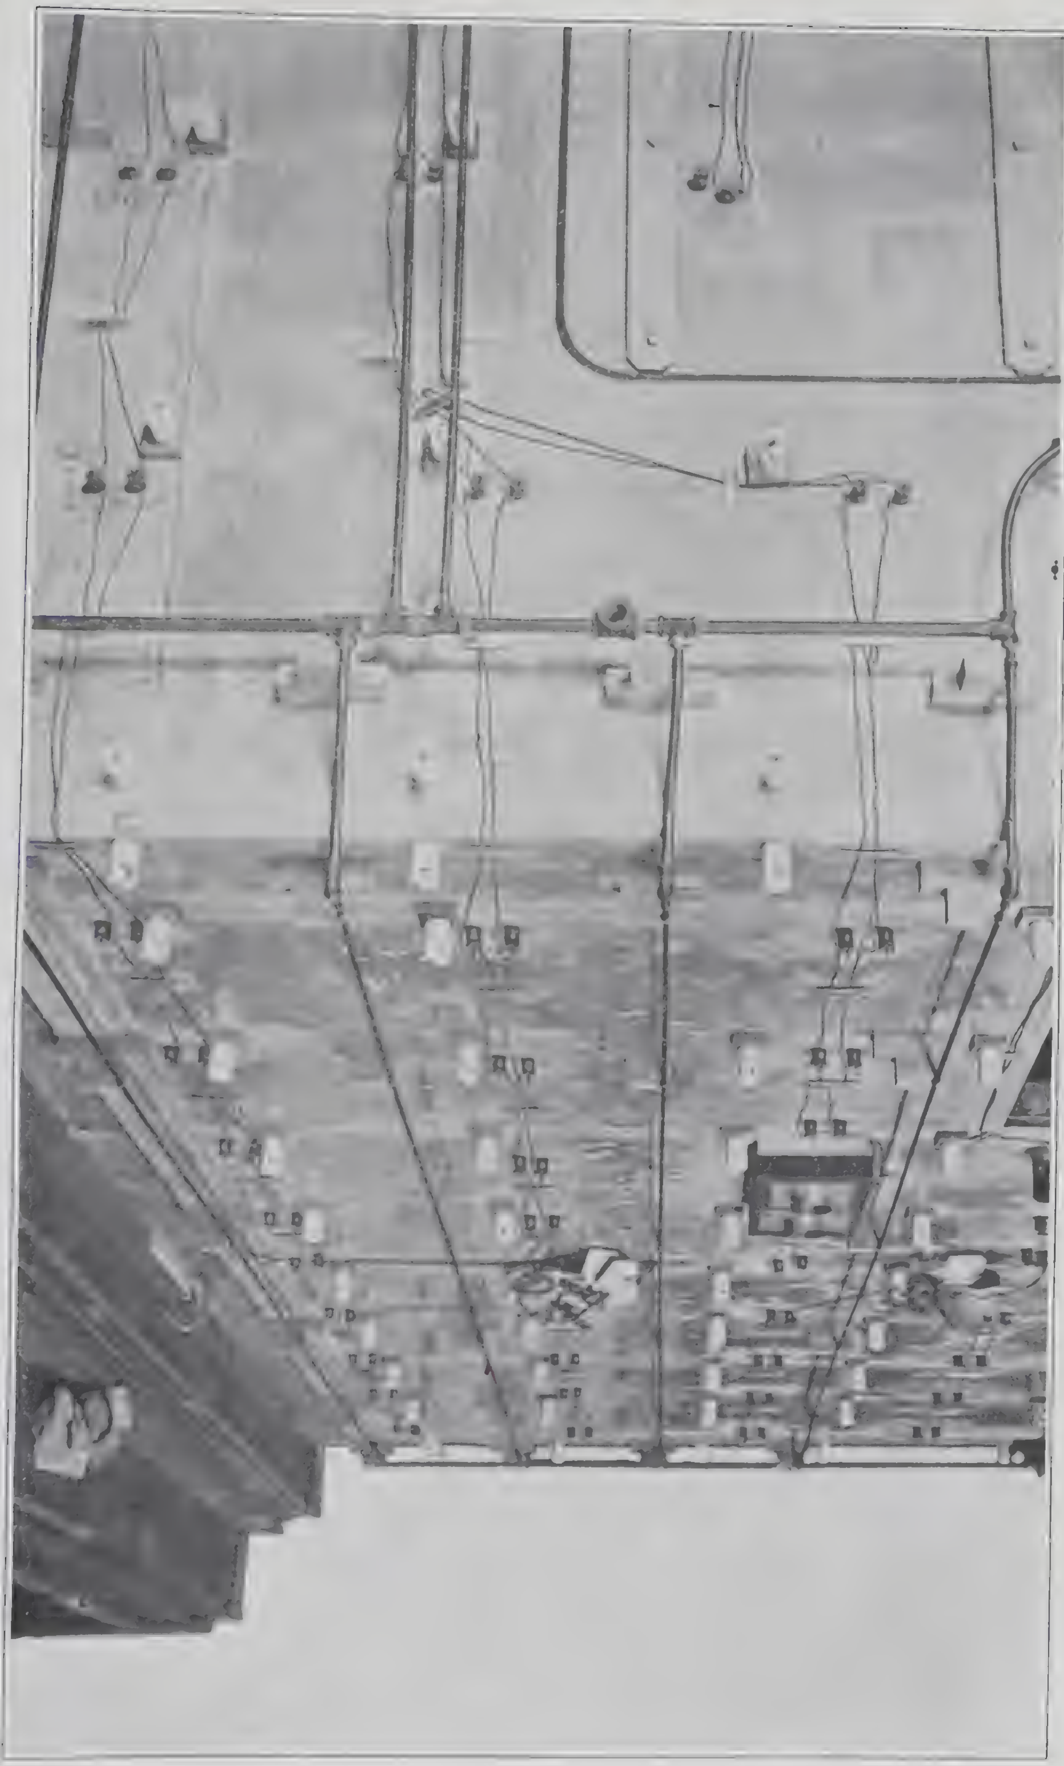
This meter pump, which was designed and built especially for this apparatus by Mr. Frederick Hart, of Poughkeepsie, New York, acts upon the same principle as the Blakesley meter pump used in the Atwater-Rosa apparatus, but differs materially from it in mechanical details. A full description of it has been published.[a] The pump consists essentially of two cylinders of drawn-steel tubing, 19 inches in diameter, moving up and down in mercury. The pump is adjustable to three different lengths of stroke and four speeds. As thus far used, it has been set to deliver approximately 50 liters per stroke (exactly, 49.539) and has been run at the rate of about 14 strokes per minute, the total ventilation, therefore, being about 700 liters per minute. The number of strokes as recorded by a revolution counter, with the corrections for temperature and pressure, gives the total volume of air passing through the apparatus, and the results of the analysis of the ingoing air, calculated upon this volume, give the weights of water and carbon dioxid carried into the apparatus by the current of air.

By means of a shunt valve connected with an ingenious train of gearing, one stroke is delivered at regular intervals alternately through one or the other of two special outlets. The pump can be set to deliver thus one stroke in 200, one in 400, or one in 800. The two aliquot samples thus taken are conducted to two large pans having counterpoised rubber covers substantially like those used in the Atwater-Rosa apparatus. From these pans each sample separately is aspirated by means of a subsidiary air pump and passes through a set of six large U tubes ($10\frac{1}{2}$ inches), the first two containing pumice stone saturated with sulphuric acid, the second two soda lime, and the last two pumice stone and sulphuric acid. The increase in weight of these tubes, of course, gives the amounts of water and carbon dioxid contained in the samples, and this amount multiplied by the proper factor gives the total amount contained in the outcoming air. Subtracting from this that contained in the ingoing air, determined as above described, gives the amounts added by the animal.

From the U tubes the air is conducted to the apparatus for determining the combustible gases excreted. This consists of a 1-inch copper tube, having an effective length of about 60 inches, filled with platinized kaolin and kept at a red heat by 64 gas-burners. In this tube the combustible gases are oxidized to carbon dioxid and water, which are absorbed and weighed in a second set of U tubes similar to the first. Many difficulties were experienced in securing satisfactory results with this part of the apparatus on account of the large volume of air to be handled ($3\frac{1}{2}$ liters per minute as ordinarily used) and the considerable force required to draw the air through the numerous absorption tubes. The connections with the combustion tubes are

[a] American Machinist, 25 (1902), p. 1297.

THE METER PUMP AND ABSORPTION TUBES.



ARRANGEMENT OF HEATING WIRES, COOLING PIPES, ETC.

made with soldered joints and the absorption tubes are carefully tested with the manometer before being used. The amount of platinized kaolin employed has been demonstrated to be sufficient to oxidize much larger amounts of methane than it will ever be required to in actual use.

No parallel determinations of combustible gases are at present made in the air entering the apparatus. The amounts have been shown to be very small in this locality and corrections are made for them from the results of numerous blanks.

THE CALORIMETER.

The arrangements for determining the heat given off by the animal are in all essentials like those of the Atwater-Rosa apparatus. The heat is absorbed by a current of cold water passing through copper pipes at the top of the respiration chamber, access of air to these pipes being regulated by means of shields which can be raised or lowered by the operator. The temperature of the ingoing and outcoming water is read every four minutes by means of two mercurial thermometers, graduated to $\frac{1}{50}$° C. and carefully calibrated. The volume of water passing through is measured by means of two copper meters, each containing 100 liters. The apparatus is so arranged that the weight of the heat absorbers may be taken from outside, any condensation of moisture upon them being thus indicated.

The respiration chamber proper of the apparatus is a metallic chamber of the dimensions stated above. Surrounding this, with an air space of 4 inches between, is a double wooden wall, which in turn is surrounded by a second wall and air space of 4 inches. The walls of the respiration chamber proper are double, the inner of copper and the outer of zinc, with a 3-inch dead air space between, and through these walls are distributed some 600 iron German-silver couples connected in series with a reflecting galvanometer and serving to indicate any difference in temperature between the inner (copper) and outer (zinc) surface. Any such difference is rectified and the walls of the chamber maintained adiabatic by heating or cooling the air space surrounding the zinc wall—the former by means of an electric current through resistance wires and the latter by circulating cold water through brass pipes (Pl. VII). The double wooden wall surrounding the metallic chamber also contains a smaller number of iron German-silver couples, and is in its turn kept nearly adiabatic by regulating the temperature of the second air space. By means of very similar devices, the temperature of the ingoing air is maintained the same as that of the outcoming air.

The temperature of the interior of the apparatus is measured by means of a series of copper resistance thermometers connected to a slide-wire Wheatstone bridge, and also by means of two mercurial thermometers. By raising or lowering the shields or varying the flow

of water through the absorbers, the rate at which heat is removed through the water current may be so regulated as to keep the temperature of the interior constant within very small limits, while the slight variations are made to balance each other in the course of an experiment, so that there is practically no capacity correction. Under these conditions, all the heat evolved by the animal must leave the apparatus either as sensible heat in the water current or as the latent heat of water vapor.

In practice, of course, corrections have to be made for any heat introduced or removed as sensible heat in the feed, excreta, etc. The friction of the water in the coil of copper pipes is also the source of a minute amount of heat, which is computed from the volume of water and the fall in pressure in passing through the pipes. This difference in pressure also affects slightly the readings of the thermometers, tending to make those in the ingoing water relatively higher than those in the outcoming water. The small correction for this difference has been determined experimentally within the range of pressures used.

BUILDING.

The building in which the apparatus is housed is of brick, with heavy walls containing an air space to aid in maintaining uniform temperature. The floor is of concrete, the ceiling high enough to leave about 3½ feet clear space above the top of the respiration chamber, which stands upon three brick piers about 18 inches above the floor of the room. In this way any difficulty arising from differences in temperature at different points in the room has been avoided.

EXPERIMENTS.

The experiments thus far made have been of 48 hours' duration, this period being subdivided into subperiods of 12 hours each. The animal is placed in the apparatus 5 or 6 hours before the beginning of the experiment, which has been conveniently placed at 6 p. m. By this time the apparatus has come into equilibrium, and it is only necessary to shift the current of air from one set of cans and absorption apparatus to another in order to begin the experiment.

The experiments have followed each other at an average interval of from two to three weeks. During the intervening time the animal stands in an adjoining room in a stall which is provided with appliances for the quantitative collection of the visible excreta. An actual experiment requires the services of at least seven men, exclusive of the assistant in charge of the feeding and collection of excreta. Three series of experiments have thus far been made, the results of the first of which have been recently reviewed in these pages (E. S. R., 15, p. 799).

INTERPRETATION OF RESULTS.

A feeding experiment conducted with the aid of the respiration calorimeter is not fundamentally different from one made according to simpler and more familiar methods. In both cases we attempt to compare the results obtained, either from two or more rations under identical conditions or from identical rations under differing but controlled conditions. The difference lies in the extent to which we are able to control the conditions and in the accuracy and minuteness with which it is possible to compare the rations and their results.

The simplest and most obvious form of feeding experiment is that in which the amounts of feed consumed are noted and their effects measured by the increase in the live or dressed weight of the animal or by the weight of milk or wool produced. This method, when skillfully carried out with a considerable number of animals and under the conditions of actual practice, is particularly adapted, and indeed may be said to be indispensable, to the study of the economic aspects of stock feeding.

But while this is true, it is also the fact that no considerable or profound knowledge of the principles of feeding can be gained by means of experiments of this class. The factors entering into the problem are too complex. Chemistry has shown that each one of the feeding stuffs consumed consists of a great variety of substances—useful, indifferent, and even injurious—mingled in the most diverse and varying proportions, while physiological investigation has demonstrated not only the considerable and irregular fluctuation of live weight from day to day, but especially that a given increase or decrease may be of very varying significance according as it consists of proteid tissue, fat, mineral matter, or simply water. The result of a live-weight experiment, therefore, may be the resultant of any one of many possible combinations of these factors, and no safe conclusion as to its actual cause is usually possible. The history of this class of experiments amply corroborates this conclusion. Great accumulations of experimental data have been made, but relatively few general conclusions have issued from them.

The earliest step in advance was the attempt to separate the factor "food" into its elements. Of these attempts the one which has secured general acceptance is the familiar one of Henneberg which groups the chemical ingredients of feeding stuffs into "protein," "carbohydrates," "fat," and "ash," subdividing the carbohydrates into "crude fiber" and "nitrogen-free extract," and distinguishing further between the digestible and the indigestible portions of each group. A great mass of investigation along these lines in the laboratory and digestion stall has materially enlarged our knowledge of feeding stuffs, although much still remains to be done. It is now a comparatively easy matter, by the familiar methods of the digestion

experiment, to determine with a fair degree of accuracy the so-called "digestible nutrients" consumed in the several periods of a feeding experiment and thus to secure a more rational basis of comparison. To the conventional determinations it is of course easy to add others, such as that of amids, pentosans, etc., and particularly the heat of combustion.

A knowledge of the elements of the food consumed, however, is the smaller half of the problem. It is necessary to secure some definite and accurate measure of its effects upon the animal consuming it. This has been the weak side of investigation in stock feeding. While much labor has been expended in determining the composition and digestibility of feeding stuffs with scientific accuracy, too many experimenters have been, of choice or necessity, content to limit their determinations of nutritive effect to simple weighing of the product. As a consequence, the expenditure in the examination of the feeding stuffs has, as a whole, failed of its due reward through lack of the other term of the comparison. This is less true, of course, of experiments on milk production, since in these the material product may be subjected to chemical and physical examination, but even here half or two-thirds of the food may serve to support those nutritive functions of the body whose net result is expressed in the term "maintenance," but of whose amount and character the live-weight experiment furnishes no exact measure.

The problem is to determine the changes in the make-up of the body during an experiment. Two general methods have been applied to its solution.

The first is the method of comparative slaughter tests. Of two animals or lots, selected for their apparent identity as to weight and condition, one is killed and analyzed at the beginning of the experiment and the other at its close, and the difference in the amounts of the several ingredients found is regarded as representing the gain made by the second animal or lot. The weak point of the method, of course, aside from its laboriousness, is the impossibility of proving the fundamental assumption of identity of composition of the two animals at the beginning of the experiment.

The second method, which especially interests us here, dispenses with any knowledge of the initial composition of the animal and attempts to determine directly the increment or decrement of each important ingredient of the body during the experiment. The basis of the method is Henneberg's conception of the schematic body. This is, in brief, that for this particular purpose the animal body may be regarded as composed of water, ash, protein, and fat, each of practically invariable elementary composition. The writer has discussed this conception at some length elsewhere,[a] and it seems sufficient here

[a] Principles of Animal Nutrition, pp. 60–66.

to simply state the average composition of the protein and fat of cattle, from which that of other species differs but slightly.

Composition of protein and fat of cattle.

	Protein.	Fat.
	Per cent.	*Per cent.*
Carbon	52.54	76.50
Hydrogen	7.14	11.91
Oxygen	23.12	11.59
Nitrogen	16.67	....
Sulphur	.52	....
	100.00	100.00

According to this conception the effect of a ration is expressed by the gain or loss of ash, protein, fat, and, of course, water, by the body of the animal, and this gain or loss may be determined by comparing the amounts of ash, nitrogen, and carbon in the food with those contained in the various excreta, solid, liquid, and gaseous; that is, by a so-called balance experiment. As regards ash, the method is sufficiently obvious, and the principal interest centers in the methods for the organic ingredients, viz, protein and fat.

Since the term protein, as above used, is synonymous with total nitrogenous matter, the gain or loss of protein may be determined by a comparison of the income and outgo of nitrogen. Furthermore, since the vast majority of physiologists regard it as demonstrated that there is no material excretion of gaseous nitrogen by the body we may confine the determinations of nitrogen to the food and the visible excreta. For example, in two experiments with a steer, in which the rations consisted, respectively, of 4,531 grams and 5,750 grams of timothy hay, with the addition in each case of 400 grams of linseed meal, the following figures for daily nitrogen were obtained as the average of a ten-day period following a preliminary period of eleven days:

Nitrogen balance in two periods of a feeding experiment with a steer.

	Period A.		Period B.	
		Grams.		*Grams.*
Nitrogen in hay		23.4		32.5
Nitrogen in linseed meal		22.2		22.1
Nitrogen, total in feed		45.6		54.6
Nitrogen in feces		16.2		20.8
Nitrogen digested		29.4		33.8
	Grams.		*Grams.*	
Nitrogen in urine	36.3		33.7	
Nitrogen in hair, etc	1.3		1.3	
		37.6		35.0
Loss of nitrogen by body		8.2		1.2

In Period A the outgo of nitrogen is shown to have exceeded the income by 8.2 grams. Multiplying this by the factor 6.0 (corresponding to 16.67 per cent. nitrogen) we find that in this period the steer

oxidized 49.2 grams of the proteid tissues of his body in addition to 146.8 grams of proteids and 16.3 grams of nonproteids which he was shown to have digested from his feed. In Period B the loss of proteids was only 7.2 grams on a ration containing in digestible form 173.2 grams of proteids and 17.2 grams of nonproteids. In other words, the second ration diminished the loss of proteids by the body by 42.0 grams, while it supplied only 26.4 grams more of proteids than that of Period A. This striking result is readily explained as the effect of the large addition of nonnitrogenous matter in Period B, but it serves to illustrate the difficulty of drawing *a priori* conclusions as to the effects of a ration.

The animal body, however, usually contains relatively considerable amounts of fat, and the quantity of the latter is subject to much greater fluctuations than that of protein. The change in the store of fat in the body is usually the most conspicuous effect of a ration. The determination of its amount requires, in addition to the nitrogen balance, a determination of the income and outgo of carbon, including, therefore, a determination of the gaseous products of respiration and perspiration by means of some form of respiration apparatus.

In the two periods whose nitrogen balance has just been given, the respiratory products were also determined for 48 hours by means of the respiration calorimeter, affording, along with determinations of carbon in feed and excreta, data for the following daily comparisons:

Income and outgo of carbon.

	Period A.		Period B.	
	Income.	Outgo.	Income.	Outgo.
	Grams.	*Grams.*	*Grams.*	*Grams.*
Carbon of hay	1,337.6		1,876.8	
Carbon of linseed meal	172.5		170.7	
Carbon of feces		649.8		858.0
Carbon of urine		88.1		101.3
Carbon of carbon-dioxid		934.1		1,075.6
Carbon of methane		55.2		70.4
Carbon of hair, etc		8.0		8.0
Carbon lost by body	225.1		65.8	
Total	1,735.2	1,735.2	2,113.3	2,113.3

In Period A we have already computed a daily loss of 49.2 grams of protein. This protein contains 52.54 per cent of carbon, equal to 25.9 grams, while the total loss of carbon, as shown above, was 225.1 grams. The difference of 199.2 grams must, therefore, according to our basal assumption regarding the make-up of the schematic body, represent a loss of fat, and since this fat contains 76.5 per cent of carbon, the loss of 199.2 grams is equivalent to the loss of 259.0 grams of fat. In precisely the same way, we compute the loss of fat in Period B to be 80.6 grams.

The net results in these two periods, then, may be summarized as follows:

Balance of nutrients.

	Period A.	Period B.
	Grams.	*Grams.*
Proteids digested	146.8	173.2
Total organic matter digested	1,831.1	2,539.7
Protein lost by body	49.2	7.2
Fat lost by body	259.0	80.6

In other words, the increase of 708.6 grams in the organic matter digested in Period B took the place of 42.0 grams of body protein and 178.4 grams of body fat oxidized on the lighter ration; that is, these latter figures represent the contribution which the added hay made to the maintenance of the body.

Still another method of comparison is afforded when we turn from considering the food as a supply of matter and regard it as the source of energy to the vital machinery.

The potential energy of feed and of visible excreta is measured by their heats of combustion, which are readily determined by means of the bomb calorimeter. The production of heat by the animal is determined directly by the respiration calorimeter. Adding to these data the heat of combustion of the methane excreted, which is readily computed from its amount, we have all the data for the construction of a balance of energy similar to the balance of matter. In the two cases selected as examples this was:

Balance of energy.

	Period A.		Period B.	
	Income.	Outgo.	Income.	Outgo.
	Calories.[a]	*Calories.*[a]	*Calories.*[a]	*Calories.*[a]
Energy of hay	13,035		18,463	
Energy of linseed meal	1,824		1,811	
Energy of feces		6,432		8,574
Energy of urine		853		965
Energy of methane		984		1,253
Energy of hair, etc		88		88
Energy of heat produced by steer		9,215		10,296
Loss of energy by steer	2,713		902	
Total	17,572	17,572	21,176	21,176

[a] The calorie here used is the large calorie (kilogram-calorie), usually written with a capital C.

In Period A, out of a total of 14,859 calories of energy in the food 8,357 calories reappeared as unused potential energy in the various excreta. The remainder, 6,502 calories, was used to support the vital activities of the body, and these required in addition 2,713 calories of energy, which was supplied by the oxidation of body tissue. The 49.2 grams of protein lost by the body would supply for this purpose 280 calories and the 259 grams of fat 2,461 calories, or a total of 2,741 calories, which is practically the same as the amount computed from the energy balance.

In Period B the energy of food, minus excreta, is 9,394 calories, and the contribution from body tissue 902 calories (or 807 calories as computed from the loss of protein and fat), making a total requirement of 10,296 calories of energy, which was evolved by the body as heat.

A comparison of the two periods shows that the extra hay given in Period B supplied, after deducting the losses in the excreta, 2,892 calories more of energy for the uses of the body and that this diminished the draft on the body tissues for energy by 1,811 calories. In round numbers, then, 63 per cent of the added energy was available to diminish the loss of tissue—that is, for maintenance.

Our final comparison of the two periods, then, takes the following form, in which, for convenience, the losses are expressed as negative gains:

Gains or losses in the animal body.

	Period A.	Period B.	Difference.
Food:			
Proteids digested ....grams..	146.8	173.2	26.4
Total organic matter digested ....do....	1,831.1	2,539.7	708.6
Energy supplied ....calories..	6,502	9,394	2,892
Body changes:			
Gain of protein ....grams..	− 49.2	− 7.2	42.0
Gain of fat ....do....	− 259.0	− 80.6	178.4
Gain of energy ....calories..	−2,713	−902	1,811

The object of these two periods was to ascertain the actual feeding value, under the conditions of the experiment, of 1,219 grams of timothy hay added to the ration of Period A. This we determine, just as in the simplest feeding experiment, by trying it and noting the results, and the value of the latter depends as absolutely in the one case as in the other upon the maintenance of uniform and normal conditions of experiment, both external and internal. The difference is simply that by means of more refined methods we have been able to make a more detailed, definite, and accurate comparison of results.

It is evident that the same general method is equally applicable to experiments in which an actual gain is made by the animals, and that the kind and amount of gain made may be accurately compared with the supply of matter and energy in the food used to produce it. In fact a large amount of work along this line has been done by Kellner and his associates, a consideration of which would lead us too far afield. In general, the method opens the prospect of being able to predict with a good degree of accuracy the amount and kind of gain, or, otherwise expressed, the amount of energy storage in the body which may be anticipated from the consumption of a given amount of matter or energy in this or the other feeding stuff, while it also enables us to formulate the demands of the vital processes for energy and measure the extra expenditure of the latter required in the digestion and assimilation of the coarser as compared with the more concentrated feeds.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

On the determination of the citric-acid soluble phosphoric acid in Thomas slag, R. Sorge (*Ztschr. Angew. Chem., 17 (1904), p. 393; abs. in Chem. Ztg., 28 (1904), No. 33, Repert. No. 9, p. 116*).—In studies of Kellner's method for this purpose (E. S. R., 14, p. 834), the author found that (1) the phosphoric acid precipitate contained as much silicic acid after separation of this substance as without such separation; (2) the error due to solubility of ammonium-magnesium phosphate in ammonium citrate was as great as that due to the simultaneous separation of silicic acid; (3) the lower results obtained by this method are apparently due to the increased solubility of the ammonium-magnesium phosphate precipitate, resulting from longer action of the ammonium citrate on this precipitate which takes place in the method.

On citrate-soluble phosphoric acid, P. M. Van Haarst (*Chem. Weekblad, 1 (1903), pp. 205–211, 221–226, 234–239; abs. in Chem. Centbl., 1904, I, No. 9, p. 694*).—The methods employed in studying Thomas slag are discussed and tests of a number of them are reported.

On the solubility of soil constituents, F. Mach (*Chem. Ztg., 27 (1903), No. 77, p. 941; abs. in Centbl. Agr. Chem., 33 (1904), No. 5, p. 348*).—Tests of the solubility in pure water, in water containing carbon dioxid, hydrated silicic acid, and suspended humic acid, and in dilute citric acid, of sandstone, shell limestone, basalt, feldspar, gray wacke, zeolites, and other substances are reported, 5 gm. of the pulverized material being treated for 6 to 8 weeks with 1 liter of the various solvents. In the case of the sandstone, graywacke, and basalt, and especially shell limestone, the water containing carbon dioxid dissolved considerably more than pure water.

The phosphate present was almost entirely dissolved in citric acid, but the water containing carbon dioxid dissolved less of this substance than pure water. An appreciable amount was dissolved in water containing hydrated silicic acid and humic acid. A larger proportion of calcium carbonate was dissolved in water containing carbon dioxid than in pure water. Water containing silicic acid dissolved twice as much of this substance as pure water; that containing humic acid 10 times as much, and that containing citric acid 53 times as much. Magnesium carbonate was dissolved in large proportion by all of the solvents. The author was led to make these tests as a result of observation that many plants are able to make a comparatively vigorous growth in a soil composed of freshly ground stone.

Water-soluble plant food of soils, H. Snyder (*Science, n. ser., 19 (1904), No. 491, pp. 834, 835*).—This is a study of the amounts of phosphoric acid removed from the soil by wheat at different stages of growth, the results showing that the wheat plant removes from the soil more phosphoric acid than is dissolved by extraction with water for 15 days. The paper was presented at the St. Louis meeting of the Society for the Promotion of Agricultural Science (E. S. R., 15, p. 543), and contains a critical analysis of the data given in Bulletin 22 of the Bureau of Soils of this Department.

A short method for the determination of potash in soils, potash salts, and similar compounds, J. Hasenbäumer (*Chem. Ztg., 28 (1904), No. 18, pp. 210, 211*).—In the method proposed the hydrochloric-acid solution of the soil is evaporated to dryness in a porcelain dish, taken up in water, and transferred to a platinum dish. Ammonia and ammonium carbonate are added and the solution evaporated to dryness. The residue is heated gently over a gas burner until the ammonium salts are driven off and the organic matter destroyed. The residue is treated for a short while with hot water, the solution filtered, and after acidification of the filtrate with hydrochloric acid, the potash is precipitated with perchloric acid or platinum chlorid.

Satisfactory tests of the method are reported. The object of evaporating to dryness and heating after the addition of ammonia and ammonium carbonate is to destroy the power of the bulky precipitate to occlude potash, as first pointed out by J. König.

On the determination of the available amounts of lime and magnesia in the soil, T. Katayama (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1904), No. 2, pp. 103–124, pls. 2*).—A series of pot experiments with onions grown in sandy and loamy soils containing different proportions of lime and magnesia are reported. The available lime and magnesia in the soils were determined by extracting the fine earth (particles less than 0.25 mm. in diameter) for 50 minutes with boiling 10 per cent hydrochloric acid in the proportion of 50 cc. of acid to 25 gm. of soil. Check experiments with sand cultures were also made.

"Sand culture, as well as the cultures in two soils differing widely in character from each other, yielded the best results when the available amounts of lime and magnesia were present in the ratio 2:1; in other words, the onion has the lime factor 2. Lime and magnesia in the sand culture were added in form of solutions, hence the total amount of these salts were easily available, even if precipitated as finely divided phosphates. As to the soil culture the 'available amounts' of lime and magnesia were determined according to my modification of the usual method and their ratios changed by adding carbonate of lime in such quantities as to reach the fixed ratios of the sand culture. Since in all my experiments of 1902 and 1903 the ratio $\frac{CaO}{MgO}=\frac{2}{1}$ proved the most favorable for the onion plant, the determination of the available amounts must have been made by a reliable method."

The determination of sodium perchlorate in commercial sodium nitrate, H. Lemaître (*Monit. Sci., 4. ser., 18 (1904), p. 253; abs. in Chem. Ztg., 28 (1904), No. 31, Repert. No. 8, p. 108*).—With nitrate containing less than 4 per cent of perchlorate 5 gm. of the material is mixed with 3 gm. of pure dry sodium sulphite. The mixture is fused in a platinum dish, cooled, and taken up in water. The solution is heated to boiling and 200 cc. of a boiling 4 per cent barium nitrate solution is added. The precipitate is allowed to settle and the solution filtered. Eight and two-tenths cubic centimeters of approximately normal soda solution and 1.2 gm. of sodium persulphate are added and the solution boiled and filtered. The filtrate with the wash water is exactly neutralized with a weak acetic-acid solution, using phenophthalein as indicator, and titrated with tenth-normal silver nitrate, using potassium chromate as indicator to determine chlorin, or the chlorin may be determined gravimetrically. The treatment with sodium sulphite converts the chlorates and iodates into chlorids and iodids.

Comparison of methods for the quantitative determination of nitric acid in water, A. F. Dokatschajew (*Vrach [St. Petersburg], 1904, p. 26; abs. in Chem. Ztg., 28 (1904), No. 17, Repert. No. 4, p. 54*).—A comparison of the methods of Schultze-Tiemann, Noll, Grandval-Lajoux, Kostjamin, and Marx-Trommsdorff is reported. The most uniform and exact results were obtained by the first method.

Applicability of the Schloesing method of determining nitric nitrogen in the presence of organic matter, P. LIECHTI and E. RITTER (*Ztschr. Analyt. Chem., 43 (1904), No. 3, pp. 168–172*).—A series of experiments with mixtures of nitrates and ammonium salts and with urea, urine, and soil, is reported, which show the accuracy of this method if care is taken to insure the complete expulsion of air from the apparatus.

A comparison of simple methods of determining carbon dioxid in the air, A. F. LAUENSTEIN (*Jour. Ochran. Narodn. Sdrawija, 15 (1903), p. 422; abs. in Chem. Ztg., 28 (1904), No. 33, Repert. No. 9, p. 116*).—Comparisons of the Smith-Lunge, Lunge-Zeckendorff, Wolpert, Nagorski-Ssubbotin, and Pettenkofer methods are reported. The last two gave the most uniform and accurate results. This the author attributes to the more perfect absorption of the carbon dioxid of the air in these methods. For general sanitary analysis the Nagorski-Ssubbotin method is preferred on account of simplicity and reliability. A modification of Pettenkofer's method is described.

Contributions to technical chemical analysis, G. LUNGE (*Ztschr. Angew. Chem., 17 (1904), Nos. 7, pp. 195–203; 8, pp. 225–236; 9, pp. 265–270*).—Critical comments, based largely upon the results of original work, are made on chemical apparatus, various indicators, and numerous substances recommended for the preparation of standard solutions for use in volumetric analysis.

A possible source of error in fat determinations by the extraction methods, C. BARTHEL (*Nord. Mejeri Tidn., 18 (1903), No. 35, pp. 471, 472*).—The author finds that vigorous stirring of skim milk, as occurs in the pasteurization of the milk in some pasteurizing machines provided with stirrers, causes a subdivision of the fat globules; and that on drying the milk on paper, kaolin, sand, etc , the numerous minute globules thus formed can not be dissolved out by the ether, presumably because the surface attraction of the absorbing medium can not be overcome.

The Gottlieb method, on the other hand, gives correct results in the case of such milks, the percentages being from about one-tenth to four-tenths above those obtained by the Adams method, depending upon the fat content of the milk. The greater differences were observed in case of milk containing considerable quantities of fat. When samples of new milk were churned for 5 to 15 minutes at about 48° C. the results obtained with the separator skim milk by the extraction method were 0.18 to 0.44 per cent too low, while the results obtained by the two methods of analysis agreed within 0.01 to 0.04 of 1 per cent when the milk was not subjected to vigorous agitation.—F. W. WOLL.

On the quantitative separation of maltose and lactose, C. I. BOYDEN (*Vermont Sta. Rpt. 1903, pp. 198–201*).—This has been noted from another source (E. S. R., 14, p. 225).

Analysis of formaldehyde sold in North Dakota, E. F. LADD (*North Dakota Sta. Bul. 60, pp. 386–395*).—Analyses were made of a number of samples of commercial formalin. The content of formaldehyde was frequently below 40 per cent, and the packages were often short in weight or measure. The average formaldehyde content of a large number of these samples was about 33 per cent.

Miscellaneous analyses, C. H. JONES (*Vermont Sta. Rpt. 1903, pp. 201–203*).—Analyses are reported of 32 samples of fertilizing materials, home mixtures, and wood ashes, 3 samples of butter, 1 sample of maple sirup, and 1 of maple sugar.

Report of the division of chemistry, A. M. PETER (*Kentucky Sta. Rpt. 1900, pp. XI–XXXIV*).—During the year 1,211 samples, of which 599 were fertilizing materials, were analyzed. In this report analyses are given of 35 samples of butter, 67 of sorghum-cane juice, 72 of sugar beets, 2 of silicate of potash, 4 of feeding stuffs, 7 of soils, 2 of tobacco extract, 5 of tobacco stems and stalks, 3 of potassium nitrate, 1 of

crude petroleum, 1 of phosphatic limestone, 26 of mineral waters, and the stomach contents of several animals suspected of having been poisoned.

Report of the chemical control station, Trondhjem, Norway, 1902, E. SOLBERG (*Aarsber. Offent. Foranstalt. Landbr. Fremme, 1902, pp. 249–300*).—Several lines of work are reported upon briefly.

Maximum and minimum data for 151 samples of butter from 6 Norwegian creameries are as follows: Specific gravity 0.8632 (June) and 0.8672 (January); index of refraction 39.1 (December) and 43.1 (June); Reichert-Meissl number 21.6 (June) and 33.9 (December). The water content of 63 samples was as follows: Minimum 10.33, maximum 17.25, and average 12.71 per cent. The addition of potassium bichromate to milk samples did not affect the determination of fat by the Adams or Lindström methods for a period of at least 2 months.

Comparative tests of different methods of determining fat in feeding stuffs are reported and analyses of barley, rye, potatoes, and other crops are given.

A number of fertilizer experiments with pastures, cereals, and potatoes are reported. In the experiments with potatoes the effects of fertilization with sea weeds were studied, mixtures of *Fucus nodosus* and *F. vesiculosus*, *Laminaria digitata*, etc., and eelgrass (*Zostera marina*) were applied either alone, at the rate of 7,200 kilos per 10 are ($\frac{1}{4}$ acre), or in connection with nitrate of soda and superphosphate. The results did not agree with those obtained in similar trials during the preceding season, and therefore do not permit of generalization.

The report of the control work of the station contains summary statements and discussions of analyses of the usual agricultural products.—F. W. WOLL.

Report of the chemical control station and the seed control station, Christiania, Norway, 1902, S. HALS (*Aarsber. Offent. Foranstalt. Landbr. Fremme, 1902, pp. 198–248*).—The report contains the usual summary of results obtained in the examination of feeding stuffs, fertilizers, soils and soil amendments, food materials, etc. Brief accounts of analyses made in special investigations of barley, root crops, potatoes, and peat fuel are also given in the report.

The report of the seed control station during the year contains statements of analyses of 1,287 seed samples and also an account of the system of agreement with seedsmen, arranged for by the station, by which free-seed examinations may be had by all buyers of goods, the price of which exceeds 25 kroner ($6.70), with a copy of the contract made between the station and the dealers, and the rules governing the examinations of seeds.—F. W. WOLL.

Concerning the nomenclature of enzyms, E. O. VON LIPPMANN (*Ber. Deut. Chem. Gesell., 36 (1903), No. 2, pp. 331, 332*).—In view of the confusion which exists in the names of enzyms, the author proposes a system of compound names in which the first part shows the substance acted upon and the second part the principal product produced; for instance, the name of the enzym producing maltose from starch would be amylo-maltase.

Physical chemistry for physicians and biologists, E. COHEN, trans. by M. H. FISCHER (*New York: Henry Holt & Co., 1903, pp. VIII + 343, figs. 49*).—This is an authorized translation.

ZOOLOGY.

Report of the New York Zoological Society for 1903 (*Eighth Ann. Rpt. New York Zool. Soc., 1903, pp. 216, pls. 27, figs. 20*).—As in previous reports of this society, lists are given of the officers, managers, members, etc., of the society, together with a detailed report by the director, W. T. Hornaday, and special articles on the care and diseases of various animals in confinement.

Experiments were carried on for the purpose of determining whether oysters could be readily infected with typhoid bacilli. C. W. Field, who did this work, found that while typhoid bacilli were destroyed to a considerable extent by the action of fresh

sea water, oysters could, nevertheless, be infected when exposed to conditions similar to those of ordinary fattening. It is suggested, therefore, that the sale of fattened oysters should be prohibited and greater care be exercised in preventing the contamination of oysters with sewage.

W. R. Blair presents a report on the diseases of animals in the zoological park for the year. During the year deaths occurred from pneumonia, gastro-enteritis, various digestive disturbances, and intestinal parasites. The subject of cage paralysis was studied by H. Brooks. It was found from a careful examination of a number of cases of this disease that the affection differs in different cases and is due to different causes, as in similar affections in man. Most cases of cage paralysis are forms of spinal paralysis of which the etiology is not well known.

The internal parasites of wild animals received considerable study by W. R. Blair. Notes are given on the morphology, life history, and means of eradicating a number of such parasites. The volume also contains articles on lizards, birds, manatee, raccoon dog, and on the origin and relationship of the large mammals of North America.

Second report on economic zoology, F. V. THEOBALD (*London: British Mus. (Nat. Hist.), 1904, pp. X + 197, figs. 29*).—As in the previous report of the author, the insects and other animals discussed in this volume are classified according to the manner in which they affect man, animals, cultivated plants, and household materials. Notes are given on the mosquito nuisance in various parts of Great Britain with especial reference to the best means for combating these pests. Notes are also given on *Stomoxys calcitrans* and other insects affecting domestic animals.

The author discusses sheep scab, ticks on poultry, lice on geese and pigs. Numerous miscellaneous notes are also given on the insects injurious to cereals, legumes, fruits, forest trees, garden vegetables, stored grain, food materials, tapestry, etc. Mention is made of the value of pigs and poultry in destroying insects in orchards. Quite elaborate accounts are presented of cabbage-root maggot, spruce aphis, goat moth, and the insects injurious to wine corks.

Zoological record, D. SHARP (*Zool. Rec., 39 (1902), pp. XLII + 1190*).—As usual in this publication detailed lists of literature have been brought together, pertaining to the various groups of the animal kingdom, and published chiefly during the year 1902.

Index-catalogue of medical and veterinary zoology, C. W. STILES and A. HASSALL (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 39, pt. 6, pp. 437–510*).—A continuation of the author catalogue relating to medical and veterinary zoology, including names beginning with F.

Catalogue of living and fossil mammals, E. L. TROUESSART (*Catalogus Mammalium tam Viventium quam Fossilium. Quinquennale Supplementum. Berlin: R. Friedländer & Son, 1904, No. 1, pp. 288*).—This constitutes a supplement to the author's catalogue of mammals, published in 1897, and contains additional names, together with changes which have occurred since that date in the groups—Primates, Prosimiæ, Chiroptera, Insectivora, Carnivora, and Pinnipedia.

The rabbit pest in New South Wales, C. FETHERSTONHAUGH (*Jour. Dept. Agr. West Australia, 8 (1903), No. 6, pp. 555–557*).—The author briefly recounts the history of the rabbit pest in New South Wales with notes on the means which have been adopted for exterminating these animals. It is reported that satisfactory results have been obtained from the liberal use of poisoned water and poison baits.

The resistance of rats to arsenical poisoning, F. BORDAS (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 13, p. 836*).—According to the author's experiments, rats may withstand unusually large single doses of arsenic, but are especially susceptible to repeated daily small doses. In some instances rats were destroyed by small doses of arsenic before the total quantity had reached an amount equal to single doses, which were withstood without injurious effects.

Destruction of rats and mice, J. K. GOWDY (*U. S. Dept. Com. and Lab., Mo. Consular Rpts., 75 (1904), No. 284, pp. 417–419*).—A brief outline is presented of the work carried on by Roux and Chamberland in distributing cultures of pathogenic bacteria for the destruction of rats and mice. Fields in which this material was distributed were subsequently plowed up and examined with the result that the methods seemed to have proved very effective. Apparently 95 per cent of the field mice were destroyed.

Combating field mice, G. GUÉNAUX (*Bul. Agr. Algérie et Tunisie, 10 (1904), No. 4, pp. 82–84*).—A report is made concerning the results obtained in combating field mice by the use of pathogenic bacterial cultures as recommended by the Pasteur Institute of Paris. The results thus far obtained indicate that the method is exceedingly effective in destroying field mice and apparently no danger is to be feared from the infection of other animals.

A new field mouse in Japan, C. SASAKI (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1904), No. 1, pp. 51–55, pl. 1*).—The author describes as a new species under the name *Arvicola hatanedzumi*, a field mouse which he discovered and studied with reference to its habits and economic status. The nests are carefully described and notes are given on the methods by which the mouse may be captured. Good results are reported from the use of mouse typhus bacillus in destroying this pest.

The distribution of cultures of mouse typhus, K. KORNAUTH (*Ztschr. Landw. Versuchsw. Oesterr., 7 (1904), No. 3, pp. 158, 159*).—The author states that a considerably increased demand has been made for cultures of mouse typhus bacilli to be distributed in infested fields. This increased demand is apparently due to the uniformly effective results obtained by the use of the cultures.

A review of parthenogenesis, E. F. PHILLIPS (*Proc. Amer. Phil. Soc., 42 (1903), No. 174, pp. 275–345*).—A critical review is given of the literature of this subject in connection with an extensive bibliographical list. The author discusses in a historical manner the various theories which have been proposed regarding the origin of the different kinds of individuals in the colonies of bees. The evidence thus far obtained by various experimenters indicates that the theory of Dzierzon is a most plausible one. Notes are also given on other cases of parthenogenesis observed in insects, crustacea, trematodes, rotifers, spiders, and vertebrates. A brief account is also given of the causes of parthenogenesis in connection with a discussion of the determination of sex, pædogenesis and partial parthenogenesis.

A guide to the birds of New England and eastern New York, R. HOFFMANN (*Boston: Houghton, Mifflin & Co., 1904, pp. XIII+357, pls. 4, figs. 95*).—The purpose of this book is to awake an interest in the study of bird life by a description of methods of observing birds in the field with notes on their migration, nest building, and other habits. Keys are given to assist in the identification of species of birds common for various months of the year.

With the birds in Maine, OLIVE T. MILLER (*Boston: Houghton, Mifflin & Co., 1904, pp. IX+300*).—This volume contains miscellaneous notes on the habits and economic relations of a number of species of birds which occur in Maine and other eastern and middle States.

Birds of California, IRENE G. WHEELOCK (*Chicago: A. C. McClurg & Co., 1904, pp. XXVIII+578, pls. 10, figs. 77*).—In this volume the author presents a popular discussion of over 300 species of birds recognized as of common occurrence in California and adjacent islands. In connection with each species notes are given on the feeding and nesting habits of the birds. The analytical key which serves to assist in the identification of the species is based on the color and certain other characteristics of the species concerned. The identification of different species of birds is thus rendered comparatively simple. A supplementary list is also given of rare migrant birds and subspecies occasionally observed in the State.

The birds of Ohio, W. L. Dawson (*Columbus: The Wheaton Pub. Co., 1903, pp. XLVII+671, pls. 81, figs. 215*).—In this volume the author presents an elaborate account of the habits and economic relations of the 320 species of birds known to occur in Ohio. Of this number 80 species are well illustrated on colored plates and the nests and eggs of various other species are shown in half-tone illustrations. An analytical key is given for the purpose of assisting in the identification of the species of birds and in an appendix a list is presented of birds which are supposed to have occurred in Ohio, and also a migration table showing the average dates of arrival and departure for different species.

Birds observed by Wellington Field Naturalists' Club, 1903 (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 34–36*).—Statistical data are presented regarding the prevalence of a number of species of birds.

Fieldbook of wild birds and their music, F. S. Mathews (*New York: G. P. Putnam's Sons, 1904, pp. XXXV+262, pls. 53*).—The author describes in a popular manner the habits of species of birds most common in eastern United States, with special reference to their songs as a means of identifying the species.

Birds in relation to agriculture, Gunning (*Transvaal Agr. Jour., 2 (1904), No. 6, pp. 148–151, pls. 5*).—The feeding habits and economic importance of various species of eagles, kites, and owls are discussed.

What birds do for the farmer, Josephine C. Horney (*Ohio State Bd. Agr. Rpt. 1902, pp. 501–506*).—Attention is called to the economic importance of various species of birds in the destruction of injurious insects and weed seeds.

Bird problems as related to horticulture, J. S. Cook (*Trans. Illinois Hort. Soc., n. ser., 37 (1903), pp. 327–335*).—The relationship of birds to the production of fruits is briefly discussed. Notes are given on the feeding habits of certain birds and on the necessity of bird protection.

Birds, fruits, and insects, J. B. Smith (*Proc. New Jersey State Hort. Soc., 29 (1904), pp. 88–93*).—The economic relation of birds to fruit raising is briefly discussed. It is argued that no important fruit insect is controlled or even appreciably reduced in numbers by the agency of birds. The author believes, therefore, that the destruction of fruit by birds, particularly robins, brings about a loss to the fruit grower which is quite out of proportion to the advantage gained by the presence of the birds. It is recommended, therefore, that in framing bird-protection laws the proviso should be inserted that these laws should not be construed to prevent farmers and fruit growers from killing birds which actually injure or destroy fruit, berries, or other farm crops.

The economic value of our native birds, H. A. Surface (*Pennsylvania State Dept. Agr., Zool. Quart. Bul. 1 (1904), No. 4, pp. 32, pls. 4*).—The author discusses in a popular manner the feeding habits and economic relations of the various species of owls found in Pennsylvania.

The economic relations of crows, Schleh (*Arb. Deut. Landw. Gesell., 1904, No. 91, pp. 167*).—The author's observations were made on *Corvus corona*, *C. frugilegus*, and *C. cornix*. The detailed results of the examination of stomach contents of these birds are presented in a tabular form.

In all, 474 stomachs were examined, of which 93.7 per cent contained animal food and 92.2 contained plant food. The plant food consisted of various grains, legumes, garden crops, fruits, weeds, etc., while the animal food consisted of portions of mammals, birds, fish, and other vertebrates, together with insects, snails, etc. The species of insects eaten by crows are presented in a tabular form. The author concludes as a result of his study of these birds that while much damage is done by them under certain conditions, the beneficial actions of the species in question more than counterbalance their attacks upon cultivated crops.

Experiments in the acclimatization of Leiothrix lutea, H. von Berlepsch (*Abhandl. u. 48 Ber. Ver. Naturk. Kassel, 1902–3, pp. 270–284, figs. 3*).—A number of

these birds were introduced and reared in confinement with considerable success. They were then set at liberty and succeeded in establishing themselves as shown by nests which were observed by the author. Later, however, they were apparently exterminated by hunters. Further attempts at introducing them will be made.

Thirteenth annual report of the society for the protection of birds (*London, 1903, pp. 52*).—This report contains a brief account of the work of the society during the year 1903 in studying the feeding habits of birds and in encouraging the protection of birds and birds' nests.

The avicultural magazine, D. SETH-SMITH (*London: R. H. Porter, 1903, n. ser., vol. 1, pp. XX+431, pls. 32, figs. 17*).—This volume contains numerous short articles on the birds of England and other countries in freedom and captivity. The avicultural magazine is the journal of the avicultural society whose purpose is to study the habits and relations of birds. Many articles are of an economic nature and contain data on the relationship of birds to man both in rural and city districts. Notes are also given on the influence of diet on the death rate among birds.

METEOROLOGY—CLIMATOLOGY.

Meteorological summary for 1900 (*Kentucky Sta. Rpt. 1900, pp. XXXVII–XLII*).—Summaries of observations on pressure, temperature, precipitation, cloudiness, wind, thunderstorms, snow, hail, etc., are given for each month of 1900.

Meteorological observations, D. V. C. MANSO DE ZUÑIGA (*Mem. An. Estac. Enol. Haro, 1903, July, p. 47*).—A summary is given of observations at this station during the year ended June 30, 1903, on atmospheric pressure, temperature, precipitation, humidity, evaporation, sunshine, cloudiness, and wind movement.

Relations of climate to horticulture, J. W. SMITH (*Jour. Columbus Hort. Soc., 18 (1903), No. 4, pp. 143–151*).—The meteorological and phenological records kept by T. Mikesell, at Wauseon, Fulton Co., Ohio, since January, 1870, are reported and briefly discussed.

Climatic limits, J. B. REYNOLDS (*Ontario Agr. Col. and Expt. Farm Rpt., 1903, pp. 5–9*).—Reports from different parts of Ontario regarding the northerly limits of successful culture of various crops, especially peaches, grapes, pears, cherries, apples, tomatoes, and corn, are summarized and discussed.

The economic geography of Chile, J. R. SMITH (*Bul. Amer. Geogr. Soc., 36 (1904), pp. 1–21; abs. in Science, n. ser., 19 (1904), No. 490, p. 802*).—This paper contains notes on the climate of Chile in which emphasis is laid on the striking contrast between the northern desert regions and the southern cool and rainy districts lying within the latitudes of the prevailing westerly winds.

Atmospheric tides (*Abs. in Nature [London], 69 (1904), No. 1799, p. 597*).—This is a brief note on an article on this subject by W. Krebs in *Das Weltall* of December, 1903, in which an attempt is made to explain, as a result of gravitation, the atmospheric oscillation in the course of a lunar day first discovered by Mädler.

A new sunshine recorder (*Science, n. ser., 19 (1904), No. 490, pp. 801, 802*).—This is a brief description of a sunshine recorder, a more detailed account of which is given in *Symons' Meteorological Magazine* for March, 1904.

Lightning report, J. B. REYNOLDS (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 4, 5*).—A record is given of barns and trees struck and live stock killed in Ontario during 1903, with estimated value of losses. An analysis of the species of trees and animals and the kinds of buildings struck during 1901–1903 is also given. The records show the frequency of the destruction of unprotected barns, and that "such trees as spruce, elm, or maple, planted near the farmstead, are a permanent and an increasing means of protection from lightning."

WATER—SOILS.

Water softening, J. O. HANDY (*Engineer. News, 51 (1904), No. 21, pp. 500–508, figs. 7*).—This article deals quite fully with the processes and appliances for softening water for boiler, domestic, and manufacturing purposes, especial attention being given to the feasibility of softening the entire supplies of municipalities as is now done at Winnipeg, Manitoba, and other places.

Studies of color in water; Metropolitan water supply, Massachusetts, E. G. HOPSON (*Engineer. News, 51 (1904), No. 17, pp. 414–416, figs. 3*).—A study of the water from the drainage area of the Ashland reservoir of the Metropolitan Waterworks is reported, from which the conclusion is drawn that "a brook whose color is increased temporarily to a high point during and after rains, but which in general flows of a light color, shows indications of pollution from the flushing of stagnant surface pools in swampy lands, and a remedy for the temporary high color may probably be found by the construction of shallow channels to prevent the accumulation of such surface water.

"A brook that steadily maintains a high degree of color for long periods gives sure proof of the accession of leachings from peat beds, and the remedy may only be found by a system of deep drainage. . . .

"A brook whose color is generally very low excepting during or immediately after rains shows an almost entire freedom from swamp pollution, with the exception of surface washings, which are unavoidable."

Elements of water bacteriology, S. C. PRESCOTT and C. E. A. WINSLOW (*New York: John Wiley & Sons; London: Chapman & Hall, Ltd., 1904, pp. X+162, fig. 1*).—It is stated to be the purpose of this book to present the results of American investigation on the bacteriology of water in such form as to "give a correct idea of the best American practice," and to do this "with such completeness as shall render the volume of value to the expert and at the same time with such freedom from undue technicality as to make it readable for the layman."

The topics discussed in the different chapters are: The bacteria in natural waters, the quantitative bacteriological examination of water, the interpretation of the quantitative bacteriological analysis, determination of the number of organisms developing at the body temperature, the isolation of specific pathogenes from water, methods for the isolation of the colon bacillus, significance of the presence of *Bacillus coli* in water, presumptive test for *B. coli*, other intestinal bacteria, and the significance and applicability of the bacteriological examination. A list of 180 references to sources of information used in the book is given.

The bacteriological examination of water, J. C. THRESH and G. SOWDEN (*Public Health [London], 16 (1904), No. 8, pp. 459–492*).—The accuracy and value of various methods of bacteriological examination of water are discussed and results of a large number of such examinations, especially with reference to the occurrence of *Bacillus coli communis*, are reported.

The significance of bacteriological methods in sanitary water analysis, C. E. A. WINSLOW and C. P. NIBECKER (*Public Health [London], 16 (1904), No. 8, pp. 493–501*).—The subjects discussed in this paper are sanitary inspection and its limitations, the quantitative bacteriological examination of water, the isolation of intestinal bacteria, the fermentation and litmus-lactose-agar plate tests. The results of examinations by means of gelatin and litmus-lactose-agar plates and dextrose broth tubes of over 250 samples of water from apparently unpolluted sources are reported and discussed. A list of 14 references to articles relating to the subject is given.

The Michigan method for the bacteriological examination of water, V. C. VAUGHAN (*Public Health [London], 16 (1904), No. 8, pp. 502, 503*).—The method is briefly described.

The bacteriological analysis of soils, F. D. CHESTER (*Delaware Sta. Bul. 65, pp. 51–76, figs. 5*).—This is a discussion, based upon station investigations, of the

relations of bacteriological processes to soil fertility, and the conditions affecting the development of soil bacteria, with descriptions of the method of making a bacteriological analysis of soils and the results of a number of such analyses of Delaware soils.

The results reported include data relating not only to the number of bacteria in different types of soil at different depths, but also their ammonifying and acidifying efficiency, the first representing "the number of parts of ammonia produced in 10 days in a standard peptone broth medium culture, kept at 20° C., compared with the amount present in the blank inoculated medium, kept under the same conditions, and taken as unity;" the second representing "the amount of normal acid produced in a 10-day 2 per cent cane sugar broth culture compared with that present in the blank taken as unity." The principal results are summarized in the following table:

The relation of the number of bacteria in the soil to ammonifying and acidifying efficiency.

Soil.	Total number of bacteria per gram of dry soil.	Total ammonifying efficiency.	Total acidifying efficiency.
Experiment station garden:			
First analysis	3,130,000	13.75	2.22
Second analysis	1,294,000	2.48	1.81
Murray soil, Viola	250,000	2.13	.69
Killen soil, Felton	540,000	8.90	.58
Detrich soil, Chestnut Hill	4,040,000	26.68	8.57

"The above table shows that while zymotic efficiency is generally proportionate to the total number of bacteria present in a soil, it is not exactly proportionate; that is, zymotic efficiency may increase at a much greater rate than the numbers. In other words, it is not only numbers of bacteria but also kinds which determine the efficiency of a soil; or, again, a high bacterial potential is quite as important as high numbers.

"The kinds of bacteria in a soil seem to be an extremely fortuitous matter. There is a possibility that the future will develop some practical means of introducing favorable bacterial forms into the soil and thus of raising bacterial potential.

"It will then become merely a question of increasing numbers to attain the highest possible efficiencies.

"Numbers can be increased by the introduction of sufficient humus into the soil to form food for the bacteria and by stimulating their growth by active tillage.

"Deep plowing means that a thicker zone of soil will be brought under bacterial action. More frequent cultivation means better comminution, better aeration, and a better conservation of moisture. These are all necessary conditions for bacterial development."

Soil moisture investigations for the season of 1903, J. D. TINSLEY and J. J. VERNON (*New Mexico Sta. Bul. 48, pp. 15*).—This is an account of a continuation with wheat in place of corn of investigations which have been carried on at the station for a number of years (E. S. R., 15, p. 343). The principal objects in view in the experiments here reported were to study "(1) the effects of different numbers of irrigations on the yield of wheat, especially the effect of frequent irrigations from the time of heading until the crop began to ripen; (2) the relation between the number of irrigations, the amount of moisture in the soil, and the yield; (3) the distribution of the soil moisture in depth, percolation; (4) the relation between the amount of water applied and the soil moisture."

The plan of experiment and the general methods of procedure were the same as in previous investigations. The results obtained are summarized as follows:

"(1) Too much water causes growing wheat to turn yellow, retards ripening a few days, and causes a decreased yield of grain.

"(2) This (adobe) soil when kept three-fourths saturated throughout the season is too wet for wheat.

"(3) Wheat will do well up to the time of filling in a soil that would be comparatively dry for corn, and if the soil is kept quite moist at the time of filling the yield will be about as good as if this high moisture content had been maintained throughout the season.

"(4) Adjacent plats kept in nearly identical moisture condition show considerable differences in yield, and also plats which vary very much in moisture content may give nearly the same yield. This shows that other factors exert a marked influence on yield.

"(5) The most of the water applied to these plats was held in the first 3 ft. of the soil.

"(6) When this soil is fairly dry it will absorb about 5 acre-inches of water."

Soil temperatures at various depths, J. B. Reynolds (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, p. 12, fig. 1*).—A record is given of monthly soil temperatures at depths of 3 and 6 in. and 1, 2, and 3 ft. from April to December, 1903, inclusive. The daily variations are also summarized.

Investigation of the composition of soils rich in vegetable matter, E. G. De Coriolis (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 38–40, fig. 1*).—Pot experiments with such a soil shown by analysis to be deficient in available potash are reported. The results indicate that the greatest need of the soil was an improvement of the conditions necessary to the growth of nitrifying organisms.

Analyses of soils of the State, G. d'Utra (*Bol. Agr. São Paulo, 4. ser., 1903, No. 12, pp. 551–557*).—Chemical analyses of 91 samples of soils from different parts of São Paulo are reported, with suggestions as to their fertilizer requirements.

Analyses of soils, C. F. Juritz (*Rpt. Senior Analyst, Cape Good Hope, 1903, pp. 45–48*).—Chemical analyses of 24 samples of soil from different parts of the Colony are reported and discussed.

Analyses of soils from Armant, F. Hughes (*Jour. Khediv. Agr. Soc. and School Agr., 6 (1904), No. 1, pp. 13–16*).—Total and available (by Dyer's method) potash and phosphoric acid and nitrogen are reported. Only a very small proportion of the total potash and phosphoric acid were available.

Preliminary analytical studies of the cultivated soils of Padua, G. Ongaro (*Staz. Sper. Agr. Ital., 36 (1903), pp. 926–930; abs. in Chem. Centbl., 1904, I, No. 15, pp. 1098, 1099*).—Data for mechanical and chemical analyses of some of these soils are reported.

Experiments in washing salt land (*Jour. Khediv. Agr. Soc. and School Agr., 6 (1904), No. 1, p. 12*).—In a comparative test of warping, washing by means of open drains, and washing by means of tile drains, the best results in yield of cotton were obtained by the last method.

The work of the Bureau of Soils (*U. S. Dept. Agr., Bureau of Soils Circ. 13, pp. 13*).—A condensed account of the work of the Bureau with particular reference to its practical side, intended for distribution at the Louisiana Purchase Exposition.

Geology, T. C. Chamberlin and R. D. Salisbury (*New York: Henry Holt & Co., 1904, vol. 1, pp. XIX+654, pls. 24, figs. 471*).—"In the preparation of this work it has been the purpose of the authors to present an outline of the salient features of geology, as now developed, encumbered as little as possible by technicalities and details whose bearings on the general theme are unimportant. In common with most writers of text-books on geology, the authors believe that the subject is best approached by a study of the forces and processes now in operation, and of the results which these forces and processes are now bringing about. Such study necessarily involves a consideration of the principles which govern the activities of geologic agencies. These topics are presented in Volume I, and prepare the way for the study of the history of past ages, which is outlined in Volume II.

"The general plan of the work has been determined by the experience of the authors as instructors. Little emphasis is laid on the commonly recognized subdivisions of the science, such as dynamic geology, stratigraphic geology, physiographic geology, etc. The treatment proceeds rather from the point of view that the science is a unit, that its one theme is the history of the earth, and that the discussions of dynamic geology, physiographic geology, etc., apart from their historical bearing, lose much of their significance and interest. The effort has, therefore, been to emphasize the historical element, even in the discussion of special themes, such as the work of rivers, the work of snow and ice, and the origin and descent of rocks. This does not mean that phases of geology other than historical have been neglected, but it means that an effort has been made to give a historical cast to all phases of the subject, so far as the topics permit."

After a preliminary outline dealing with astronomic geology and geognosy, the topics treated in separate chapters of this first volume are the atmosphere as a geological agent, the work of running water, the work of ground (underground) water, the work of snow and ice, the work of the ocean, the origin and descent of rocks, structural (geotectonic) geology, the movements and deformations of the earth's body (diastrophism), the extrusive processes, and the geologic functions of life.

FERTILIZERS.

Essentials of plant life, T. Jamieson (*Agr. Research Assoc.* [*Scotland*] *Rpt. 1903, pp. 22–27*).—The results of experiments during 18 years on the fertilizer requirements of the leading botanical families of plants are briefly summarized. The results tend to confirm the generally accepted opinion that nitrogen, phosphorus, and potassium are essential to plant growth. They also indicate that sulphur is not essential, and "that the influence of calcium and magnesium on the actual growth of the plant is so slight, if any, that it may be disregarded in practice, especially as both soil and the ordinary manures always contain a certain proportion of these elements."

Effect of manure on exhausted soil, T. Jamieson (*Agr. Research Assoc.* [*Scotland*] *Rpt. 1903, pp. 13–21, figs. 4*).—In experiments with turnips grown on small plats higher yields were obtained with manure than with any of the mixtures of artificial fertilizers used. The use of heavy applications of artificial fertilizers apparently hastened maturity and reduced the final yield.

Gypsum as a means of preventing loss of ammonia in the decomposition of manure, S. A. Severin (*Centbl. Bakt. u. Par., 2. Abt., 11* (*1904*), *Nos. 12–13, pp. 389–396; 14–15, pp. 442–451; abs. in Chem. Ztg., 28* (*1904*), *No. 17, Repert. No. 4, p. 56*).—In experiments in which the manure was first sterilized and then inoculated with pure cultures of manure bacteria it was observed that gypsum combined with the ammonia produced and reduced the loss of nitrogen one-half, at the same time promoting slightly the oxidation of the organic matter.

The agricultural value of city sewage in India, J. W. Leather and J. Mollison (*Agr. Ledger, 1903, No. 2* (*Agr. Ser., No. 36*), *pp. 37–54*).—Modern methods of sewage purification are briefly described and experiments begun at Poonah and Manjri in 1898 to test methods of purification and to determine the value of sewage and sewage effluent as a fertilizer are reported. These experiments show in general that purified sewage has a considerable fertilizing value for sugar cane and other crops.

On the influence of different ratios of lime to magnesia on the growth of rice, K. Aso (*Bul. Col. Agr., Tokyo Imp. Univ., 6* (*1904*), *No. 2, pp. 97–102, pl. 1*).—The results of a series of pot experiments are reported which show that "(1) the lime factor for rice agrees nearly with that of other Gramineæ which is between 1

and 2; (2) the rice plant seems to possess a relatively considerable resistance power against an excess of magnesium carbonate, since this does not depress the yield so much as the same excess of lime; (3) rice culture demands special attention to the proper ratio of lime to magnesia, since the maximal yield depends to a great degree upon the ratio 1:1."

The effect of liming in connection with the application of mineral fertilizers, P. VAN BIERVLIET (*Rev. Gén. Agron.* [*Louvain*], *13* (*1904*), *No. 2, pp. 81–83*).—A brief general statement.

Stone lime v. ground lime as a fertilizer, M. SAUL (*Deut. Landw. Presse, 31* (*1904*), *No. 36, pp. 321, 322*).—A brief discussion of the relative merits of these two kinds of lime under different conditions.

The preparation of soluble phosphoric acid from crude phosphates for fertilizing purposes, A. YSTGAARD (*Teknisk Ugeblad, Christiania, 50* (*1903*), *p. 329; abs. in Chem. Ztg., 28* (*1904*), *No. 17, Repert. No. 4, p. 56*).—A method of rendering phosphates soluble by fusion with carnallit is described, and the fertilizing value of the product thus obtained is discussed. Pot experiments comparing the product with Thomas slag on oats and peas are reported. The results showed that the prepared phosphate was more effective, especially as regards seed production, than the slag. The author attributes this result to the fact that the phosphoric acid in the prepared phosphate is in the form of a magnesium salt and the use of the phosphate resulted in a more favorable relation between lime and magnesia.

Rock phosphates and other mineral fertilizers: Their origin, value, and sources of supply, C. CHEWINGS (*Adelaide, South Australia: C. E. Bristow, 1903, pp. 48, map 1*).—This pamphlet discusses sources of nitrogen and potash in fertilizers and tests for these substances as well as tests for phosphoric acid and the origin, sources, mining, and preparation and use in fertilizers of the various phosphates.

The century in phosphates and fertilizers, P. E. CHAZAL (*News and Courier* [*Charleston*], *1903, Centennial ed., pp. 62–65, figs. 4; 1904, Apr. 20, pp. 12, 13*).—An historical review.

From mine to field, E. WILLIS (*News and Courier* [*Charleston*], *1904, Apr. 20, pp. 10, 11*).—This is a review of the trade in rock phosphate and fertilizers for the year ended September 1, 1903.

Mines and quarries (*U. S. Dept. Com. and Labor, Bureau of the Census Bul. 9, pp. 59*).—This is a preliminary report for the year ended December 31, 1902. The data of special agricultural interest contained in this bulletin are statistics relating to the production and value of phosphate, gypsum, and marl. The product of the phosphate mines of the United States during 1902 is reported as 1,548,720 long tons worth $4,922,943. The production of gypsum during the same year was 816,478 short tons, worth $2,089,341; of marl, 12,439 short tons, worth $12,741.

The mining and preparation of nitrate of soda, V. SCHOULTZ (*Deut. Landw. Presse, 31* (*1904*), *No. 39, pp. 341, 342, figs. 6*).—A brief description of the methods employed in Chile.

Potash fertilizers: Sources and methods of application, H. J. PATTERSON (*Pennsylvania State Dept. Agr. Bul. 117, pp. 45*).—Substantially a reprint of Maryland Station Bulletin 89 (E. S. R., 15, p. 461).

Analyses of commercial fertilizers and Paris green, W. C. STUBBS and C. H. O'ROURKE (*Louisiana Stas. Bul. 76, 2. ser., pp. 266–359*).—This bulletin is a detailed report on the fertilizer and Paris green inspection in Louisiana during the season 1902–3. It includes also the text of the State fertilizer law as amended at the last session of the legislature.

Fertilizer inspection, C. D. WOODS and J. M. BARTLETT (*Maine Sta. Bul. 101, pp. 21–36*).—"This bulletin contains the analyses of manufacturers' samples of brands of fertilizers licensed before March 1, 1904."

Commercial fertilizers, W. W. MILLER and N. W. LORD (*Offic. Rpt. Sec. Ohio State Bd. Agr. on Com. Ferts., 1903, pp. 90*).—This is a report of analyses of 567 samples of fertilizers examined by the State chemist during the year 1903, with a list of certificates filed by manufacturers, etc., under the State law. The analyses are accompanied by explanatory notes and the text of the State fertilizer law.

Analyses of commercial fertilizers, W. FREAR (*Pennsylvania State Dept. Agr. Bul. 119, pp. 115*).—This bulletin gives the results of analyses and valuations of samples of fertilizers collected by the State Department of Agriculture from August 1 to December 31, 1903, with a statement of guaranties filed by manufacturers.

Commercial fertilizers, J. L. HILLS, C. H. JONES, and F. M. HOLLISTER (*Vermont Sta. Bul. 107, pp. 275–296*).—This bulletin gives an abstract of the State fertilizer law as amended in 1902, a schedule of trade values used in Vermont with a discussion of the valuation of fertilizers, a list of registered fertilizer firms and brands, analyses and valuations of fertilizers examined during the season, and the average composition of the principal fertilizers examined by the station during 5 years, 1899–1903.

Commercial fertilizers, J. H. STEWART and B. H. HITE (*West Virginia Sta. Bul. 91, pp. 56*).—This is an account of fertilizer inspection under State law during the first half of 1903.

FIELD CROPS.

Alfalfa in Wisconsin, R. A. MOORE (*Wisconsin Sta. Bul. 112, pp. 10, figs. 4*).—This bulletin gives directions for the culture of alfalfa, pointing out especially the manner of harvesting the crop, and presents conclusions based on the experience in growing alfalfa at the station and the data obtained from former students throughout the State.

These data favor the use of at least 20 lbs. of good seed per acre, early spring sowing, fall plowing, and growing with barley or oats as a nurse crop sowing 1 bu. per acre. It was observed that the varieties of alfalfa grown at the station showed very little difference in appearance or yielding capacity, and that in the alfalfa fields of 17 counties of the State the plants developed the root tubercles without special soil inoculation. The crop was found to cure with no greater difficulty than heavy cuttings of clover. A method of testing alfalfa seed is described.

Cañaigre, R. F. HARE (*New Mexico Sta. Bul. 49, pp. 15*).—This bulletin describes in a popular manner the culture and uses of cañaigre, points out the importance of the crop for New Mexico, and reviews experimental work with this plant at the Arizona, California, and Texas Experiment Stations. Results at the station have shown that cultivated plants with sufficient soil moisture will produce seeds which germinate readily. As fertile seed can not be purchased the plant is propagated from the roots exclusively. It was further found that the crowns of the roots should be covered with about 6 in. of soil to protect them against frost. Reference is made to a previous bulletin on the subject by the station (E. S. R., 6, p. 984).

Report of the experimentalist, C. A. ZAVITZ (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 113–151, figs. 4*).—The experiments in agronomy for 1903 are reviewed and statistics on the production of farm crops in Ontario for the season are reported. The work of former years has been previously noted (E. S. R., 15, p. 26).

Average results of 4 experiments in growing different farm crops under similar conditions show that Joanette oats led in the weight of grain produced per acre, the yield being 2,693 lbs.; Mandscheuri barley, with 2,611 lbs. per acre, ranking second, and Emmer, with 2,556 lbs., third. Of the crops under trial Alaska oats ripened first and Spring Vetch last. White Hulless barley and Alaska oats produced the weakest and Wild Goose spring wheat the stiffest straw. In cooperative experiments through-

out Ontario with a number of the same crops, Emmer led in yield with 1,968 lbs. per acre, being followed by Mandscheuri barley and Siberian oats, yielding 1,915 lbs. and 1,796 lbs. per acre, respectively.

The results with selected seed show that in the average of 7 years oats from large seed produced about 8 bu. per acre more than from medium-sized seed, and 15½ bu. more than from small seed. Large plump barley seed gave nearly 8 bu. per acre more than shrunken seed in the average yields for 6 successive years. Broken barley yielded an average of 10.6 bu. less per acre than large plump seed. Split peas and broken wheat gave very poor results. The results obtained in 1903 from experiments in the continuous selection of seed oats in progress for 11 years were as follows: Large plump seed, 76.9 bu.; light seed, 57.7 bu., and hulled seed, 72.2 bu. per acre. The crop from the large plump seed showed the heaviest weight per bushel. The hulled seed produced the largest proportion of hulled grains.

The greatest yield from different proportions of oats and barley was obtained this season from one bushel of oats and ½ bu. of barley per acre. In a second test in progress for 2 years the average results are in favor of a mixture of 1 bu. of oats, 1½ bu. of barley, and ½ bu. of emmer, the yield being 2,673 lbs. per acre. The smallest yield, 2,591 lbs., was obtained where grass peas were sown with the oats and barley. Methods of cultivation for oats and barley have been compared in duplicate for 3 years on an average clay loam soil. The largest yield of grain per acre of both crops was secured where the land was cultivated 3 in. deep and then drilled and rolled. Different treatments for the prevention of smut in oats and winter wheat were again tested, and the results were practically the same as those in previous years.

A comparison of seed wheat and seed oats from Missouri and Ontario is in progress, and the results to date show that the southern oats produced the largest yield, while the Ontario oats were best in quality. This season Dawson Golden Chaff wheat from Ontario gave slightly better results than that obtained from Missouri.

The average results obtained from sowing 2 varieties of winter wheat on different dates for 9 years indicate that the seeding should be done the last week of August or the first 10 days of September. For 6 years spring wheat, barley, oats, and peas were sown on 6 different dates, the first seeding being made as soon as the ground was in proper condition, and the others at weekly intervals afterwards. The average results were in favor of the earliest seeding with spring wheat, and of the second seeding with the other crops. It is further indicated that the order of sowing should be as follows: Wheat, barley, oats, peas. After the first week the average decrease in yield per acre for every day's delay in seeding amounted to 56 lbs. with oats, 53 lbs. with barley, 29 lbs. with spring wheat, and 23 lbs. with peas. Spelt and emmer were sown this season at weekly intervals on 8 different dates, beginning with April 2. Emmer produced more straw and a heavier grain than spelt from each of the seedings. For the first and the last dates of seeding for emmer and spelt the yields of grain were 4,297 and 3,103 lbs. and 3,499 and 658 lbs. per acre, respectively.

Sowing winter wheat at the rates of 1, 1½, and 2 bu. per acre gave average yields for 6 years of 40.2, 43.3, and 43.9 bu. per acre, respectively. Broadcasting the seed by hand gave practically the same results as drilling it in with a machine. In one test, winter wheat after field peas, used as green manure, produced an annual average of 22.1 per cent more wheat per acre than after buckwheat plowed under; and in a second test, a crop following clover stubble produced 20.7 per cent more grain per acre than a crop following timothy stubble. In a 2-years' test 160 lbs. of nitrate of soda per acre increased the yield 18.8 per cent, or 7.2 bu. The results of 7 years' work show that the heaviest grain was obtained from thoroughly matured seed.

The different species of wheat are described and their importance for Ontario briefly noted. The following table presents the results of some of the best varieties of winter wheat grown at the college:

Average results with varieties of winter wheat grown for 5 years.

Varieties.	Color of grain.	Tons of straw.	Pounds per bushel.	Bushels per acre.
Dawson Golden Chaff	White	4.2	59.7	63.5
Imperial Amber	Red	4.4	61.0	61.0
Prize taker	White	4.2	59.0	60.3
Early Genesee Giant	White	4.5	59.9	60.1
Rudy	Red	3.9	61.0	57.7
McGarvin	Red	3.9	61.1	57.7
Egyptian Amber	Red	4.6	61.8	57.5
Early Red Clawson	Red	4.1	59.4	57.4
White Golden Cross	White	4.5	58.9	57.3
Buda Pesth	Red	3.9	61.3	57.2
Michigan Amber	Red	4.6	60.2	55.4
Treadwell	White	4.0	61.0	54.2
Turkey Red	Red	3.7	61.5	53.4
Bulgarian	White	3.9	61.1	53.0

The average yield for 9 years of Polish wheat (*Triticum polonicum*) was 22.3 bu. per acre and of Wild Goose (*T. durum*) 35.1 bu. At the college the average yield of emmer for 4 years has been fully 72 bu. per acre by measure. All comparisons of emmer and spelt conducted by the author were in favor of emmer. For the last 2 years the average weight per measured bushel of emmer was about 10 lbs. greater than that of spelt. The straw of emmer was very clean, being almost free from rust.

The average yields for 5 years of Mammoth and Common winter rye were 4 tons of straw and 60.8 bu. of grain, and 4.1 tons of straw and 57.2 bu. of grain per acre, respectively. The yields of spring rye were decidedly smaller. Winter barley was found to completely winterkill in some years, but when it survived high yields of grain were obtained, the average for 7 years being 68.7 bu. per acre. The following average yields were secured in 10-year tests with varieties of 6-rowed barley: Mandscheuri, 70.9; Oderbrucker, 66 bu.; Scotch Improved, 66.2 bu.; Common Six-rowed, 65.5 bu.; Mensury, 64 bu.; and Success, 47.8 bu. per acre. For the last 5 years California Brewing, Mandscheuri, Common Six-rowed, Oderbrucker, and Scotch Improved have given the best yields. Among 2-rowed varieties of barley under comparison for 10 years, Canadian, Vermont Champion, Gold Foil Hansford, New Zealand Chevalier, and French Chevalier produced the greatest yields. In 1903, Imported No. 5591 and Hanna No. 5590 varieties, obtained through this Department, led in productiveness. Of 8 varieties of Hulless barley grown for 10 years, the following gave the highest average yields: Guy Mayle, 48.8 bu.; Black Hulless, 45.6 bu.; and Purple, 45.2 bu. per acre. Eight varieties of oats have been under test for 15 years and of these Joanette, Siberian, and Oderbrucker ranked first, yielding 88.9, 87.2, and 81.5 bu. per acre, respectively. The average results for 5 years with 25 varieties show that the best yields were secured from Siberian, Liberty, American Banner, German, Rust-Proof, and Michigan Wonder, in the order given. In 4 years' experiments in growing 9 early varieties of corn for grain production, King Phillip ranked first with a yield of 58.1 bu. per acre, and Compton Early last with a yield of 41.6 bu. per acre. California and Siberian millets and Hungarian grass are reported as good seed producers. For 3 successive years fall-sown hairy vetches produced an average of 10.8 bu. of seed per acre. The fall-sown vetches yielded a little more seed than those sown in the spring. The following varieties of beans have given the highest average yields for 7 years: White Wonder, 22.8 bu.; Pearce Improved Tree, 22.2 bu.; Medium or Navy, 21.7 bu.; Burlingame Medium, 21.6 bu.; Schofield Pea, 21.1 bu.; Day Improved Leafless, 20.8 bu., and Buckbee Electric Tree, 20.5 bu. of

seed per acre. Early Yellow soy bean has given good results as a grain producer and Medium Green as a forage crop.

The yields of different varieties of sugar beets are here reported, but the chemical analyses of the corresponding samples have been given elsewhere (see E. S. R., 15, p. 1072). Of 19 varieties grown for 4 years, 11 gave an average yield of over 20 tons per acre. In a 10-years' test with 8 varieties, Red Top, Lane Improved, and White Silesian headed the list with average yields of 19.8, 19.5, and 19.5 tons, respectively. Kleinwanzlebener gave an average yield of 18.81 tons per acre for 4 years. In 4 tests during 2 years, drills 18 and 20 in. apart produced an average of about 2 tons per acre more than drills 28 in. apart. Thinning experiments made in duplicate in 1903 with the Kleinwanzlebener variety showed that an increase in the average size of the root, together with a gradual decrease in the yield, took place as the distance between plants in the row increased from 2 to 10 in. Planting sugar beets on the level gave over a ton of beets more per acre than planting on ridged land. Four tests made in each of 5 years with selected beet seed resulted in the following average yields: Large seed balls, 22.9 tons; medium-sized seed balls, 21.9 tons; small-sized seed balls, 14.3 tons. In 2 tests made this season an average of 15.8 tons per acre was obtained from seed soaked 12 hours, as compared with 13.9 tons from unsoaked seed.

The largest yields of sound potatoes per acre in 1903 were as follows: Empire State, 336.7 bu.; Pearl of Savoy, 325.4 bu.; Seedling No. 230, 322.1 bu.; Up-to-date, 315 bu.; Salzer Earliest, 312.9 bu.; American Wonder, 312.1 bu.; White Elephant, 309.1 bu.; Dempsey Seedling, 306.3 bu.; New Main Crop, 288.8 bu., and Howe Premium, 281.7 bu. The percentage of rotten potatoes of each variety for the season is also given. Of different varieties tested for 10 successive years, Empire State, Pearl of Savoy, Rose New Invincible, Rural New Yorker No. 2, American Wonder, and White Elephant have been among the best yielders. This season the following sorts produced the largest average yields 9 weeks after planting: Acme, 233 bu.; Early Dominion, 215 bu.; Early Andes, 214 bu., and Early Ohio, 210 bu. per acre. The average yields in this test for 8 years were as follows: Stray Beauty, 107 bu.; Early Ohio, 105 bu.; Early Dominion, 101 bu.; Howe Premium, 99 bu., and Burpee Extra Early, 79 bu. The results and cost of different methods of treatment for the potato beetle, as determined by experiments, are given. Bordeaux mixture, applied in combination with Paris green, reduced the rot.

Thirty-three varieties of mangels were under test this season. Yellow Leviathan and Sutton Mammoth Long Red, yielding 43.1 and 42.4 tons per acre, respectively, headed the list in productiveness. All other varieties yielded under 40 tons per acre. Among 15 varieties tested for 6 years in succession Yellow Leviathan, Sutton Mammoth Long Red, Oblong Giant Yellow, Mammoth Golden Giant, and Steele-Briggs Giant Yellow Intermediate ranked first, the yields being 33.5, 33.2, 32.6, 32.2, and 31.8 tons, respectively. In a comparison of unsoaked seed and seed soaked 12, 24, and 36 hours, the average yield for 2 years was in favor of the seed soaked 12 hours. The average results for 5 years show that the yield of mangels decreased as the depth of planting increased from ½ to 4 in. Better yields were obtained from unbroken seed balls of mangels and sugar beets than from those broken or crushed. On a series of plats the first crops of common red clover, alsike clover, and timothy were plowed under and the land then planted to mangels. The average results of the season show that the common red clover land yielded 2.1 tons and the alsike clover land 3.6 tons per acre more than the timothy land. The average results for several years in comparing varieties of swedes, fall turnips, carrots, and parsnips, were in favor of Sutton Magnum Bonum, Red Top White Globe, Mammoth Intermediate Smooth White, and Improved Half Long, respectively, the yields being 21.5, 27.5, 31.3, and 11.8 tons per acre, in the order indicated. Planting carrot seed ½ and 1 in. deep gave the same average results for 10 different tests, while planting at greater depths reduced the yield considerably.

The following varieties of corn led in the production of silage in 1903: New Century Wonder, 29.3 tons; Cloud Early Yellow, 26.9 tons; Eureka, 26.9 tons; Pennsylvania Early Dent, 26.4 tons; Mastodon Dent, 26.3 tons; and 100 Day Bristol, 26.2 tons. The average data from different depths of planting show the greatest yield of total crop and ears from planting 2 in. deep. In 1902 and 1903 corn cultivated deeply immediately after planting and shallower as the season advanced gave a better yield than corn cultivated shallow at first and deeper latter on. The results obtained with 15 varieties of sorghum, including sugar cane, broom corn, Kafir corn, milo maize, and other varieties, are given in a table. The greatest yields of forage were obtained from the varieties of sugar cane. The yields of varieties of sunflowers, millet, rape, kale, cabbage, and other forage crops are also given.

Sixteen mixtures of grasses and clovers, each consisting of one grass and one clover, were tested 4 times with an average yield for all of 3⅓ tons of hay per acre. The average yield for the second year after the seed was sown was 4 tons, and the third year 2.7 tons. Alfalfa and tall oat grass head the list with an average yield of 4.41 tons per acre, followed by alfalfa and timothy, alfalfa and orchard, and alfalfa and tall fescue, with yields of 4, 3.84, and 3.78 tons per acre, respectively. A mixture of 8 grasses and 5 clovers in different proportions, amounting to 35 lbs. of seed per acre, and one of 5 grasses and 4 clovers, amounting to 24 lbs. per acre, have been under test for 9 years and have furnished 21 cuttings. The average yield of hay per acre for the first mixture was 4.47 tons, and for the second 5.14 tons.

Corn culture, R. J. REDDING (*Georgia Sta. Bul. 62, pp. 81–98*).—Previous work of this kind has already been noted (E. S. R., 14, p. 855). Sixteen varieties were tested but unfavorable conditions interfered with the results. Marlboro Prolific gave the best yield, and of this variety 175 ears were required to shell one bushel, while of Henry Grady, which stood second, only 115 ears were required. The average number of ears to the bushel for the best eight varieties in the test was 156 and for the remainder 137.

In comparing methods of harvesting in 1901 and 1903, it was found in each year that cutting the stalks and curing them in the shock gave the best returns. The stalks in the experiment of 1903, rated at 50 cents per 100 lbs., were worth $8.41 per acre.

Planting corn on beds and in the water furrow gave practically equal results, and applying cotton seed composted for several weeks about one week before planting showed no advantage over the use of crushed cotton seed used in the same way.

The results of a tillage experiment indicate that cultivation once a week for corn on unfertilized land is better than less frequent but more thorough working of the soil, while on well-fertilized land the more thorough tillage at longer intervals is the more advantageous.

Fertilizer tests with different applications of equal cost did not give conclusive results, but they indicated that the larger proportion of cotton-seed meal, furnishing nitrogen, is of greater benefit under the prevailing conditions than a larger proportion of acid phosphate and muriate of potash. On the fertilized plats an average of 76 per cent and on the unfertilized plats an average of 67.1 per cent of a perfect stand was obtained.

Cooperative variety tests of corn in 1902–3, T. L. LYON (*Nebraska Sta. Bul. 83, pp. 20, map 1*).—Nineteen varieties were tested by 59 farmers in various parts of the State. For the purpose of the experiments the State was divided into 6 sections corresponding in general with the variations in the natural vegetation. Not more than 12 varieties were grown in any one section. The larger varieties were grown in the eastern, the late maturing varieties in the southeastern, the early maturing sorts in the northern and western, and the smaller eared varieties in the western sections. The results of germination tests of the seed used and the yields obtained at the station and by a number of farmers in the different sections are shown in tables, and

the characters of each variety together with a brief history and statement of the source of the seed used are noted.

With the notable exception of Reid Yellow Dent, the introduced varieties did not give as good results as those grown from seed produced within the State. The late maturing varieties gave better yields than the earlier ones and the yellow varieties were in general better yielders than the white varieties. Neither the proportion of corn to cob nor the size of the ear seemed to bear any relation to the yield. Of the introduced varieties Reid Yellow Dent, Boone County White, Leaming, and Silver Mine are considered promising varieties and capable of being adapted to Nebraska conditions.

Increasing the yield of corn, A. M. SOULE and P. O. VANATTER (*Tennessee Sta. Bul. Vol. XVII, No. 2, pp. 25–48, figs. 11*).—The experiments in improving the yield of corn here described represent cooperative work between the station and the Bureau of Plant Industry of this Department. The importance of increasing the yield within the State is discussed, and directions for the improvement of varieties are given in addition to experimental results.

Of 62 varieties grown at the station only 36 of those under test for 4, 3, and 2 years are considered. The best average yields for 4 years were made by Hickory King, Champion White Pearl, Improved Leaming, White Rockdale, and Early Leaming, producing 46.87, 43.11, 42.13, 41.66, and 41.51 bu. per acre, respectively. The smallest percentage of cob, 13.09 per cent, was shown by Hickory King, and the largest, 27.07 per cent, by Large White Flint with Yellow Creole and Improved Leaming, with 27.78 per cent and 19.76 per cent, respectively, ranking next. Among the varieties grown for three years Wisconsin Early White Dent, Reid Yellow Dent, and Virginia Horsetooth, yielding on an average 43.52, 43.11, and 42.30 bu. per acre, respectively, were leaders.

The authors recommended the following varieties for different Tennessee soils: For light uplands, Hickory King, Early Leaming, Iowa Gold Mine, 100 Day Bristol, and Golden Beauty; for soils of medium fertility, Cocke Prolific, Virginia Ensilage, and Virginia Horsetooth; and for rich river bottoms, Huffman, Cocke Prolific, and Shaw Improved. In observing the influence of weather and soil it was found that Huffman on medium upland yielded 29.23 bu. per acre in 1900, 8.93 bu. in 1901, 59.48 bu. in 1902, 24.55 bu. in 1903, and an average of 30.55 bu. for the 4 years.

Culture tests were made with Hickory King and Cocke Prolific. Hills of 2 stalks each were planted at distances of 30, 36, 42, 48, 54, and 60 inches. The average results for 3 years with Hickory King were as follows: 30 in., 48.93 bu.; 36 in., 45.15 bu.; 42 in., 42.49 bu.; 48 in., 42.52 bu.; 54 in., 37.44 bu., and 60 in., 32.56 bu. The results with the other variety were similar. At 30 inches the yield was largest, but the ears were small and deformed, while at 48 in. the form of the ear and the quality of the grain was good. The following statement is based upon the results obtained: "One hundred acres of Hickory King planted at 48 in. would have yielded 500 bu. more grain than if planted at 54 in., and 1,000 bu. more grain than if planted at 60 in."

In selection experiments it was noticed that there was a variation of 7 to 19 days in the dates of ripening and from 9.8 to 14 tons in the yield of green crop and from 54.65 to 68 bu. in the yield of ears per acre with Cocke Prolific corn planted in single rows.

In fertilizer experiments, Cocke Prolific on a plat receiving 8 tons of barnyard manure per acre produced 22.10 bu. more than on the check plats. Where 25 bu. of lime per acre was applied the increase was 20.09 bu., and where a complete fertilizer consisting of 100 lbs. of nitrate of soda, 150 lbs. of acid phosphate, and 50 lbs. of muriate of potash was used the increase was 18.31 bu. For Hickory King the fertilizer applications proved of but little value, the gains over the check plats being as follows: From lime, 7.28 bu.; from barnyard manure, an average of 6.77 bu.; and from the complete application only a little over 3 bu.

The crop of corn, J. A. JEFFERY (*Michigan Sta. Spec. Bul. 22, pp. 15, figs. 2*).—This popular bulletin presents statistics on corn production, points out the value and uses of the crop, and discusses briefly methods of culture and improvement. A series of questions with reference to the production, value, uses, and culture of corn are given "to arouse in the reader a desire to answer some things for himself." The bulletin is intended for use in the study of the corn crop.

What kind of corn shall be planted for silage? J. L. HILLS (*Vermont Sta. Rpt. 1903, pp. 284–287*).—Four varieties, Sanford, Red Cob, Leaming, and a dent corn variety from Virginia were grown in 1900 and 1901 on different kinds of soil. Sanford is a relatively small flint corn, while the other varieties are of a larger type. As compared with Sanford the larger varieties produced from 50 to 70 per cent more gross weight, but an average of only 10 per cent more dry matter.

In the silo Sanford and Red Cob, the drier varieties, lost only 2 per cent in total weight, while Leaming and the Virginia Dent corn lost 20 per cent. The loss of dry matter in Sanford and Red Cob silage was slight, while in the other 2 varieties it amounted to 14 per cent. Sanford silage in a feeding test with dairy cows proved to be a better milk producer than silage from the larger varieties. Analyses of the different varieties as they were harvested and as they came from the silo show that Sanford was a little richer in protein and contained a much larger proportion of the desirable and a smaller proportion of the less desirable carbohydrates than the other varieties. It is believed that owing to the greater maturity of the Sanford its dry matter contained less potash than the dry matter of the other sorts.

Crops for the silo, A. M. SOULE and J. R. FAIN (*Tennessee Sta. Bul. Vol. XVII, No. 1, pp. 24, figs. 9*).—In the introduction the authors compare the carrying capacity of land when grazed and when producing silage crops, and note briefly the merits of different plants grown for silage, of which corn and sorghum are considered the most important. The results of experiments to determine the cost of cultivating silage crops and the cost of producing silage are reported.

Sorghum and corn and sorghum were planted in rows 2, 2½, 3, 3½ ft. apart. Corn and soy beans were grown in rows 3 and 2 ft. apart, respectively. The average cost of a ton of silage from sorghum, corn, corn and sorghum, and soy beans was $1.41, $2, $1.86, and $2.83, respectively. The yield varied considerably with the distance of planting. While the largest yield of sorghum, 19.8 tons per acre, was obtained from the closest planting, it is believed that 3-foot rows for sorghum, corn, and corn and sorghum are more desirable, when the convenience and cost of cultivation are considered. The cost of growing an acre of sorghum, corn, corn and sorghum, and soy beans for silage was $19.48, $14.92, $19.14, and $19.86, respectively.

Cocke Prolific and Virginia Ensilage corn were grown for 3 years on a total area of 40.93 acres. The largest yields were obtained from 3-foot rows. These varieties matured on an average in 108 days and produced 7.15 tons per acre at a cost of $2.21 per ton. It is estimated that in favorable seasons the cost of producing corn silage need not exceed $1.50 per ton.

During the last 4 years a total of 32.96 acres of sorghum was grown at the station and the silage obtained from the crops was produced at an average cost of $1.52 per ton. Of the varieties grown Red Head, partly because it stands up well, proved to be one of the best for silage purposes. The average rate of seeding in these tests was 7.3 lbs. per acre, and the average number of days required for the crops to mature 113. It is stated that as a first crop sorghum will yield from 12 to 20 tons per acre, while from the second crop not more than from 8 to 9 tons can be expected. The cost of silage per ton from first crops ranged from $1.15 to $1.78. The average cost from second crops was about $2.80. Red Head sorghum and Virginia Ensilage corn were grown in combination with satisfactory results.

The effects on the quality of silage, the yield, and the cost of production were all in favor of growing these crops together, as compared with corn alone. Grown in com-

bination the crops required 114 days to mature and yielded on an average 10.4 tons per acre, at a cost of \$1.85 per ton. The lowest cost per ton was \$1.41 and the highest \$2.08. In one instance the combined crop consisted of 66 per cent of corn and 34 per cent of sorghum, and in another 45 per cent of corn and 55 per cent of sorghum. It is suggested that about 12 lbs. of corn and 5 lbs. of sorghum seed be used per acre and planted in rows $2\frac{1}{2}$ or 3 ft. apart. Peas were grown with corn and sorghum for the purpose of increasing the protein content of the silage, but the quantity of the peas in the crop never exceeded 15.1 per cent, and in some instances amounted to only 5 or 6 per cent. This quantity was insufficient to materially influence the composition of the silage.

Mammoth Yellow soy beans produced an average of 7.5 tons per acre. About $\frac{1}{2}$ bu. of seed was used per acre. The crop required 138 days to mature, and the cost of the silage per ton was \$2.83. The silage was not palatable to cattle, and the authors believe that soy beans for silage should be grown with corn or sorghum rather than alone.

The use of fertilizers in connection with these experiments showed that heavy applications are not always satisfactory. The results indicated that the use of from 100 to 150 lbs. of high-grade acid phosphate and from 25 to 50 lbs. of muriate of potash will often prove profitable. Barnyard manure is considered the best fertilizer, and 5 tons of it per acre applied annually more effective than 10 to 15 tons at a time.

Notes are given on harvesting silage crops, filling the silo, and the use and value of silage.

Cotton culture, R. J. Redding (*Georgia Sta. Bul. 63, pp. 101–130*).—The experiments here described are similar to previously reported work (E. S. R., 14, p. 1060). The results of a test of 21 varieties are reported in a table. The total value of lint and seed per acre at 12 cts. per pound of lint and 70 cts. per 100 pounds of seed, amounted to \$78.17 in the case of Cook Improved, the leading variety, and in the cases of Prize, Moss's Improved and Texas Bur to \$67.24, \$66.92, and \$65.26, respectively. The values for all other varieties ranged from \$51.40 to \$64.32. Cook Improved and Texas Bur also stood among the 4 earliest varieties.

For the past 10 years a number of varieties have been grown for the purpose of comparing the relative merits of the half which were most productive each year with the remaining less-productive sorts. The results for the entire series of years shows that the average yield of lint, based on the production of seed cotton, was 34 per cent and 32 per cent for the most productive and the least productive varieties, respectively, the number of bolls to the pound, 70.4 and 76.1, the number of seeds to the pound, 4,124 and 4,179, and the average of total yield harvested to the time of the second picking, 56.3 per cent and 58 per cent. The leading varieties grown in this test are briefly noted.

This season Schley, a medium early variety, gave a better yield than either Mascot, an early sort, or a mixture of these 2 varieties; but the average results for 6 years are in favor of the mixture, which consisted of an equal number of seeds of the varieties.

As in former years a nitrogen test was conducted, using different fertilizer applications, each representing a cost of \$4.15, but with an increase in phosphoric acid and potash and a decrease in nitrogen in the series. The best returns were obtained from 250 lbs. of acid phosphate, 25 lbs. of muriate of potash, and 200 lbs. of cotton-seed meal, the value of the increase in yield at 4 cts. per pound of seed cotton amounting in this case to \$15.04. This application contained 8.98 per cent of phosphoric acid, 2.68 per cent of potash, and 3.26 per cent of nitrogen. A potash test on the same general plan as the nitrogen test just noted was conducted on two 1-acre fields. In this case the applications represented a cost of \$6.50 each per acre. The first field did not give very uniform results, but the first series, consisting of

an application of 520 lbs. of acid phosphate, 65 lbs. of muriate potash, and 195 pounds of cotton-seed meal, containing 11.33 per cent of phosphoric acid, 4.25 per cent of potash, and 1.94 per cent of nitrogen gave the best returns, the value of the increase at 4 cents per pound of seed cotton being $22.13. On the second field this application showed an increase in yield worth $24.93, while an application of 628 lbs. of acid phosphate, 13 lbs. of muriate of potash, and 235 lbs. of cotton-seed meal, containing 12.19 per cent of phosphoric acid, 0.75 per cent of potash, and 2.08 per cent of nitrogen was accompanied by an increase in yield worth $31.09. The author concludes from these results that a fertilizer for cotton should contain the 3 elements in approximately definite proportions to each other.

On fertilized plats, cotton planted on beds gave a yield of 1,407 lbs. of seed cotton per acre, as compared with 1,419 lbs. from a planting on the level. On 2 unfertilized plats the yields were 1,141 lbs. and 1,038 lbs. for planting on beds and on the level, respectively.

Bedding on the fertilizer in the usual way gave better results than applying it with the seed. The results of this test further showed that the 130 lbs. of cotton-seed meal contained in the application of 604 lbs. of fertilizer per acre did not interfere with the growth of the seed.

The bulletin contains a review of the weather conditions for this and previous seasons and suggestions on cotton culture with special reference to the use of fertilizers in that connection.

Sea Island cotton in Porto Rico, R. M. WALKER (*Porto Rico Sta. Circ. 3, pp. 4*).—This circular issued in both English and Spanish editions consists of brief notes on preparing the soil for Sea Island cotton and planting, cultivating, and harvesting the crop under Porto Rico conditions.

The potato in England, F. W. MAHIN (*U. S. Dept. Com. and Labor, Mo. Consular Rpts., 75 (1904), No. 284, pp. 432–434*).—Information is given regarding the Eldorado, Evergood, Sir John Llewellyn, and Northern Star varieties of potatoes, the first named being a recently introduced variety.

Methods and benefits of growing sugar beets, C. F. SAYLOR (*U. S. Dept. Agr., Office of the Secretary, Circ. 11, pp. 27*).—This circular is a brief popular treatise on the culture of the sugar beet. In addition to discussions of the different phases of beet culture the production of beet seed is described and the results of experiments with home-grown seed and with different fertilizer applications are reviewed. Tables are given showing the sugar content of beets from home-grown seed as determined at the Washington Experiment Station and the results of germination tests of foreign and home-grown sugar-beet seed secured in the Seed Laboratory of the Bureau of Plant Industry of this Department.

Tests of different varieties of sugar beets, R. HARCOURT (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 45–50*).—Sugar beets were grown in 1903 on a clay-loam soil in rows 21 in. apart and the plants thinned to 8 in. apart in the row. The yield and feeding value, judged from the sugar content of the various varieties, were determined and compared with the results of the 2 previous years. In general the larger growing varieties were not equal in food value to the smaller ones. Kleinwanzlebener contained 17.4 per cent of the sugar in the juice with a purity of 88.3, and of the 33 varieties tested one was equal and 7 even better than this standard variety. The results of distance experiments show practically no difference in the quality of beets grown in rows 18 or 20 in. apart at intervals of 8 in. in a row. The best distance between rows depends upon the cost of cultivation and the yield, but spacing to 18 in. is usually recommended.

The data from fertilizer tests show that barnyard manure has a tendency to force growth late in the season. Sugar content and purity were lowest on this plat. Muriate of potash applied alone increased the yield more than any other single fertilizer, the increase being almost as large as with barnyard manure. When sodium

nitrate was applied with the potash, the increase was greater, and still more so when phosphoric acid and potash were used together. The omission of potash considerably reduced the yield. The results with 2,400 lbs. of lime per acre corresponded somewhat closely with the results from potash alone.

The composition of dried pulp and dried pulp and molasses is given and the sugar-beet industry of the province is briefly reviewed.

Composition of an ancient Egyptian wheat, H. SNYDER (*Minnesota Sta. Bul. 85, pp. 211, 212, fig. 1*).—A sample of emmer 3,700 years old was examined. After the removal of the chaff it showed well formed though somewhat dry and shriveled kernels, some of which were more perfectly preserved than others and had highly polished surfaces. As a whole the kernels looked as if they had been slightly parched. This, however, may have been due to slow oxidation. The chaff contained 11.79 and the kernels 3.94 per cent of ash. The phosphoric acid content of the ash was 41.1 per cent. These values indicate, in the author's opinion, that little oxidation had taken place. The total nitrogen in the wheat was found to be 3.5 per cent, equivalent to 21.87 per cent protein. The fuel value was 4.086 calories per gram.

"From the chemical examination of this sample, it does not appear to be materially different from modern wheat of the spelts variety.

"A microscopic examination of the wheat kernels showed the presence of starch grains identical in form and structure with the starch in modern varieties of spelt."

The germinating powers of the Egyptian wheat were tested, but none of the kernels showed any indications of germ activity.

Wheat and flour, R. HARCOURT (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 41, 42*).—Samples of wheat grown in Manitoba and the Northwest Territories in 1902 were tested for their gliadin content and were compared in this respect with samples of the previous year. The samples of the year before contained from 63.3 to 67.3 per cent of the total nitrogen in the form of gliadin, as compared with 48.5 per cent for the wheat grown in 1902.

Macaroni wheat; its milling and chemical characteristics, J. H. SHEPARD (*South Dakota Sta. Bul. 82, pp. 3–34, pls. 6*).—A description of the samples of macaroni wheats analyzed in connection with these experiments is given and the method of milling the samples is discussed. The samples represented Russian and Mediterranean varieties, together with several varieties from various sources. The milling and chemical characteristics of macaroni wheat are considered, and the data obtained in the investigation are tabulated at some length. A summary of these data, which are calculated to the air-dry sample, is given in the following table:

Principal milling and chemical data for macaroni wheats.

Variety.	Number of analyses.	Mill products.			Crude protein.				Gluten in flour.		
		Bran.	Shorts.	Flour.	In whole wheat.	In bran.	In shorts.	In flour.	Wet gluten.	Dry gluten.	Water capacity of one gram gluten.

Walnak	1	13.43	4.24	1.77	7.19	31.57	13.18	53.54

The author points out that the Russian varieties have given better results than the Mediterranean wheats. Of the Russian wheats, Kubanka, Arnautka, Gharnovka, and Velvet Don are considered desirable sorts. The original imported seed of Kubanka contained 14.1 per cent of protein, and the crop grown on South Dakota soil in 1901, a favorable season, contained 18.8 per cent. In 1902, a wet season, the protein content of the crop from seed of the previous year was 13.9 per cent. The protein content varied not only with the variety but also with the physical condition of different samples of the same variety. The percentage of protein passing into the flour was largest with the Russian varieties.

A report on the range conditions of central Washington, J. S. COTTON (*Washington Sta. Bul. 60, pp. 45, figs. 18*).—After reviewing the physical features of central Washington, the author describes the range conditions of the region and enumerates, with brief notes as to their habits of growth and forage value, the different plants affording feed for stock on the winter and summer ranges. The methods of handling horses, cattle, and sheep on the ranges are discussed and suggestions for range improvement are given.

A list of the more important forage plants observed by the author, including 43 grasses, 11 rushes and sedges, 8 leguminous plants, and 8 salt sages and allied plants, is given, and the different species are briefly described. The value of cultivated forage plants for the region is also considered. The author believes that fencing and moderate grazing will greatly benefit the range, and recommends that where stock is pastured several pastures be provided, so that each season one of them may be given a chance to rest and reseed itself. It is suggested that the restoration of the native meadows would be materially benefited by sowing bunch grass seed on the thin places and by the more extensive use of the grasses and other forage plants capable of thriving under the prevailing conditions.

HORTICULTURE.

Report of the professor of horticulture, H. L. HUTT (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 88–95*).—The author outlines the work of instruction and investigation in his department during the year. Experiments were made in the cultivation and management of various fruits and cover crops. It was found that the best results were obtained when one cover crop was used alone. In cases where two or three were planted in the same orchard, one appeared to check the growth of the others. As the result of a test of 300 varieties of strawberries, the author recommends the following varieties for the whole season: Splendid, Wesley, Clyde, Warfield, Irene, Saunders.

Cook Islands horticulture, T. W. Kirk and W. A. Boucher (*New Zealand Dept. Agr. Rpt. 1903, pp. 423–434, pls. 9*).—The authors visited officially the different islands of the Cook group, and in their report give an account of the various horticultural products grown on each island and the possibilities of future commercial development.

Commercial gardening, M. A. Oshanin (*Promuishlennoe Ogorodnichestvo. Rostov: A. K. Oppel, 1904, pp. 231, figs. 159*).—Brief directions are given regarding the most successful methods of cultivating, harvesting, and marketing various garden crops, together with notes on the present extent of the industry in the region of Rostov.

Experiments in crossing sweet corn. A new variety: The Voorhees Red, B. D. Halsted and J. A. Kelsey (*New Jersey Stas. Bul. 170, pp. 22, pls. 4*).—This is an account of the development of a new variety of sweet corn by crossing Black Mexican upon Egyptian and selecting in successive years the ears showing the largest percentage of red grains.

The first cross was made in 1900, and in 1903 a very large percentage of ears came true to type. The mature grains of Black Mexican are black in color, while those of Egyptian are white. The ears of the new variety when picked green have a pink color and when mature they are red. The ears of Black Mexican are 8 rowed and of medium size, while those of Egyptian are 10 to 14 rowed and of large size. The cross obtained follows the Egyptian in size of ears and number of rows on the ear, but is perhaps a little earlier. It has the good qualities of both parents and in addition the pink color of the ears when prepared for the table. It has been named the Voorhees Red in honor of Director Voorhees of the station. A thousand packets of 25 grains each are offered for free distribution to farmers throughout the State.

Many of the details contained in the bulletin regarding the work in crossing have been previously noted (E. S. R., 14, p. 369). Supplementary to that work it was noticed that self-pollinated corn frequently produced albino plants, while such plants were never obtained from cross-pollinated corn. Illustrations are given which show the much greater vigor of cross-pollinated seedling corn as compared with the seedlings of inbred corn. The bulletin contains some historical notes concerning corn, notes on the botany and races of corn, with a list of the varieties of sweet corn in current seed catalogues.

Solanum commersonii and its rose, yellow, and violate-skinned varieties, Labergerie (*Rev. Vit., 21 (1904), No. 536, pp. 335–339, figs. 7*).—This relative of the potato was introduced into France by M. Heckel in 1901. Since then it has been under cultivation, and rose, yellow, and violet-skinned varieties have been obtained from it.

The violet-skinned variety seems to be most promising. This variety resembles the potato in appearance. The vines exceed 3.8 meters in length and are so vigorous as to suppress all other vegetation. The violet-colored flowers are paler than the primitive type, are without odor, and appear sterile. The stems produce numerous bulblets in the axils of the leaves. Some of these bulblets, without contact with the soil, attain a weight of 0.6 of a pound. The tubers are formed around the central stem in a compact mass emerging out of the soil. The flesh of the tuber is white, yellowish, and sometimes striated with violet or green. The flavor is reported as slightly aromatic. The form of the tuber is varying, but tends toward two types, round and flat. Some agglomerated forms weighed as much as 1,400 gm. Good, smooth specimens sometimes reached a weight of 800 to 900 gm. In good soil the yield in 1903 in one instance was at the rate of 103,000 kilos per hectare, while on a well-manured soil containing only a small amount of sand the yield was at the rate of 53,000 kilos per hectare.

One of the peculiarities noted in the culture of this plant was that when the stalks were replanted after the tubers had been removed new tubers formed, which, in

quality, were as good as those of the best varieties of early table potatoes. The plant appeared to be entirely resistant to disease, in spite of being in close proximity to a field of potatoes which were completely destroyed by disease.

The starch content of the tubers has been found by analyses to vary between 13.5 and 16 per cent. The flat form of tubers was found more edible and less watery than the round form. The tubers kept in perfect condition in storage. They appeared to do especially well in humid soils. In a plat receiving an abundance of irrigation water the tubers averaged about 300 gm. larger in size than in another part of the same plat not irrigated. The author notes that with the original form of the tuber planted in 1901 the flowers are very numerous and emit an odor of jessamine. The tubers, while relished by animals when cooked, were too bitter for human consumption. When 70 to 90 per cent of potatoes were destroyed by disease but 2 per cent of the *Solanum commersonii* was affected.

The onion (*Bul. Dept. Agr. Jamaica, 2 (1904), No. 3, pp. 59–72*).—Reports by many farmers are given on the success obtained in the culture of onions from seed sent out by the Jamaica Department of Agriculture.

Ginseng, H. B. Miller (*U. S. Dept. Com. and Labor, Mo. Consular Rpts., 75 (1904), No. 284, pp. 496–500*).—A summary of information regarding the preparation of ginseng for market, the value of different varieties in China, and related topics.

Symposium of progress of pomology in America, F. M. Hexamer et al. (*Proc. Amer. Pomol. Soc., 1903, pp. 49–71*).—This is composed of 7 papers which were read before the American Pomological Society at its meeting in Boston in September, 1903. The paper presented by F. M. Hexamer gives a general survey of the pomological progress in America during the past 50 years. That of W. C. Strong is devoted to the horticultural progress in New England during the same period. Progress in New York was discussed by W. C. Barry, in Ontario by W. T. Macoun, in Quebec by W. Craig, jr., in Nova Scotia by R. W. Starr, and in the Middle West by Col. G. B. Brackett.

A symposium of ideals in pomology, E. W. Wood et al. (*Proc. Amer. Pomol. Soc., 1903, pp. 106–123*).—Nineteen papers are here presented by as many different authors on such subjects as the ideal dessert pear, ideal raspberry, apple, fruit package, cluster of grapes, horticultural society, blackberry, text-book for the fruit grower, etc.

Report of special committee on revision of rules of nomenclature, W. A. Taylor et al. (*Proc. Amer. Pomol. Soc., 1903, pp. 39–43*).—This is the report of the committee appointed by the American Pomological Society to revise the rules of the society on fruit nomenclature. The code of pomological nomenclature adopted (E. S. R., 15, p. 206) is printed in full.

Report of committee on nomenclature and standards, W. A. Taylor et al. (*Proc. Nat. Nut Growers' Assoc., 1903, pp. 34–39*).—This report follows closely the code adopted by the American Pomological Society for pomological nomenclature. In addition a scale of points is given for the guidance of the association in the judging of commercial varieties of pecans.

Judging fruits by scales of points, F. A. Waugh (*Proc. Amer. Pomol. Soc., 1903, pp. 131–138*).—A paper read by the author before the American Pomological Society at its meeting in Boston in 1903. The scale of points for judging fruits established by the Massachusetts State Board of Agriculture is given, together with the score cards used in Ontario for apples, pears, and grapes, and the score cards used by the author in his class work at the Massachusetts Agricultural College for apples, peaches, and plums. The score card used by J. R. Reasoner, of Illinois, in judging strawberries is included.

Best fruits for Utah planting (*Utah State Bd. Hort. Bul. 9, pp. 18–22*).—A list is given of the varieties of apples, peaches, pears, cherries, apricots, grapes, and berries, and bush fruits best adapted for home culture and in commercial orchards.

The fruit industry of Jamaica, W. E. Smith (*Proc. Agr. Soc. Trinidad, 6 (1904), pp. 18–34, pls. 2*).—The author visited Jamaica and here reports the results of his observations on the fruit industry of that island, more particularly as related to bananas and oranges. The cost of clearing and preparing the land for bananas in that island is placed at £10 per acre, and the net profits under good management about £10 per acre. The author suggests the desirability of this industry for Trinidad, provided it can be operated upon a sufficiently large scale to induce the regular visitation of fruit vessels during the shipping season.

The fruit supply of Auckland, W. A. Boucher (*New Zealand Dept. Agr. Rpt. 1903, pp. 438–442, pls. 9*).—Some statistics are given on the importations of fruit and on the present status of the citrus and deciduous fruit industry.

Fruit buds, P. Evans (*Missouri Fruit Sta. Bul. 10, pp. 14*).—Tables are given which show the percentage of a full crop of fruit buds which set on 118 varieties of peaches, 15 varieties of plums, and 6 varieties of cherries in the fall of 1903, the percentage of buds which were alive soon after the severe weather of January 26, 1904, and the percentage of leaves on the trees November 16, 1903. In addition, tables are given showing the maximum and minimum temperatures for each day of the months from April, 1903, to January 31, 1904, with the amount of precipitation on the same dates. It is expected that from these tables information can be obtained as to the relative hardiness of different varieties of peaches and the suitability of the same with respect to this point for use in breeding purposes.

Freezing points of fruit juices, J. B. Reynolds (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 13, 14, fig. 1*).—The freezing point of the juice of apples, plums, peaches, pears, grapes, and quinces was determined by the following method:

"A test tube about 6 in. long and ½ in. in diameter was placed erect in a larger vessel and was packed about with salt and ice, approximately in the proportion of one part of salt to two of ice by weight. This produced a very active freezing mixture. A small quantity of the juice was then poured into the test tube, a thermometer was inserted, the juice constantly stirred, and the temperature watched, the tube being lifted out of the freezing mixture from time to time for this purpose and the thermometer read through the tube. The temperature continued to fall until flakes of ice had formed throughout the juice, when a stationary point was reached. At this point the temperature remained until nearly all the juice was frozen, when it again began to fall. This stationary temperature was taken as the freezing point. As a check upon the work, the stationary point was watched for as the juice melted. It was found to correspond very closely with that observed during freezing."

The average results, which are taken as representing the minimum temperature for cold storage rooms, were as follows: Apples 29.3° F., plums 29.8°, peaches 29.66°, grapes 27.86°, pears, 28.88°, quinces 29.12°.

Storing nursery stock (*Nat. Nurseryman, 12 (1904), No. 3, pp. 31, 32*).—This article is based on the information obtained by observation and from letters of inquiry sent out to representative nurserymen. From the information obtained, it appears that the majority of nurserymen, especially the larger and more progressive, are using frost-proof winter storage facilities of one kind or another for nursery stock. It is believed that nursery stock is in a better condition to thrive when dug in the fall and stored in an even temperature approximating the freezing point than when allowed to stand in the nursery subject to wide fluctuations of temperature such as occur in winter.

Breeding apples in Minnesota, W. Elliott (*Proc. Amer. Pomol. Soc., 1903, pp. 124, 125*).—An account is given of the growing by Mrs. T. E. Perkins of seedlings from Malinda apple seed. The seed was planted in 1893 and in 1903 132 trees bore fruit. From these trees 109 kinds of apples, representing early fall, early winter, and late winter sorts were exhibited at the meeting of the American Pomological Society in Boston in 1903.

The seedless apple (*Fruitman's Guide, 17 (1904), No. 428, p. 1*).—This is a letter by John F. Spencer describing the characteristics of a new seedless apple which he has originated. Relative to the nature of the fruit Mr. Spencer states that there are stamen and pollen as usual, but no flowers or blossoms. The fruit resembles a small berry in shape. "It retains this appearance until half grown, and then assumes the shape and form of the fruit. The fruit loses none of its flavor because it is seedless and coreless. There is nothing but meat to the apple, save the small navel end, which has every appearance of the navel in the orange." Mr. Spencer states that he has been working to produce this seedless apple for the past 7 years. He considers it a revolutionary acquisition to the apple industry.

Commercial orchards of south Missouri, F. HORSFALL (*Missouri Fruit Sta. Bul. 8, pp. 12, map 1*).—Lists are given of the commercial orchards in 6 counties of southern Missouri showing the acreage of apples, peaches, pears, plums, grapes, strawberries, and blackberries planted. The territory reported upon lies between Springfield and Thayer, along the line of the Frisco railroad. A sectional map is given showing the location of the different orchards visited. The most of these are within 4 miles of the railroad.

In the 6 counties noted 348 orchards were visited. In these orchards there were 1,107 acres of apples of bearing age and 1,613 acres not yet come to bearing. Of the land devoted to peaches 5,491 acres were in bearing, and 1,232 acres not yet of bearing age. About 60 per cent of all the apples planted are of the Ben Davis variety, 7 per cent of the Jonathan variety, 4 per cent of the Gano, and small quantities of Ingram, Winesap, Missouri Pippin, etc. The Elberta made up 95 per cent of the peach trees planted.

Notes are given on the soils of the region and on the cultural methods generally observed by orchardists. The most common method of planting appears to be to crop the land in corn while the orchard is young and to sow it to grass or to let weeds or sprouts take it when it is old. Poor results are obtained in this way. In the best paying orchards the land is cropped with a rotation of corn, cowpeas, and rye as long as possible and then given clean, shallow culture. This is the method practiced at the station. Notes are also given on orchard insect pests and plant diseases most commonly found.

The date palm and its utilization in the Southwestern States, W. T. SWINGLE (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 53, pp. 155, pls. 22*).—This bulletin is the first of a series in which it is proposed to present complete life-history studies of crop plants, "treating the crop from every possible standpoint and bringing together all useful information." Such a treatment is here presented on the date palm. A considerable portion of the matter contained in the bulletin has already appeared in one of the Yearbooks of this Department (E. S. R., 13, p. 248).

In addition to such cultural details as the propagation of date palms, cultivation, pollination, harvesting, packing, etc., special attention has been paid to the heat requirements of this palm, its resistance to alkali in soil and in irrigation water, and to the suitability of the soil and climate of certain portions of the Southwest for date-palm culture. This matter, together with many original analyses of date-palm soils which were secured by the author in different portions of the Sahara Desert, is presented in great detail, accompanied by many comparisons of similar analyses made by other authors. The successful culture of the date palm for fruit appears to depend upon a high temperature and dry climate. "The date palm can endure any degree of heat and any amount of dryness in the air, and is even favored by hot winds and by a rainless summer. The best sorts can mature only in regions having a very long and very hot growing season."

A study of the alkali resistance of the date palm in the Sahara Desert shows "that although this plant can grow in soils containing from 3 to 4 per cent of their weight of alkali, it does not produce fruit unless its roots reach a stratum of soil where the alkali content is below 1 per cent, and does not yield regular and abundant crops

unless there are layers in the soil with less than 0.6 per cent of alkali. The surface soil may, however, be very much more salty and may even be covered with a thick crust of alkali. It is probable that amounts of alkali below 0.5 per cent of the weight of the soil exert no appreciable injurious influence on the date palm." So far as known, the date palm is more resistant to alkali than any other crop plant.

The Colorado Desert, or Salton Basin, is believed to be peculiarly adapted to date culture as it has a hotter, drier climate even than the Algerian and Tunisian Sahara, where the famous Deglet Noor, the most highly valued variety of date palm flourishes. The soil is also more fertile and the irrigation water of better quality. The Deglet Noor is a long-season variety, and the Salton Basin would appear to be about the only place in the United States where this variety can be successfully grown on a commercial scale. Many other earlier and mid-season varieties can be successfully grown in other regions of the Southwest and suitable locations for these sorts in California, Nevada, Arizona, New Mexico, and Texas are described in detail.

It is believed that there would be considerable profit in the culture of the date palm, particularly of the better varieties, and that little competition, if any, might be expected from Mexico, since in no place in Mexico or in the world, so far as known, are the conditions so favorable for date-palm culture, particularly of the Deglet Noor variety, as in the Salton Basin.

Relative to the culture of second-class dates and the ordinary dates of commerce, the author summarizes as follows: "It is very probable that the culture of the best second-class dates, suitable for employment in confectionery and for household uses, will prove a profitable industry in the Salt River Valley, Arizona, and it is possible that the Deglet Noor variety may mature there. Even the growing of ordinary sorts such as the oriental dates, which are imported into this country in enormous quantities, may pay in some favored regions, such as the flood plain of the Colorado River in Arizona and Calfornia, where exuberantly fertile lands can be had cheaply, and where the annual overflow and seepage from the river render artificial irrigation unnecessary. Although date palms are likely to be grown first on soils too alkaline for other crops, the culture of the finer sorts promises to be a most profitable fruit industry that would warrant planting on the very best lands and the employment of the most modern horticultural methods."

The bulletin is accompanied by a notable collection of illustrations showing different phases of date culture.

Persian Gulf dates and their introduction into America, D. G. FAIRCHILD (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 54, pp. 30, pls. 4*).—An account is given of the date industry about the Persian Gulf, including soil, climate, irrigation, descriptions of a number of the better varieties in the different date-producing districts, notes on the date as food, etc. In connection with the discussion on the varieties of dates their possible value for American conditions is pointed out.

Ripening persimmons (*Florida Agr.; abs. in Queensland Agr. Jour., 14 (1904), No. 3, p. 186*).—A method which has been found successful is here given for the hastening of the ripening of persimmons. In the experiment recorded the fruit of 20 red persimmons on a tree of 40 was punctured to the center about the middle of October by the big blade of a pocketknife. Within 8 or 10 days all the punctured persimmons were ripe while the other 20 persimmons on the tree were still red and hard. The puncturing of the fruit did not affect the taste or shipping quality, as the wound made soon closed up.

French v. American prunes and cherries, A. W. TOURGÉE (*U. S. Dept. Com. and Labor, Mo. Consular Rpts., 75 (1904), No. 284, pp. 352, 353*).—The French prune and cherry industry is briefly spoken of and the manufacture of brandied cherries and maraschino cherries is described.

Tests of small fruits, J. TROOP (*Indiana Sta. Bul. 99, pp. 61–68*).—From 100 to 150 varieties of small fruits have been grown annually at the station during the past 15 years. From the data thus accumulated notes are given on a number of the

newer varieties of strawberries and tabulary matter on the ripening period and relative vigor, productiveness, size, form, quality, etc., of 27 varieties of raspberries and 14 varieties of blackberries.

Among the older varieties of strawberries Brunette is recommended for people with impaired digestion. Clyde is especially recommended where one has only a small piece of ground. Gandy is considered one of the best late varieties. Warfield is excellent for canning. The experience of the station during the past 8 years has been in favor of subsoiling for raspberries and blackberries. The author is convinced that subsoiling 15 inches deep will pay well where the subsoil is hard and compact.

The development of the seedless currant berry, A. J. PERKINS (*Jour. Agr. and Ind. South Australia, 7 (1904), No. 8, pp. 431–439, figs. 9*).—A record is given of some experimental work done to determine whether or not the seedless Zante currant forms fruit without pollination. Preliminary work showed that the pollen from Zante currants, as well as from a number of other varieties of grapes, germinated in sugar solutions. A number of illustrations are given showing the pollen grains and the different forms they assumed in germination. The size of the pollen grains was found to be not more than 3 or 4 times the size of ordinary yeast cells. The individual grains are invisible to the naked eye and can not be discerned even with the ordinary magnifying glass such as can be used out of doors.

In emasculating the Zante currants it was found that, notwithstanding the great care taken and the fact that the emasculation took place indoors instead of in the field, a few pollen grains regularly adhered to the stigma; and germination experiments showed that these pollen grains were sufficiently ripe to germinate and thus cause fertilization of the ovules. In normal fertilization of the currant it was found that the fertilized ovules increased in size for about 10 days and then finally aborted. A table is given showing the length and breadth of ovules of the Zante currant and of several other varieties of grapes at various stages of development.

From the results of the work the author concludes that the pollen of the seedless Zante germinates as freely as that of other seeded varieties; that the pollen is mature; and that it is extremely difficult, if not impossible, to avoid leaving pollen on the stigmas of vines when emasculating them 2 or 3 days prior to their expansion. It is held, therefore, that certain experiments which have been reported heretofore and in which emasculated flowers set fruits, are inconclusive as to the alleged absence of fertilization in the development of seedless fruit. Nothing in this experiment was discovered which would justify the assumption that fruit is produced in the ovule of the Zante currant without the intervention of pollen.

The condition of the coffee industry in Porto Rico, J. W. VAN LEENHOFF (*Porto Rico Sta. Circ. 2, pp. 2*).—Reasons are given for the present distressed condition of the coffee industry in Porto Rico, the primary cause of which appears to be the cyclone of 1899. It is believed that if Porto Rican coffee were better known in the United States there would be a greater demand for it.

Grape growing and raisin making in southern Utah, T. JUDD (*South. Utah Expt. Farm Bul. 1, pp. 14*).—A number of suggestions are made relative to the culture of grapes in southern Utah with reference to raisin making, and descriptions given of a number of varieties best suited for raisins. Thompson Seedless is recommended as the best grape of its class for the southern grape district of Utah. Thirty-five vines of Thompson Seedless grapes planted at the experiment station in 1900 gave an average yield of 13½ lbs. of grapes or 3½ lbs. of raisins per vine in 1903. One specially vigorous vine produced 8½ lbs. of cured rasins. Of the commercial table grapes the Black Cornichon has proved the best variety thus far tested. Forty vines planted in 1900 yielded an average of 11 lbs. of grapes each in 1903.

Suggestions are given for grafting grapes and on the use of resistant vines. The European varieties of grapes are the varieties grown. The phylloxera has not made

its appearance as yet in the vineyards of southern Utah, but as a future protection the use of resistant vines is urged.

Experiments with commercial fertilizers for grapes, E. Zacharewicz (*Prog. Agr. et Vit. (Ed. L'Est), 25 (1904), Nos. 1, pp. 17–19; 2, pp. 37–40; 3, pp. 72–76*).—The varying results secured in cooperative fertilizer experiments with vineyardists in a number of different localities are here reported in more or less detail.

On the duration and variations in grafted vines, L. Degrully (*Prog. Agr. et Vit. (Ed. L'Est), 25 (1904), No. 13, pp. 383, 384*).—A controversial article in which the author points out that the variations in characteristics of vines due to grafting are not sufficient on the whole to cause vineyardists any apprehension. The thousands of acres of French vineyards which have been reconstructed on American stocks still continue in a thriving condition and produce an abundance of wine 20, 25, and 30 years after grafting. The subject of variations brought about as a result of grafting is wholly in an experimental stage, and as yet is of scientific interest only.

Notes on the reconstruction of French vineyards by grafting, L. Daniel (*Rev. Vit., 21 (1904), Nos. 532, pp. 210–215; 534, pp. 269–275; 535, pp. 301–305*).—Contrary to the general belief, grafting has been found to change the character of the scion graft as well as of the wine produced from the fruit grown on it. The variation in vine and product is due in a large measure to change in nutrition which takes place as a result of the callusing of the grafted parts, and the consequent greater difficulty of sap circulation. By taking advantage of the changes thus brought about it is believed that it will be possible to produce by grafting new varieties which shall combine the good qualities of the French grapes with the phylloxera resistance of the American sorts. Grape growing by the use of direct producers is considered highly desirable, and scientists are urged to experiment along the line of the production of new varieties, by means of grafting, which shall be direct producers.

Report of the viticulturist, R. Bragato (*New Zealand Dept. Agr. Rpt. 1903, pp. 451–461*).—This deals largely with the results secured in tests of varieties and in the analyses of must and wine obtained from European varieties of grapes. A paper read by the author at the recent meeting of the Auckland Fruit Growers' Union on phylloxera pest in vines is included in the article.

Experiments on the coloration of lilac flowers due to forced culture, E. Laurent (*Bul. Agr. [Brussels], 19 (1903), No. 5, pp. 659–669*).—It is stated that in the winter forcing of lilacs the flowers obtained are usually white; and this is true even when varieties normally producing violet-colored flowers are forced. The author made a series of experiments to determine the cause of the production of white flowers. The results obtained are recorded in detail, but they are conflicting and no general conclusions are drawn.

Pictorial practical chrysanthemum culture, W. P. Wright (*London and New York: Cassell & Co., Ltd., 1904, pp. 128, figs. 62*).—This is a practical treatise on the culture of home and show chrysanthemums, dealing with all the different phases of the plant from propagation to final exhibition. It is the sixth of this series, and as in the earlier numbers, pictures form a prominent and valuable feature of the book.

Alabama-grown bulbs for forcing, W. J. Stewart (*Amer. Gard., 25 (1904), No. 478, p. 223*).—This is a report on the blooming of the Paper White *Narcissus grandiflorum* and *N. princeps* from bulbs grown in Alabama. It is reported that the Paper Whites which flowered were very fine and fully equal to imported stock. "There were, however, a good many 'sets' in the collection, the bulbs evidently having been grown in a clump and taken up as such and separated." It is believed that had the sets been planted out as is done in general bulb culture and grown for one season they would have made a much better showing. The results with *N. princeps* were not so satisfactory, and in the opinion of the experimenter the climate of Montgomery is too warm for the growing of bulbs of this class.

Annual flowering plants, L. C. CORBETT (*U. S. Dept. Agr., Farmers' Bul. 195, pp. 48, figs. 55*).—This bulletin contains suggestions on the uses of flowers about the dwelling, plans for school gardens, general cultural suggestions, and special directions for the culture of about 50 annual flowering plants.

FORESTRY.

Forest fires in the Adirondacks in 1903, H. M. SUTER (*U. S. Dept. Agr., Bureau of Forestry Circ. 26, pp. 15, map 1*).—During the early summer of 1903 over 600,000 acres of timber land in northern New York were burned over, with a direct total loss of $3,500,000. The burned region was thoroughly studied by agents of the Bureau of Forestry for the purpose of determining the conditions which led to these fires and their immediate causes. The general conditions were favorable for fire on account of the unprecedented drought of the season. The fires varied according to the local conditions, being merely surface fires in some places and ground or crown fires in other locations.

Some of the more important fires in this region are described in detail and notes are given on the methods which were employed in fighting them. The most effective fire fighting was done between daybreak and 9 o'clock in the morning when the fires were least aggressive. All of the usual methods of fighting fire were adopted. The fires in general appeared to break out along the lines of railroad, and it is stated that there was a lack of proper patrolling of railroad tracks, indifference on the part of section men, and failure to use spark arresters on locomotives.

Reclamation of flood-damaged lands in the Kansas River Valley by forest planting, G. L. CLOTHIER (*U. S. Dept. Agr., Bureau of Forestry Circ. 27, pp. 5, fig. 1*).—The injuries caused in the Kansas River Valley by the flood of 1903 fall under 4 heads: Sanding of the land, erosion, deposition of silt, and caving of river banks. In reclaiming lands which were covered with sand it is recommended that cottonwood trees be planted at once in order to prevent the drifting of the sand to other fertile lands. Cottonwood seedlings germinated in immense numbers during the season of 1903 on lands which were too wet for cultivation and such seedlings may be used to plant as sand binders.

On eroded lands it is recommended that willows and cottonwoods be planted or that these trees be allowed to grow in order to assist in collecting silt and building up the soil to its former level.

In the protection of river banks against caving a successful scheme has been proposed by E. Bayles. This plan consists in fastening together willow poles 18 to 20 ft. long by means of wire and allowing these poles to remain in an inclined position against the banks. They gradually become covered with soil and take root.

Attention is called to the fact that cottonwood and catalpa are rapid growing trees and may be depended upon to produce valuable crops within a comparatively short period of years.

Reforesting mountain slopes, T. P. LUKENS (*Water and Forest, 4 (1904), Extra No. 1, p. 4*).—A brief account is given of the investigations of the author in the problems of reforesting mountains in southern California. The plan pursued consists in growing the trees in nurseries to an age of about 2 years, during which time they are frequently transplanted and finally planted during the wet season so as to become thoroughly established. Where trees were transplanted in this way a large percentage grew and seemed to be in a thriving condition. Where the mountain slopes are too steep or rocky to grow trees chaparral will be grown and data obtained to compare the relative value of chaparral and forest growth as mountain covers.

A study of California forests, W. C. HODGE, Jr. (*Water and Forest, 4 (1904), Extra No. 1, pp. 3, 4*).—A brief account is given of cooperative work in the study of

California forests carried on with the Bureau of Forestry of this Department. This work was made possible through a State appropriation which became available July 1, 1903. The work thus far performed consists of mapping and describing 17,250,000 acres of forest land, together with suggestions for its proper management, studies of the problems of fire destruction and prevention, and forest extension. A plan has been provided for fire protection which has been put in operation on a small scale on a tract of land in order to test the exact cost of such protection.

Under the forest extension studies, investigations have been pursued in the reproduction of the forests in the San Gabriel, San Bernardino, and San Jacinto mountains to determine the methods of forest reproduction. In the same regions a study is being made of chaparral to determine its extent, condition, and importance as a cover. Investigations are also being made on the growth and area of planted eucalyptus, as well as on problems of forest fires.

The revenue to be expended in this investigation up to December 31, 1904, is approximately $15,000, $6,028 of which is provided by the State of California, the balance, being salaries and other expenses, paid by the Bureau of Forestry of this Department.

An outline is given of the work to be pursued during the coming season, and estimates made as to its cost.

Planted pine in Nebraska, C. A. Scott (*Forestry and Irrig., 10 (1904), No. 2, pp. 77–79, fig. 1*).—A report is given of a plantation started 13 years ago in the sand hills of western Nebraska. The plantation consisted of about one-half acre and was planted in the spring of 1891 with 3-year-old seedlings in alternate rows of jack pine (*Pinus divaricata*), and Scotch, Austrian, Norway, and western yellow pine.

The jack pine seedlings were secured from forests, and about 50 per cent of them died during the first year. Since planting the trees have received no cultivation whatever, but have been protected from fire and stock with the result that fully 90 per cent of those surviving the first season have made a comparatively good growth. The jack pine has by its growth proved adapted to the conditions of the sand hills, the dominant trees averaging 19.4 ft. in height and 3 in. in diameter breast high, with the intermediate trees about 15 ft. in height. The estimated volume of wood on the half acre was 586.2 cu. ft. Many individual specimens of the other species of pines are making thrifty growth, but are hardly to be compared with those of the jack pine.

The blue gum, J. B. Anderson (*Forestry and Irrig., 10 (1904), No. 2, pp. 65–70, figs. 3*).—A study is given of *Eucalyptus globulus* and other species of the same genus in California. The forest characteristics of blue gum are described; its value as timber pointed out, and methods of planting, cultivation, etc., enumerated. The blue gum is said to be one of the most rapid growing trees, and on average soil in California will produce 500 cu. ft. of new wood per acre each year. In addition to *E. globulus* a number of other species of less extended distribution are enumerated and briefly described.

Practical forestry for lumbermen, O. W. Price (*Forestry and Irrig., 10 (1904), No. 2, pp. 60–63*).—This is an address given before the Southern Lumbermen's annual meeting at New Orleans, in which the author gives reasons for conservative handling of timber lands and the financial results that may be expected from such treatment.

Wood pulp and wood-pulping machinery (*Queensland Agr. Jour., 14 (1904), No. 1, pp. 44–46*).—On account of frequent inquiries regarding wood pulp and its manufacture, the department of agriculture of Queensland has prepared a statement showing the various kinds of timber suited for wood pulp and describes some of the more important processes in its manufacture. According to the article there are in operation in the United States 1,115 paper and pulp mills with an annual output of 2,500,000 tons of paper, the greater portion of which is made from wood pulp.

SEEDS—WEEDS.

Alfalfa seed, E. BROWN (*U. S. Dept. Agr., Farmers' Bul. 194, pp. 13, figs. 8*).—It is stated that the quality of the alfalfa seed offered on the market during the present season is very low, and special care is urged in buying seed in order to avoid poor and adulterated samples.

The adulteration of alfalfa seed appears to be accomplished chiefly by the addition of the seed of yellow trefoil or bur clover. The bur clover is used as an adulterant of alfalfa seed under the name of Chilean lucern. Intending buyers of alfalfa seed are urged to remember that the fresh seed is light olive green in color while brown seed is almost always dead. The appearance of dodder seed is also described. This has proved to be one of the most destructive weeds in alfalfa fields. It is recommended that no adulterated or brown alfalfa seed be bought and that samples be tested before buying in large quantities.

Temperature in relation to seed germination, J. B. REYNOLDS (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 9–11, figs. 2*).—An account is given of tests of different seeds at various temperatures ranging from 45 to 95° F.

"This investigation was carried on by means of a seed germinator, consisting of an interior oven surrounded on all sides by double walls, within which water is kept. Heat applied to the base of the apparatus maintains the oven at any desired temperature, the circulation of the water distributing the heat evenly within the surrounding walls. In the oven the seed is germinated between two concave plates laid face to face. On the lower plate a square of saturated blotting paper carries the seeds to be tested, another square of damp paper is laid over the seeds, and another plate laid face down over the whole. Fifty or one hundred seeds of one kind, according to their size and to the space available, are placed on each plate."

The average results are summarized in the following table:

Temperatures of germination.

Species.	Best.	Second.	Third.	Remarks.
	° F.	° F.	° F.	
Cabbage	80	68–72	90	Vitality impaired above 80°, below 68°.
Onion	80	90	....	
Parsnip	80	90	....	Vitality destroyed at 95°.
Cauliflower	80	68–72	55–65	Vitality impaired beyond 80°.
Oats	80	68–72	55–65	Do.
Beans	90	80	68–72	Mildewed at 95°.
Peas (smooth)	80	68–72	55–65	Vitality almost destroyed at 90°.
Peas (wrinkled)	68–72	....	....	
Wheat	68–72	55–65	80	Vitality impaired at 80°.
Barley	80	90	68–72	
Corn (dent)	80	90	68–72	Some mildew at 80°.
Peas (sweet)	68–72	55–65	80	Earlier germination, but impaired vitality at 80°.
Carrot	80	90	68–72	Vitality impaired beyond 90°.
Turnip (Swede)	80–90	68–72	....	Do.
Turnip (white)	90	80	68–72	Do.
Rape	90	80	....	
Beet (common)	80	90	68–72	
Beet (sugar)	80	....	....	
Clover (red)	90	80	68–72	Vitality impaired at 95°.
Clover (alsike)	80	68–72	90	
Radish	80	68–72	....	Mildewed at 90°.
Cucumber	90	80	68–72	Vitality impaired at 95°.
Tomato	90	80	68–72	Do.
Squash	80	90	....	

The bearing of the results on the methods of cultivation of the soil best suited to maintain proper conditions of heat and moisture for germination is discussed.

Respiration experiments with dry and moist oats, OLAF QUAM (*Norsk Landmandsblad, 23 (1904), No. 5, pp. 61–64*).—It is shown that the presence of a considerable quantity of moisture in the seed oats shortens the dormant period of the seed, and that if sufficient moisture is present the oats will germinate and develop into young plants.

Comparative respiration experiments with dry and damp Ligowo oats containing, respectively, 9.16 and 18.64 per cent water, showed that the following quantities of carbonic acid were exhaled during 5-day periods by 2.8 kilos of oats: By the dry oats, 0.0248, 0.0142, and 0.0200 gm. (total, 0.0590 gm.); by the damp oats, 0.8320, 2.4527, 2.4989 gm. (total, 5.7836 gm.); i. e., nearly 98 times more than for the dry oats.

On the assumption that this loss takes place at the expense of the starch in the grain, there is a 3 per cent larger loss in the total amount of starch contained in the oats in the case of the damp than in the dry oats, if the oats be kept for about 5 months. The money value of this loss to the oat grower is apparent. The destruction of the starch is accompanied by a decomposition of the fats, and the proteids may also be attacked; hence the importance of careful drying of grain.—F. W. WOLL.

Report on the work of the Stockholm Seed Control Station for 1902–3, O. STJERNQUIST (*Red. Verks. Stockholms Läns Hushållningssäll. Frökontrollanst., 1903, pp. 13*).—Statistical data are presented relative to experiments carried out by the station concerning the weight, size, purity, germinating power, and other characteristics of various kinds of seeds submitted for examination.

Notes on certain threatening weeds, L. R. JONES and W. J. MORSE (*Vermont Sta. Rpt. 1903, pp. 169–173, figs. 3*).—Brief descriptive and economic notes on king-devil weed, creeping sow thistle, blue thistle, Russian thistle, clover dodder, and prickly lettuce.

The shrubby cinquefoil as a weed, L. R. JONES and W. J. MORSE (*Vermont Sta. Rpt. 1903, pp. 173–190, pls. 4, figs. 5*).—During recent years in certain portions of southwestern Vermont, *Potentilla fruticosa* has become exceedingly aggressive and in some instances has taken complete possession of pastures and tilled lands. The authors describe this plant and give notes on its botanical relationship, habitat, and geographical distribution. The species occurs generally throughout the northern portions of both hemispheres and extends far south into the mountainous regions of Asia and North America. It appears to thrive best on calcareous soils. The use of the plant in the manufacture of coarse stable brooms has been suggested, but the plant appears to have no other economic value.

Among the methods of prevention or destruction the authors recommend mowing, burning, plowing, grubbing and pulling, and grazing with live stock. Sheep and cattle browse upon it to some extent, but goats are much more effective in destroying it. The hope is expressed that the Angora goat may control or entirely exterminate this shrubby cinquefoil, as well as hardhack and other shrubby weeds of Vermont pastures. The pest also yields to reforestation, and for this purpose the author recommends planting white pine, yellow locust, willows, and butternuts.

Spraying for wild mustard, J. L. STONE (*New York Cornell Sta. Bul. 216, pp. 107–110*).—Experiments were instituted by the author for the purpose of testing the value of copper sulphate in the destruction of wild mustard. It was found that young plants of wild mustard are more quickly and certainly destroyed than older plants.

Among the weeds which were destroyed by copper sulphate solutions mention is made of wild mustard, wild radish, wild barley, shepherd's purse, etc. Curly dock, black bindweed, dandelion, etc., were severely injured, while wild rose, pig weed, field thistles, etc., were not affected. It was found safe to spray this solution on cereals, grasses, peas, and sugar beets, while beans, potatoes, turnips, and rape were killed or injured. In the first list of crops, therefore, wild mustard may be destroyed by spraying with copper sulphate in a 3 per cent solution, at the rate of 40 to 50 gals. per acre.

Report of the biologist, W. LOCHHEAD (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 21–32, figs. 13*).—The experiments and demonstrations conducted throughout Ontario have shown that wild mustard may be almost entirely eradicated by

spraying with copper sulphate at the rate of 9 lbs. to 45 gal. of water. One barrel of the solution is sufficient for an acre and costs about 90 cts.

The solution should be applied on a sunshiny day just as the wild mustard is coming into bloom. No serious harm is done by this application to barley, oats, or clover. Notes are also given on wild barley, rosin plant, and bracted plantain. A blight was observed on Egyptian peas and is believed to be due to *Ascochyta pisi*. A brief account is also given of raspberry cane blight and early and late blight of potatoes.

DISEASES OF PLANTS.

Preliminary treatment of seed grain as a source of vegetative energy, J. L. Jensen (*Tidsskr. Landbr. Planteavl, 10 (1904), pp. 46–63*).—The investigations of the author as to the prevention of grain smut, which led to the Ceres-powder and the hot-water methods, suggested that an increase in the vegetative energy of the seed might be brought about by an appropriate preliminary treatment of the seed, that would favor a more vigorous development of the enzyms of the germinating seed, without impairing thereby the germination of the seed through the heat or the chemicals applied.

It was recommended to use a temperature of 53 to 54° C. in the hot-water treatment for smut in oats, wheat, and rye, while for barley a softening of the grain for 2 hours in cold water and subsequent submerging in water of 50 to 51° was found necessary. By this method of preliminary treatment an increase of about 8.5 per cent of grain and a similar increase in straw was secured, as the average result of 53 trials conducted during 5 years, compared with seed not treated. At a temperature higher than 51° a diminished yield was obtained, e. g., as the average of 10 trials with grain treated at 52.5° a 3 per cent smaller yield of grain than when the seed grain was not treated.

Through the adoption of a proper method of disinfection of the seed and a longer time of treatment, viz, 4 to 5 days, an increase in the development of the ferments that transform the albuminoids during the germination is secured, which will result in a marked increase in the yields harvested. The average increase in the yields obtained by the 2 methods of smut prevention proposed by the author, followed by a 4 to 5 days of "fore-culture," during a series of years, are shown below. In these experiments 72 lots of oats and 53 of barley received the hot-water treatment and 54 oats and 45 barley were treated with the Ceres powder.

Increased yields due to treatment for smut prevention.

	Hot-water method.			Treatment with Ceres powder.	
	Oats.	Barley.		Oats.	Barley.
	P. ct.	P. ct.		P. ct.	P. ct.
1890 increase	11.2	8.1	1891–1894 increase	11.5	7.2
1891 increase	11.3	8.4	1895 increase	16.3	12.7
1892 increase	14.0	10.6	1896 increase	15.6	8.1
1893 increase	12.5	8.7	1897 increase	(8.3)	8.2
1894 increase	11.8	7.1			
Average	12.8	8.6	Average	12.9	9.0

Only about 1.25 per cent of the increase in the yield of oats and 0.25 per cent in the case of barley came from the eradication of the smut, the rest being due to the "fore-culture." In these experiments 25 per cent of the weight of the seed grain was added of steeping liquid, and this quantity was added in 6 portions in case of barley and in 3 portions in case of oats. Where the seed grain is not wet in a tank or a barrel, but on the barn floor, some of the liquid will be likely to drain off, and

it is therefore preferable to add the liquid in 6 portions also for oats under such conditions.

The author shows that the effect of preliminary treatment is restricted, and the increase in yield lessened, by a too short period of germination in the seed grain. Seed sown 1 to 4 days after the treatment by the hot-water method gave the following results, the yield from seed not treated being placed at 100: One day after treatment, oats, 106.4; barley, 107.9; 2 days after treatment, 116.1 and 111.0; 4 days after treatment, 125.7 and 113.0, for oats and barley, respectively.

The effect of only a few hours "fore-culture" of seed subjected to Ceres treatment proved to be unfavorable, the average yield obtained being 95.9 against 100 for seed not treated and 128.9 for treated seed which was sown after 4 days' "fore-culture." From the information at hand the author is of the opinion that enzyms will develop appreciably in seed grain even after a few hours' treatment, but the potassium sulphid of the Ceres liquid coating the seeds appropriates the available oxygen in the air and in the soil interstices directly after sowing, thus placing the treated seed somewhat at a disadvantage in the case of a too brief period of preliminary treatment.

Experiments with treatment of seed grain with a weak extract of malt gave an increase in the yields obtained at harvest time, in comparison with seed treated with water only, showing that the extract produced an increased vegetative energy, and indicating that the advantage observed in the "fore-culture" method comes from a formation of ferment during the progress of this culture.

The method of "fore-culture" proposed by the author consists in treating the seed grain with 25 per cent of its weight of Ceres solution, this being added in 6 portions and the grain shoveled over repeatedly once or twice a day for 4 to 5 days. By this time the germ will be just ready to break through the seed coat. With the quantity of liquid applied there is little danger that it will grow much longer, so as to render difficult the sowing by grain drill or otherwise. Studies of various phases of the "fore-culture" method, especially as regards its practical application, will be continued by the author.—F. W. WOLL.

Oat smut and its prevention, R. A. MOORE (*Wisconsin Sta. Bul. 111, pp. 10, figs. 2*).—Oat smut prevails largely throughout the State and has caused great losses, especially during the last 3 years. An inspection tour was made for the purpose of learning how extensively the formaldehyde or other treatment was employed by farmers in preventing this disease. Of the farms visited on this tour 87 treated their seed grain for smut and 245 did not. The disease is checked during wet seasons.

In treating seed the author recommends 1 pint of formalin to 36 gal. of water. This is sufficient to treat 30 bu. of oats. The oats should be left in the solution for 10 minutes. Barley smut may be prevented by a similar immersion in a solution containing 1 pint of formalin to 20 gal. of water.

Occurrence of plant diseases in Vermont in 1903, L. R. JONES and W. J. MORSE (*Vermont Sta. Rpt. 1903, pp. 153–155*).—The early part of the season of 1903 was unusually dry, and this drought was followed by copious rains and cool cloudy weather. These conditions affected the time of appearance and prevalence of fungus diseases. Apple scab was less injurious than usual. Early potato blight did little damage until about September 1. The application of insecticides and fungicides was less effective than during normal seasons. A soft rot of turnip, onion mildew, and club root of cabbage were quite injurious.

Potato diseases and their remedies, L. R. JONES and W. J. MORSE (*Vermont Sta. Rpt. 1903, pp. 155–168*).—The results obtained during 14 years' experiments with potato diseases at the station indicate that the Bordeaux-arsenical mixture is superior to any other remedy. As a rule 2 applications have been found profitable. In 1903, however, the development of potato blight was checked by one application on account of the late appearance of the disease. One application of Bordeaux-

arsenical mixture produced a gain of 124 bu. per acre. The addition of Bug Death and Paris green to the Bordeaux mixture was apparently without much effect on account of the unusually small numbers of potato beetles and other insects. Neither Paris green nor Bug Death have any value in controlling potato blight, the Bordeaux mixture alone being quite effective.

Experiments were carried on for the purpose of determining the relation between the date of digging potatoes and development of the rot. Four rows of potatoes were dug on each of 5 days, that is, August 31, September 7, 14, 21, and 28. All of the potatoes were stored under similar conditions. The results indicated that whenever there is danger of rot it is best to delay digging the potatoes for 10 or more days after the tops die.

A test of sprinkling potatoes with air-slaked lime before placing them in the cellar showed that this method is of no value in controlling the development of the rot.

In experiments with potato scab it was found that corrosive sublimate and formalin were equally efficient. The formaldehyde gas treatment, however, is recommended as preferable for this purpose. An air-tight room is required, and it is recommended that not less than one pound of formalin be used for each 1,000 cu. ft. of space.

The dry rot of potatoes due to Fusarium oxysporum, E. F. Smith and D. B. Swingle (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 55, pp. 64, pls. 8, figs. 2*).—This disease of potatoes has long been recognized in the United States and foreign countries under various names, such as bundle blackening, dry end rot, etc. The authors made a study of the morphological and biological characters of the fungus, the methods of infection, and remedial measures.

The disease commonly enters the plants through the roots and slowly spreads until the whole underground portion of the plant is infected. In infected plants the fungus is always present in the darkened fibrovascular bundles of the tubers. The symptoms of infection are a slow change of color, the checking of growth, and slight curling of the leaves, followed by wilting and falling of the stems. The fungus grows readily in a considerable variety of culture media and tolerates comparatively large amounts of malic, citric, and tartaric acids. It is checked in growth, however, by formic, acetic, and butyric acids. The fungus is aerobic and grows most vigorously at temperatures between 15 and 30° C.

Dry rot attacks potatoes from the soil, and winters over in infected plants. The use of fertilizers, even in large amounts, failed to check the development of the disease. The fungus persists in stored potatoes, whether kept in moist or dry rooms, unless a low temperature is maintained.

It is recommended that infected land be planted to other crops for a number of years, and that the possibility of the disease infecting tomatoes, eggplants, and peppers be kept in mind. Great care should be exercised in the choice of seed tubers. Some difference in the resisting power of different potato plants to disease was noted, and further investigations will be conducted to determine whether highly resistant varieties may be developed.

Spraying fruit trees, E. P. Sandsten (*Wisconsin Sta. Bul. 110, pp. 28, figs. 12*).—The author discusses in a general manner the method of preparing and applying insecticides and fungicides and presents notes on the more important insect enemies and fungus diseases of fruit trees.

Spraying grapes for black rot in Erie County, Pa., G. C. Butz (*Pennsylvania Sta. Bul. 66, pp. 16, pls. 2, map 1*).—During the season of 1902 the vineyards of the Chautauqua grape belt were greatly injured by the attack of black rot. The disease was investigated by the station and arrangements were made to supervise experiments which were carried out by vineyardists. The Concord variety is grown almost exclusively in this region. The fungicide used in these experiments was Bordeaux mixture in the 4-6-50, 4-4-50, and 3-6-50 proportions. In some cases ammoniacal solutions of copper carbonate were used for later applications.

The results obtained were very satisfactory and furnished strong evidence in favor of spraying with Bordeaux mixture to prevent black rot. In one instance a saving of 33⅓ per cent was brought about by spraying.

Dust or powder sprays, J. CRAIG (*New York Cornell Sta. Bul. 216, pp. 111–117*).—A number of experiments were carried out for the purpose of determining the relative value and effectiveness of dry fungicides. It was found that the labor and expense of applying dust sprays were less than in the case of liquid sprays, but that more applications were required. The brown rot of peach and plum is apparently not controlled by fungicides applied in the dry form. It is recommended that dust sprays be applied in the early morning, late afternoon, or in damp weather. In general, it appears that there is no sufficient reason for adopting the dry spray in place of the wet form on grounds sufficiently level to admit the manipulation of a spraying outfit.

ENTOMOLOGY.

Proceedings of the Entomological Society of Washington (*Proc. Ent. Soc. Washington, 6 (1904), No. 2, pp. 61–126, fig. 1*).—This number contains an account of the meetings of the Entomological Society of Washington from January 14 to March 10, 1904. A considerable number of entomological papers were read, some of which had an economic bearing and will be noted in this connection.

A brief synopsis of honey bees by W. H. Ashmead divides these insects into two genera, Megapis and Apis. The first genus includes only *M. dorsata* and *M. zonata*, while to the genus Apis 7 species are referred.

E. A. Schwarz describes a new coccinellid enemy of the San José scale. A new species of ladybug beetle is reported as occurring abundantly on fruit trees infested with San José scale and is efficient in controlling the scale. The species is described under the name of *Pseudoweisea suturalis.*

F. Benton discusses the specific name of the common honeybee, concluding that it should be *Apis mellifera* rather than *A. mellifica.*

Report of the entomologist, C. FRENCH (*Jour. Dept. Agr. Victoria, 2 (1903), No. 3, pp. 245–249*).—During the year under report the author carried on a number of experiments with grasshopper fungus, spraying for San José scale with lime-sulphur-salt wash, fumigation, and along other lines. Notes are also given on the inspection of orchards and nurseries and on injurious birds, of which the English starling appears to be the most important.

The cause and control of insect depredations, E. P. FELT (*Proc. Soc. Prom. Agr. Sci., 1904, pp. 73–83*).—The author discusses the biological factors which are concerned in determining the prevalence of insect pests. In discussing general methods of controlling insects reference is made to clean culture, rotation of crops, the encouragement of natural enemies of insects, and the application of various insecticide treatments.

Insects injurious to plants, F. CORBOZ (*Chron. Agr. Canton Vaud, 17 (1904), No. 9, pp. 297–307, figs. 4*).—Attention is called to the desirability of protecting insectivorous birds on account of their help in controlling various insects. Brief notes are given on the depredations of *Melolontha vulgaris*, fruit-tree bark-beetle, and other insects injurious to trees.

Insects injurious to fruits in Michigan, R. H. PETTIT (*Michigan Sta. Spec. Bul. 24, pp. 79, figs. 70*).—This bulletin is issued as the first of a series on insects affecting various classes of crops. The habits, life history, and means of combating most common species of insects which affect different fruit trees are discussed in considerable detail. The insect pests are classified according to the fruit trees which they injure most, and according to the part of the tree or fruit affected.

Injurious insects of 1903, F. L. WASHBURN (*Minnesota Sta. Bul. 84, pp. VIII + 184, pl. 1, figs. 119*).—This has already been noted as the annual report of the author as State entomologist (E. S. R., 15, p. 784).

Orchard enemies, F. Horsfall (*Missouri Fruit Sta. Bul. 9, pp. 31, figs. 17*).—Notes on the habits, life history, and means of combating flat-headed apple-tree borer; round-headed apple-tree borer; giant root borer; peach-tree borer; fruit-bark beetle, codling moth; woolly aphis; apple-tree aphis; cankerworms; fall webworm; San José scale; tent caterpillars; plum curculio, etc. Brief notes are given on the methods of preparing approved insecticides.

Injurious insects, W. Lochhead (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 32, 33, fig. 1*).—Brief notes on the habits, life history, and means of combating pear psylla, Hessian fly, and codling moth. The pear psylla was unusually injurious during the past year, and special attention is given by the author to this insect. In combating the pest the author recommends spraying with kerosene emulsion, whale-oil soap, lime-sulphur wash, or crude petroleum.

Preliminary bulletin on insects of the cacao, C. S. Banks (*Philippine Dept. Int., Bureau Govt. Lab., 1903, No. 11, pp. 58, pls. 52*).—On account of the importance of the cacao crop in the Philippine Islands the author undertook an investigation of the insect pests of this plant. The present report is a result of this study and is to be considered as of a preliminary nature.

Notes are given which are believed to be useful for the farmers in the Philippines in identifying the various pests of cacao and in applying suitable remedies for controlling them. The chief insect pests of cacao in the Philippines appear to be black ants, cicadas, white grubs belonging to the genus Anomala, various borers in the trunks, white ants, a species of psocus, plant lice, thrips, various leaf-eating caterpillars, scale insects, and mealy bugs. A number of wasps and bugs as well as parasitic insects and spiders assist in controlling the injurious species. Notes are given on the injuries to cacao caused by rats and on insects injurious to dried cacao and some of the common fungus diseases.

On a plague of grasshoppers in the Central Provinces, S. Stockman (*Agr. Ledger, 190? No. 3* (*Ent. Ser., No. 10*), *pp. 55–85*).—The author investigated the habits, life history, and means of combating the grasshoppers which are commonly injurious to rice in India. It was found that the eggs were usually laid in damp, loose soil. The incubation period for the eggs was about 41 days. Young grasshoppers were not very seriously affected by heavy rains, but were susceptible to flooding, especially on muddy soil.

The author tested the South African locust fungus without any satisfactory results. A description is given of a trawling net useful for catching young locusts, and recommendations are made regarding methods of preventing the locusts, viz, rotation of crops, burning of grass, and other methods of preventing locust injuries.

The cotton-boll weevil, L. de la Barreda (*Com. Parasit. Agr.* [*Mexico*], *Circ. 6, pp. 35*).—An account is given of the habits, life history, and depredations of this pest, based in part upon publications of this Department. Experiments were conducted by the Mexican Commission of Agricultural Parasitology for the purpose of determining successful means of combating the pest. It is recommended that attention be given to the proper rotation of crops, careful selection of seed, flooding of the lands, and destruction of cotton plants in the fall.

The Mexican cotton-boll weevil in Texas, E. D. Sanderson (*Proc. Soc. Prom. Agr. Sci., 1904, pp. 157–170, figs. 6*).—Already abstracted from another source (E. S. R., 15, p. 545).

A note on the root maggots, C. M. Weed (*Proc. Soc. Prom. Agr. Sci., 1904, pp. 142, 143*).—During the season of 1903 the attacks of root maggots upon onions, cabbage, cauliflower, etc., was of unusual severity. Observations made for the purpose of determining the cause of this outbreak indicated that wild mustard and other related species serve as trap plants for the eggs of root maggots and that the prevalence of these pests is to some extent dependent upon the prevalence of the mustard family.

Coccidæ of Ohio, J. G. SANDERS (*Ohio State Univ. Bul., 8. ser., No. 17, pp. 25–92, pls. 9*).—Descriptive biological and economic notes are presented on all species of the subfamily Diaspinæ found in Ohio. In this subfamily 6 new species are described. A list is also given of the species of Coccinæ found in the State. An analytical key is presented for convenience in identifying the genera and species.

The San José scale in Japan, S. I. KUWANA ET AL. (*Imp. Agr. Expt. Sta., Japan, 1904, pp. 33, pls. 8*).—An elaborate study was carried out by the entomologists of the Imperial Agricultural Experiment Station of Japan for the purpose of determining the origin, distribution, and means of combating San José scale.

A description is presented of the horticultural conditions of Japan with especial reference to the bearing of these conditions upon the distribution of the scale. Notes are given on the prevalence of the San José scale in the various provinces of the Japanese empire. A long list of food plants is also presented. Contrary to supposition which has been made by various writers on the San José scale, this pest is not found in high, uncultivated regions of Japan nor upon native species of wild pear or apple. It is concluded as a result of these studies that the San José scale was introduced into Japan in 1871 on infested stock shipped to Awoyama. The pest has subsequently been distributed on trees sent all over the empire.

Low and comparatively moist regions appear to be favorable to the development of the San José scale. The natural enemies mentioned by the author are *Chilocorus similis* which is said, however, to prefer *Diaspis pentagona* and also the parasitic fungus (*Sphærostilbe coccophila*). It is stated that the Japanese have thus far not used power pumps in combating this insect nor has fumigation with gas been practiced. The best results have been obtained from the use of kerosene emulsion.

Injurious effects of the round-headed apple-tree borer, W. STUART (*Vermont Sta. Rpt. 1903, pp. 204–208*).—The round-headed apple-tree borer caused considerable damage during the year. Brief notes are given on the life history and habits of this insect, and on preventive and remedial measures which have been recommended.

Directions for spraying for the codling moth, C. W. WOODWORTH (*California Sta. Bul. 155, pp. 20, figs. 4*).—Of the various methods tested by the author in controlling codling moth the only one which has given encouraging results is the application of arsenical sprays. For this purpose the best substances are Paris green, arsenite of lime, and lead arsenate. Paris green gave as good results as any other arsenical, and in localities where it is apt to injure the foliage the author recommends that lime be added in quantities 5 to 10 times as great as the Paris green.

Lead arsenate proved to be the safest of all arsenicals, but was less effective than either Paris green or arsenite of lime in the destruction of the codling moth. A mixture of Paris green, oil, and lime was tested on a small scale, with good results. This mixture was prepared by stirring 1 lb. of Paris green into a pint of crude oil; 4 or 5 lbs. of lime were then slaked and the Paris green and oil added and stirred until the lime united with the excess of oil. The material was then diluted to 150 gal.

In spraying for the codling moth in California 3 applications appear to be necessary. The first should be made at the proper time for thoroughly poisoning the inside of the calyx lobes in order to destroy larvæ which may subsequently attempt to enter the apple at that place. The author maintains that it is useless in making this application to direct the spray anywhere except against the blossoms from above. The second application should be made at the time when the eggs are laid. At this time the spray should be applied to all parts of the leaves and fruit. The third application is considered the most important, and is directed against the larvæ of the second brood.

Coleoptera of the family Cerambycidæ, C. HOULBERT and E. MONNOT (*Faune Entomologique Armoricaine; (Coléoptères). Rennes: F. Simon, 1903, pp. 96, pl. 1,*

figs. 116).—In this report the author gives an account of the species of the family Cerambycidæ found in Armorica, with notes on their distribution.

Flour beetle (Tribolium confusum) (*Jour. Bd. Agr.* [*London*], *11* (*1904*), *No. 2, pp. 109, 110*).—The habits of this beetle are briefly noted. The most effective remedy in controlling it is bisulphid of carbon, and directions are given for applying this treatment.

A natural history of the British lepidoptera, IV, J. W. Tutt (*London: Swan, Sonnenschein & Co., 1904, pp. XVII+ 535, pls. 3*).—This constitutes a continuation of the author's elaborate monographic work on the British lepidoptera, and concludes the account of the superfamily Sphingides. The various observations made by the author concerning the life history of the species considered in the volume are recorded with the usual detail. In the preface the author discusses certain problems connected with the reform of the nomenclature of lepidoptera. The volume is provided with an index and also with a general index to the four volumes already published.

Experiments in 1893, 1894, and 1896 upon the color relation between lepidopterous larvæ and their surroundings, E. B. Poulton (*Trans. Ent. Soc. London, 1903, pt. 3, pp. 311–374, pls. 3*).—The author carried on an elaborate series of experiments to determine the relation between the color of insects and their environment, especially upon *Odontopera bidentata* and *Gastropacha quercifolia*. The behavior and color changes of the larvæ through their various stages are minutely described. It was found that the effect of dark surroundings upon the early stages was very marked. The influence of a dark environment even for one molting stage was manifested in a decided change of color.

The economic status of the Fulgoridæ, H. Osborn (*Proc. Soc. Prom. Agr. Sci., 1904, pp. 32–36*).—Data are presented on the feeding habits and economic importance of these insects. It appears that thus far little work has been done along this line. Especial reference is made to the injurious attacks of *Liburnia campestris*, *L. lutulenta*, and cane leaf-hopper in Hawaii.

Notes on the nests of bees of the genus Trigona, C. O. Waterhouse (*Trans. Ent. Soc. London, 1903, pt. 1, pp. 133–136, pl. 1, figs. 3*).—The method of the construction of nests by this genus of bees is described in detail with notes on the differences observed in the nests of different species.

The suppression and control of the buffalo gnats in the valley of the lower Mississippi River, F. M. Webster (*Proc. Soc. Prom. Agr. Sci., 1904, pp. 53–72, figs. 7*).—Previously noted from another source (E. S. R., 15, p. 545).

A new method of combating Atta sexdens and other ants injurious to cultivated plants, A. Hempel (*Bol. Agr. São Paulo, 5. ser., 1904, No. 2, pp. 72–74*).—Brief directions are given regarding the use of parasitic fungi in the control of injurious ants and other insect pests.

The spinning habits of the North American Attaci, F. M. Webster (*Canad. Ent., 36* (*1904*), *No. 5, pp. 133, 134*).—During the past 25 years the author has observed the position of the cocoons of *Samia cecropia* and related species. The downy woodpecker destroys the insects by puncturing the cocoons and feeding upon the contents. Some species of insects belonging to the group under discussion have apparently changed the location of the cocoons so that they are not so conspicuous, and thus avoid destruction by birds.

The nutrition of the bee moth, N. Sieber and S. Metalnikow (*Arch. Physiol.* [*Pflüger*], *102* (*1904*), *No. 5–6, pp. 269–286*).—The feeding habits of the bee moth were studied for the purpose of determining the actual materials eaten by this insect, and their relative nutritive importance. It was found during this study that beeswax must be considered as an important and necessary part of the diet of bee moth in order that this insect may thrive and multiply. Extracts were made from the digestive tract of the insect for the purpose of gaining more exact data concerning the digestive ferments in this pest.

Some observations on Antheræa yamamai and the methods of its rearing in Japan, C. Sasaki (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1904), No. 1, pp. 43–50, pls. 2*).—Detailed notes are given on the habits, life history, and distribution of this moth. It appears that the artificial rearing of the insect is practiced only by the inhabitants of the village Ariakemura. The food plants of this moth are different species of oak.

A contribution to the life history of Orina tristis, T. A. Chapman (*Trans. Ent. Soc. London, 1903, pt. 3, pp. 245–261, pls. 2*).—A detailed account is given of the structure of the egg of this species with especial reference to a hatching of the larva. The habits of the adult insects are also described.

New observations on phthiriosis of grapes, L. Mangin and P. Viala (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 8, pp. 529–531*).—A continuation of the work already carried on by the authors with regard to the cause and nature of this disease indicates that the trouble is due to the attack of *Dactylopius vitis* which lives in symbiosis with the fungus *Bornetina corium.*

On the wax-producing coccid Ericerus pela, C. Sasaki (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1904), No. 1, pp. 1–14, pls. 2*).—The literature relating to the production of wax by scale insects is critically discussed. Notes are given on the habits of *E. pela* with special reference to its wax-producing powers. The insect is considered to be a native of China and Japan. The food plants differ in the two countries. In Japan *Fraxinus pubinervis* is mentioned as one of the chief food plants of this scale insect. *F. chinensis* is an important food plant in China.

Note on the habits of Chironomus sordidellus, T. H. Taylor (*Trans. Ent. Soc. London, 1903, pt. 4, pp. 521–523, figs. 2*).—The habits of these aquatic larvæ are carefully described. In some cases it was observed that after pupation the six-legged larva of a water mite was found attached to the body of Chironomus. The parasite, however, appeared to have little injurious effect upon the host.

An experimental study of hydrocyanic-acid gas as an insecticide, F. López (*Bol. Sec. Fomento [Mexico], 3 (1904), No. 11, IV–VI, pp. 203–215*).—This gas was used in hospitals for the destruction of fleas, flies, mosquitoes, bedbugs, and other insects. The toxic effect of the gas for such purposes is found to be very great and satisfactory results were obtained in all experiments.

Lime-salt-sulphur wash (*Proc. New Jersey State Hort. Soc., 29 (1904), pp. 61–76, 249–251*).—The methods of preparing this wash and of applying it together with details regarding the effects of the wash upon various scale insects and upon the trees were discussed by J. B. Smith, W. G. Johnson, and others.

Spray calendar (*New York Cornell Sta. Bul. 217, pp. 125–133, fig. 1*).—In this calendar the most important points regarding sprays have been arranged for the convenience of reference and use by fruit growers. A number of fruits and garden vegetables are arranged in alphabetical order, the more important insect enemies and fungus diseases are noted under each crop with recommendations of the most effective remedial treatment.

Insecticides, R. Harcourt (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 43–45*).—Numerous samples of Paris green were analyzed for the purpose of determining the purity of the product and the relative insolubility of the arsenious acid. Considerable percentage of the samples was found to be adulterated. Analyses are also given of Black Death, potato bug finish, kno bug, slug shot, and Bug Death.

The common mosquitoes of New Jersey, J. B. Smith (*New Jersey Stas. Bul. 171, pp. 40, pls. 11, figs. 6*).—A detailed account is given of the habits, life history, and anatomical characters of the various species of mosquitoes found in New Jersey.

According to the author's investigations of this subject, 33 species of mosquitoes occur in the State. Attention is called to the economic aspects of the mosquito question, especially in regard to the agency of these insects in carrying malaria.

In combating mosquitoes the best results have been obtained from the use of hydrocyanic-acid gas, formalin, sulphur fumes, tobacco fumes, and pyrethrum in houses. Hydrocyanic-acid gas and formalin are preferable, since they are very effective and do not injure fabrics or other materials in houses.

Attention is called to the importance of draining salt marshes and other stagnant pools of water, as well as the use of kerosene films used in combating mosquitoes. A table is presented for the purpose of the identification of mosquitoes in New Jersey.

Apiculture, E. BERTRAND (*Conduite du rucher. Geneva: R. Burkhardt, 1904, 9. ed., pp. 288, pls. 3, figs. 82*).—In this edition the author presents in a revised and corrected form a general account of the subject of apiculture, including the details of management of bees, location of apiaries, marketing honey, etc.

Report of the lecturer on apiculture, H. R. ROWSOME (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 159, 160, figs. 2*).—Experiments were carried on for the purpose of determining the most successful method of storing honey for granulation. For this purpose a tank was constructed of wood held together by clamps. The outside of the tank was painted to prevent shrinking, and the inside was covered with paraffin. After the honey had granulated the sides were removed, when it was found that the whole mass, weighing one ton, was left in a solid cake. Notes are also given on various methods of hiving bees and other details of management.

Korean race of silkworms, C. SASAKI (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1904), No. 1, pp. 21–26, pl. 1*).—In studying this race of silkworms the author observed that the fourth larval molt is omitted. The author believes that valuable races of silkworms may be obtained by improving certain promising varieties of the Korean race.

The beggar race of silkworms, C. SASAKI (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1904), No. 1, pp. 27–31, figs. 4*).—While this race appears to feed greedily upon withered or otherwise spoiled, as well as fresh, mulberry leaves, the larvæ remain as vigorous as those of other races. Notes are given on the quality of raw silk produced by this race.

Double cocoon race of silkworms, C. SASAKI (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1904), No. 1, pp. 33–35, figs. 8*).—The author has observed two varieties of this race, both of which spin yellowish cocoons. It is a vigorous race and easily reared by the native Japanese. The cocoons are almost all double, very large, and variable in shape. They usually inclose more than 2 chrysalids and sometimes as many as 8.

On the feeding of silkworms with the leaves of Cudrania triloba, C. SASAKI (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1904), No. 1, pp. 15–19, pls. 2*).—Experiments have been carried on for a number of years, during which silkworms, especially the race known as *Awobiki*, were fed on the leaves of *C. triloba*. Detailed notes are given on the appearance of the insect during its various stages when fed on these leaves.

The results obtained from the author's investigations indicate that silkworms fed on this food pass through only four larval stages instead of five, but that the total larval period is about the same as when other materials are used for food. It was noted that if silkworms were fed exclusively on the leaves of *C. triloba* they appeared to be immune to the attacks of parasitic insects. The quality and quantity of filaments reeled from cocoons were good.

On the feeding of silkworms with the leaves of wild and cultivated mulberry trees, C. SASAKI (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1904), No. 1, pp. 37–41*).—As a result of a number of experiments in feeding silkworms the author concludes that silkworms require the same time for their growth, whether they are fed on wild or cultivated mulberry leaves. Those fed on the wild leaves are larger at each stage of growth than those fed on cultivated leaves. The weight and length of silkworms fed on wild leaves are greater than those fed on cultivated leaves. The

number of silkworms infested with the larvæ of *Ugimyia sericariæ* is larger when wild mulberry leaves are used as a food. The length of the filament and the quality of the silk are superior when the wild leaves are used.

FOODS—NUTRITION.

Glutenous and starchy wheats, H. SNYDER (*Minnesota Sta. Bul. 85, pp. 179–188, fig. 1*).—The characteristics of wheat kernels were studied with the object of determining the relation between the protein content and physical conditions. As regards light and heavy seeds, "there was a decided tendency for the light-weight seeds to contain the larger percentage of nitrogen, but because of the greater weight of the heavier seeds a much larger amount of total nitrogen was always found in a given number of them than in the same number of light-weight seeds.

"In the light and heavy weight seeds selected from 6 samples of wheat it was found that the light-weight seeds contained 16.17 per cent protein, while the heavy-weight starchy seeds contained 13.69 per cent, and the heavy-weight glutenous seeds 15.56 per cent.

"From these and other analyses it would appear that the light-weight and shrunken kernels are deficient in starch, but comparatively rich in total protein. Such seeds are known to produce a lower yield of flour and, not being well filled and perfect although nitrogenous in character, are not suitable either for the production of the best quality of flour or for selection for seed purposes."

When the nitrogen content of large and small but otherwise perfect kernels selected from the same samples of wheat was determined, it was found that the former contained on an average 13.50 per cent nitrogen and the latter 12.35 per cent.

The nitrogen content in relation to color was studied with 50 samples of hard and soft wheat gathered from a variety of sources, light and dark colored kernels being selected from each sample. The average protein content of the light-colored kernels was 12.68 per cent and of the dark-colored kernels 15.33 per cent. This question was further studied with samples of wheat grown "under the best conditions" from uniform seed sent out by the station. When the 2 sorts of seed, light and dark, were selected from the same lot of wheat the dark-colored seeds from all the samples analyzed were found to be richer in protein.

"Occasionally a sample of wheat is found which is so uniform in character that it is not possible to select from it 2 kinds of seeds, viz, light and dark ones. In the course of this examination one such sample was found. . . .

"The fact that the light-colored seeds are more starchy in character, while the amber ones are more glutenous, is valuable in the selection of seed wheat. In case it is desired to select seed which is glutenous, preference should be given to the medium-sized, heavy-weight, and dark-colored flinty kernels, as they contain a larger percentage of nitrogen than the lighter-colored kernels. The hand picking of glutenous kernels is possible in selecting seed for a small area. It is believed that such hand-selected seed would ultimately result in the production of wheat of high gluten content. . . .

"For human food purposes wheats with 18 per cent of protein mainly in the endosperm or floury portion are preferable to those of low protein content. Flours of high protein content require less reinforcement with expensive nitrogenous foods."

Composition and bread-making value of flour produced by the roller process of milling, H. SNYDER (*Minnesota Sta. Bul. 85, pp. 189–202, figs. 7*).—The composition and bread-making qualities were studied of different grades of flour and

milling products ground from the same lot of No. 1 Northern wheat of good quality, weighing 58 lbs. to the bushel. The chemical composition of the samples follows:

Composition of flour and milling products ground from the same lot of wheat.

Name of sample.	Water.	Protein (N×6.25).	Gliadin number.	Carbohydrates and fat.	Acidity.	Ash.
	Per cent.	*Per cent.*		*Per cent.*	*Per cent.*	*Per cent.*
90 per cent patent	10.89	13.38	60.75	75.25	0.09	0.48
Clear grade	10.53	14.19	54.63	74.43	.13	.85
First break	11.68	13.56	60.83	74.15	.09	.61
Second break	11.10	15.00	59.17	73.38	.09	.52
Third break	10.97	16.50	59.09	72.04	.10	.49

Shorts duster	9.36	15.19	39.51	73.84	.18	1.61
Shorts middlings	9.79	17.47	....	....	....	4.03
Wheat	13.07	14.25	....	....	....	1.82

As shown by technical and baking tests the dry gluten ranged from 12.60 per cent with the first germ to 20.35 per cent with the fourth break. The greatest expansive power of the gluten was found with the second middlings and the lowest with the first middlings.

The largest-sized loaf from a given quantity of flour was obtained with the 90 per cent patent and the smallest loaf with the shorts duster. "The fifth middlings flour produced the best quality of bread, both in texture and color. The second break flour produced the best bread of the break flours. Flours from the shorts duster and tailings produced poorer breads than did the middlings or break flours. . . . [In general it may be said] that the best quality of bread was produced from the middlings flour and that the largest-sized loaves were not made from the flours containing the largest amounts of gluten or protein. The quality of the gluten and the absence of impurities in the flour, as dust and débris particles, influenced the character and size of the loaf more than other factors."

The chemical composition of the whole wheat used in the above test and the wheat offals is shown in the following table:

Composition of wheat and the offals obtained from it.

	Water.	Protein.	Ether extract.	Nitrogen-free extract.	Crude fiber.	Ash.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*

The relative protein content of wheat and flour, H. SNYDER (*Minnesota Sta. Bul. 85, pp. 203–210*).—The relation between the protein content of wheat and the standard grades of flour and also the relation between the gliadin content of flour and the size of the loaf and commercial value of bread were studied. Composite sam-

ples of wheat and the principal flour products were selected for a period of a month on alternate days, from 3 large mills and analyzed, the wheat ground in every case being hard spring wheat. In general it may be said that the clear-grade flour "contained more protein than the original wheat. It has frequently been asserted that the bran and other offals contain the larger proportion of the proteid matter of the wheat kernel. These analyses of the wheat and of the flour milled from the same wheat show that this is not the case. The patent grades contain only slightly less protein than the wheat, while the lower grades contain somewhat more than the wheat itself. This suggests that, if it is desired to obtain flour of highest protein content, it can be found in the lower grades, as they contain more protein than the wheat itself. Such flours, however, produce a poorer quality of bread. [As regards] the comparative bread-making qualities of patent and clear-grade flours . . . it will be observed that the clear grades make smaller, darker loaves and a poorer quality of bread than the patent grades."

The gliaden content increased with the grade, the first patent flour showing the highest amount.

"The gliadin number is to some extent an index to the grade of the flour; the lower grades show a general tendency to contain less gliadin than the higher grades, although exceptions to this are noticeable. . . .

"While the gliadin number of the flour and the size of the loaf are not in all cases strictly in accord, there is a general relationship between the two; if a flour is abnormally low in gliadin it does not generally produce a large-sized loaf. The gliadin content of wheat and flour appears to be of more value in comparing the composition and characteristics of different types and varieties of wheat than in determining the quality or value for bread-making purposes of flour made from wheat of uniform character, such as was used in the investigations."

The acidity of the samples was also determined and is discussed in relation to gliadin, but definite conclusions are not reached. Among the author's general conclusions are the following:

"In this study of the protein content of wheat and of the various grades of flour it is manifest that the most nitrogenous flours are not always produced from wheats of the highest protein content. . . . The nitrogen may be variously distributed in different samples of wheat. . . . This is a matter of considerable importance in the selection of wheat for seed and milling and in the testing of varieties, because not all of the wheat kernel being used for human food purposes it is far more desirable to secure wheat with a large protein content in the endosperm than wheat with a large protein content in germ and bran. . . .

"The way in which the nitrogen is distributed in the wheat kernel is equally as important for bread making and human food purposes as is the total amount. It should be the aim to obtain wheat of high protein content in the endosperm rather than in the bran or germ; that is, an increase of protein in the floury portion of the kernel rather than in the offals. Furthermore, this protein should be of the best quality for bread-making purposes as well as large in amount."

Influence of storage and bleaching upon flours, H. Snyder (*Minnesota Sta. Bul. 85, pp. 213–217, figs. 2*).—The bread-making quality of samples of patent flour ground from both winter and spring wheat, stored for 4, 8, and 12 months in a dry, well-ventilated warehouse, was tested and compared with that of fresh flour ground from similar wheat. During storage the spring wheat flours lost from 1.86 to 2.21 per cent moisture, and the winter wheat flours somewhat less.

From analyses and baking tests it would appear, according to the author, that "when flour is milled from sound wheat there is no deterioration in bread-making value from storage when the flour is stored in a well-ventilated warehouse, a slight improvement in color and size of loaf being observed in the stored samples which, in part, was offset by the slight loss of absorption power. No effect upon the general

composition of the flours sufficient to influence the food value was noted. When flours are milled from unsound wheats, or contain débris particles of a fermentable nature, they possess poor keeping qualities, and such flours deteriorate in storage. In these tests a slight improvement resulted from storage of the sound flours. This is undoubtedly due to the action of the soluble ferments or enzyms which are known to be present in the wheat kernel. . . .

"In the storage of flour for family use, there is no danger of deterioration either in bread-making properties or food value provided sound flour is stored in a dry, well-ventilated room. Flour, however, readily absorbs undesirable odors, as from fresh pine wood, decaying vegetables, kerosene, and smoked meats."

The effect of bleaching upon the quality of flour was studied. Freshly generated oxygen was passed through the flour, which bleached readily. As shown by analyses, the bleaching did not materially change the percentage composition, but "it oxidized the coloring matter and had some influence upon the physical properties of the gluten."

As shown by bread-making experiments, "there appears to be no gain in bleaching purified flours made from a good quality of wheat, as the glutens were slightly oxidized, had lessened power of expansion and absorption, and the loaves from the bleached flours, although whiter in color, were smaller in size and less in weight."

The relative food value of graham, entire-wheat, and straight-grade flours, H. Snyder (*Minnesota Sta. Bul. 85, pp. 218–224*).—A summary of investigations noted from another publication (E. S. R., 15, p. 63).

The manufacture of macaroni, J. H. Shepard (*South Dakota Sta. Bul. 82, pp. 34–45, figs. 3*).—The manufacture of macaroni is described, the characteristics of a good product are pointed out, and recipes for cooking macaroni are given, together with methods of making bread from macaroni flour. According to the author the cooking quality and flavor of macaroni may be tested by boiling samples briskly for 15 minutes in slightly salted water.

"A good macaroni will be white in color and retain its shape. When eaten it will be tender and have a slightly sweetish taste, together with a peculiar nutty flavor, which is characteristic. A poor macaroni will have a starchy, unpleasant taste, and the flavor will be disagreeable. It may also be tough and leathery. If it has soured in curing the disagreeable flavor will betray the fact."

The food value of sugar, H. Snyder (*Minnesota Sta. Bul. 86, pp. 225–233, figs. 5*).—Two series of experiments were undertaken to study the nutritive value of sugar. In the first, the subjects (healthy workingmen) were given a mixed diet including sugar. In the second, the diet was the same except that sugar was omitted. With sugar 92.20 per cent of the protein, 96.08 per cent of the fat, and 95.96 per cent of the carbohydrates were digested, and 91.32 per cent of the energy was available. When sugar was omitted the values were as follows: Protein, 91.95; fat, 96.87; carbohydrates, 96.09, and energy, 89.34 per cent. In connection with the digestion experiments the balance of income and outgo of nitrogen was determined.

According to the author's calculations 98.9 per cent of the total energy of the sugar was available to the body.

"The addition of 5 oz. of sugar per day to the ration of workingmen proved beneficial. It increased the available energy of the ration 25 per cent and did not affect the digestibility of the other foods with which it was combined. The various nutrients were equally as digestible with as without the sugar.

"When sugar was added to the ration, the protein was more economically used, 25 per cent more nitrogen, one of the elements of protein, being retained in the body.

"The value of sugar in a ration depends upon its judicious use and combination with other foods."

The importance of some of the other articles consumed was also discussed. According to the author—

"Bread made from white flour supplied the largest amount of nutrients and at the least expense of any of the foods used in these digestion experiments.

"Milk exerted a beneficial action upon the digestibility of the foods with which it was combined, as the digestibility of these rations in which milk was present was found by experiment to be greater than the calculated digestibility.

"Without underestimating the value and importance of the protein in a ration, it is evident that the carbohydrates, as sugar and starch in flour and cereals, have a characteristic value, as they supply the body with more than half its total available energy."

The digestive action of milk, H. SNYDER (*Minnesota Sta. Bul. 86, pp. 234–237*).—Continuing earlier work (E. S. R., 14, p. 274), the influence of the enzyms or chemical ferments of milk upon the digestibility of the proteids of wheat was studied, samples of toasts being submitted to the action of fresh milk and milk 12 hours old under a variety of conditions.

According to the author—

"While the digestive action of milk upon the insoluble proteids of wheat is small, it is sufficient to render from 1 to 3 per cent of the total proteids soluble. The small amount of free acid in fresh milk has but little solvent action and alkaline salts in the proportion found in milk failed to dissolve any appreciable amount of proteids.

"In the presence of chloroform and ether, agents which retard the workings of organized ferments, the solvent action of the milk was not interrupted. From all of the facts, it would appear that the solvent action of fresh milk is due largely to the tryptic-like ferment or enzym which is a soluble ferment, and is a normal constituent of milk. These bodies enable milk to exert a slight digestive action. Under the conditions of these experiments from 1.5 to 3 per cent of the insoluble proteids of wheat, equivalent to from 4 to 12 per cent of the proteids in the milk used, were rendered soluble by these agents. There is a difference in the solvent action of milk; some milks have greater digestive power than others. When milk forms a part of a ration its digestive action undoubtedly adds to its dietetic value by rendering the foods with which it is combined more digestible."

The place of meat in the diet in Cologne, M. KÜHNAU (*Die Fleischkost im Kölner Haushalt. Cologne: Author, 1904; rev. in Ztschr. Fleisch- u. Milchhyg., 14 (1904), No. 8, p. 291*).—A summary of data designed for the use of housekeepers.

Composition of mushrooms, C. H. JONES (*Vermont Sta. Rpt. 1903, pp. 196, 197*).—Proximate and fertilizer analyses are reported of the following edible fungi: *Agaricus arvensis, A. rodmani, Boletus subluteus, Coprinus atramentarius, C. micaceus, C. squamosus, Lepiota naucinoides, Lycoperdon giganteum,* and *Marasmius oreades.* The ash varied within rather wide limits and was found to be rich in phosphates and potash, the latter, as a rule, predominating in 10 of the 12 samples analyzed.

"The analyses show, as has been pointed out by other observers, that mushrooms are particularly rich in water, the amount varying from nearly 89 to 95 per cent. Their chief value as food is derived from the nitrogenous matter present. . . .

"But little is known regarding the food value of the fiber and undetermined carbohydrates. The small amounts of pentosans present clearly indicate the practical absence of this important group.

"The variation in composition between samples of the same species, taken at different times and places, is quite marked and may indicate that the age of the specimen and the nature and abundance of the plant food present in the soil during the growth have an important influence."

Analyses of infant foods, C. H. JONES (*Vermont Sta. Rpt. 1903, pp. 197, 198*).—Analyses of 6 infant foods are reported. Lactose, maltose, starch, dextrin, and sucrose were determined in addition to the usual constituents.

The food production of British farms, R. H. Rew (*Jour. Roy. Agr. Soc. England, 64 (1903), pp. 110–122*).—Statistics regarding the production of vegetable and animal food products on British farms are summarized and discussed.

Borax and boric acid as drugs and preservatives (*Borax und Borsäure als Arznei- und Konservierungsmittel. Nuremberg: Bund Deutscher Nahrungsmittel- Fabrikanten- und Händler, 1903; rev. in Ztschr. Fleisch- u. Milchhyg., 14 (1904), No. 8, p. 291*).—A summary of data regarding borax and boric acid. The general conclusion was drawn that these substances have not been shown to be harmful when used as food preservatives.

Anilin dyes, G. W. Chlopin (*Kamennougolnuiya Kraski. Dorpat: K. Mattisen, 1903, pp. 300*).—The author reports the results of an elaborate study upon the composition and effects upon animal life of various dyestuffs made from coal-tar products. The different dyestuffs are classified according to their chemical relationship and notes are given on the characters of the various groups.

Numerous experiments were made in testing the effect of anilin dyes in food products upon the animal organism. It was found that a considerable variety of these dyes were harmful. The majority of poisonous dyestuffs belong to the nitro, azo, and triphenyl groups. While these groups are mentioned as especially poisonous, the author maintains the general proposition that all anilin dyes are more or less injurious to the animal organism and that their use in food products should be prohibited by law. (See E. S. R., 15, p. 494.)

A new type of anemo-calorimeter for clinical uses, A. O. Ignatowski (*Arch. Physiol. [Pflüger], 102 (1904), No. 5–6, pp. 217–248, figs. 3*).—In the apparatus described the temperature is measured by the speed of a small windmill driven by the escape from the calorimeter chamber of air warmed by the patient's body. The apparatus is of such a size that it may be placed over a cot.

Concerning the artificial transformation of albumin into globulin, L. Moll (*Hofmeister's Beitr., 4, No. 12, p. 563; abs. in Zentbl. Physiol., 18 (1904), No. 2, pp. 41, 42*).—Blood serum warmed for an hour at 60°, when diluted with water and acidulated with dilute acetic acid, gave a much larger precipitate than untreated blood serum and was found to contain an increased amount of globulin and alkali albuminate. The effect of lower temperature was also studied, and experiments are reported on crystallized serum albumin and its behavior toward a number of reagents.

In general, it was found that the globulin formed depended upon the concentration of the albumin solution, increasing with the increased concentration. Carbonates, bicarbonates, and phosphates of the alkali metals had an equally marked effect; the hydroxids, the least marked.

The cleavage of gelatin, II and III, P. A. Levene (*Ztschr. Physiol. Chem., 41 (1904), No. 1–2, pp. 8–14, 99, 100*).—Products obtained from gelatin by ferment action were studied, in continuation of earlier work (E. S. R., 14, p. 992).

Concerning ferments in organs which induce cleavage in sugar, J. Feinschmidt (*Hofmeister's Beitr., 4, No. 9–11, p. 511; abs. in Zentbl. Physiol., 18 (1904), No. 2, pp. 49, 50*).—The glycolytic power of different organs of several animals was studied.

Concerning the coagulating effect of autolytic organ extracts on albumose solutions and on milk, A. Nürnberg (*Hofmeister's Beitr., 4, No. 12, p. 543; abs. in Zentbl. Physiol., 18 (1904), No. 2, p. 43*).—The effect on albumose solutions and milk of the extracts of various organs submitted to self-digestion was studied.

On the adaptation of the pancreas, F. A. Bainbridge (*Jour. Physiol., 31 (1904), No. 2, pp. 98–119*).—A number of experiments with dogs are reported. Among the conclusions drawn were the following:

"The pancreas of adult dogs normally contains no lactase, although this enzym is present in extracts of the intestinal mucous membrane of such dogs; yet when dogs

are fed for two or more weeks on a milk diet, their pancreatic juice obtained by means of secretin invariably contains lactase.

"The formation of lactase by the pancreas is a specific reaction to lactose; it occurs only when lactose is given by the mouth, and not when it is injected subcutaneously. . . .

"The lactase of the pancreas is in no way derived from that present in the intestinal mucosa; it is formed by the pancreas itself, and represents a definite adaptation to a milk diet on the part of the pancreas. . . .

"Secretin appears to have a definite composition, is in no way modified by difference of diet, and is not concerned in the adaptation of the pancreas to food; it calls forth the secretion by the pancreas of all the enzyms present in the gland at the time."

Estimation of carbon dioxid by densimetry, A. D. Waller and B. J. Collingwood (*Jour. Physiol., 30 (1904), No. 5–6, Proc. Physiol. Soc., 1903, pp. XXXVI–XXXIX, fig. 1*).—A method of estimating carbon dioxid with a form of densimeter is described.

Note on the calculation of the respiratory quotient from volumetric data, A. D. Waller and B. J. Collingwood (*Jour. Physiol., 30 (1904), No. 5–6, Proc. Physiol. Soc., 1903, pp. XXXIX–XLII*).—The factors which should be taken into account in determining the true respiratory quotient are discussed, as well as the possible sources of error. On the basis of results obtained with the densimeter, the authors assert the theoretical possibility of experimentally estimating the respiratory quotient without volumetric determination of oxygen.

ANIMAL PRODUCTION.

Experiments with fattening steers, M. Cumming (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 84–87*).—Continuing earlier work (E. S. R., 15, p. 67), a test was conducted to determine whether in fattening steers it is more satisfactory to buy moderately heavy animals and feed them for a short period, or lighter, thinner animals, and continue the feeding for a longer period. Eight steers weighing on an average 1,271 lbs. and fed for 117 days, made an average daily gain of 2.08 lbs. at a cost of 12.75 cts. per pound, as compared with 2.16 lbs. daily gain at a cost of 10.53 cts. made by an equal number of steers averaging 1,098 lbs. in weight and fed for 160 days.

"Every pound of gain in live weight costs more to produce than it will sell for on the market. Any profit in feeding must come from increasing the value of the carcass purchased in the beginning. Therefore, the steer which requires to be increased in weight only 200 lbs. in order to be fit for market, is worth considerably more per pound than the steer which requires to be increased 300 lbs."

In order to learn the relative merits of cut and uncut hay and roots in the above tests one-half the steers were fed these feeding stuffs cut and the other half whole. The average daily gain on cut feed was 2.04 lbs., as compared with 2.16 lbs. on uncut feed, the cost of a pound of gain in the 2 cases being 10.82 and 11.54 cts., respectively. A little less meal and a little more hay and roots were consumed per pound of gain when the feed was not cut. According to the author, it will depend upon circumstances whether the slightly lower cost of a pound of gain is sufficient to pay for the labor of cutting the hay and pulping the roots.

The value of blood meal as part of the ration for steers was studied; a lot of 8 animals averaging 1,250 lbs. in weight being fed 1.20 lbs. of this material per day for 63 days in addition to corn meal, oats, and barley. The total gain made by the lot was 1,085 lbs. as compared with 1,070 lbs. made by a similar lot of 8 steers fed the same basal ration but no blood meal. With the former lot 4.29 lbs. meal and 0.54 lb.

blood meal were required per pound of gain and with the latter lot 4.43 lbs. meal with practically the same amounts of hay and roots in addition in each case. The gains were more expensive with the blood meal than without it.

"This is scarcely a fair test for blood meal as a food for cattle, as its greatest value no doubt is with the young, growing cattle that need protein for developing muscle. Moreover, the results are in accord with our previous experiments, which have gone to show that light meal rations are more economical than heavier meal rations."

The possible profits in feeding range steers was studied with 9 such animals, the test covering 147 days, during a part of which time the steers were allowed the run of a small yard. The average weight at the beginning of the test was 980 lbs., the average daily gain 1.53 lbs., the cost of a pound of gain 15.56 cts., and the food consumed per pound of gain 5.42 lbs. grain, 27.5 lbs. roots, and 18.5 lbs. hay.

"So far as this experiment is concerned, it is evident that unless they could be bought at a very low rate it would not pay to feed such steers as those experimented upon. At the same time it is worth noting that these steers made much better gains during the period they were allowed the run of a yard than when they were confined in their pens."

The feeding value of soft corn for beef production, W. J. KENNEDY ET AL. (*Iowa Sta. Bul. 75, pp. 117-133*).—The corn crop was seriously damaged in many sections of the United States in 1902 by early frosts, the yield per acre being much reduced and the corn worthless from a market standpoint, since it was soft and watery. With a view to learning the real value of this crop, the station studied the feeding value and chemical composition of such corn.

After a preliminary period, in which corn fodder and shredded corn were compared for supplementing pasturage, the test began August 11 with 2 lots of 8 steers each, averaging 1,030 lbs. per head in weight. From the first the steers were fed full grain rations, in one case soft corn, and in the other mature corn, the grain ration being supplemented by pasturage and later by hay and gluten feed. At the close of the test, April 13, the steers were sold in Chicago and slaughtered. The steers fed soft corn required 9.77 lbs. of corn with 3.9 lbs. of hay per pound of gain and those fed mature corn 9.36 lbs. of corn and 3.44 lbs. of hay, the cost of a pound of gain in the two cases being 7.92 cts. and 10.95 cts. The shrinkage in shipping the soft corn fed lot was 3.38 per cent and the dressed weight 60.8 per cent of the live weight. Similar values for the lot fed mature corn were 3.47 per cent and 60 per cent.

The soft corn used in the above trial contained a little over 35 per cent moisture at the beginning of the test and 16 per cent at its close. According to the authors the results obtained show that the soft corn was fully equal in feeding value to mature corn for fattening cattle.

"Cattle fed on such soft corn made nearly as heavy gains and finished equally as well as those fed on mature corn. . . . When soft corn similar to that used in this test could be purchased for 30 cts. per bushel, the prevailing market price, gains on fattening cattle could be made at a cost of 3.03 cts. per pound less than when mature corn, costing 50 cts. per bushel, the prevailing market price, was fed under similar conditions."

Analyses showed that both the grain and cob of soft corn contained considerably more water than similar samples of mature corn, but did not differ otherwise markedly in chemical composition. In a considerable number of analyses of samples of corn gathered from different sections of Iowa in 1902 the maximum amount of moisture present in the corn was 23.89 per cent, the minimum 11.30 per cent, and the average 18.83 per cent. In the case of the cob the maximum was 39 per cent, the minimum 6.76 per cent, and the average 27.65 per cent. As shown by these figures the variation in water content was large. According to the authors "the amount of moisture depends chiefly upon the maturity of the corn when stricken by frost.

"That the [soft] corn was affected by the frost and of a chaffy nature is noticeable when the weight of a measured bushel is taken. An average of several tests made to determine the weight per measured bushel showed it to be but 51 lbs."

Corn dries when stored, and a test was made of the amount of moisture lost by 4 varieties in 9 months from the time it was husked and cribbed. The total loss of water varied from 21.09 per cent of the amount originally present with Iowa Silver Mine to 22.05 per cent with Mammoth Red.

Cocoa-shell milk for calves, H. H. DEAN (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 73, 74*).—Two calves fed daily in addition to some grain and green feed, 1.5 to 2 gal. of a decoction of cocoa shells made by boiling 0.25 lb. of the shells in 2 gal. of water, gained 135 lbs. in 8 weeks. Under similar circumstances 2 calves fed 1.5 to 2 gal. of skim milk per day in addition to other feeds gained 148 lbs. in 8 weeks. The cocoa-shell decoction (cocoa-shell milk) when fed with grain and green feed "appears to be a very good substitute for skim milk and is worthy of a trial by those farmers who wish to rear calves and have little or no skim milk to feed. However, there is probably no substitute which will entirely take the place of milk for young stock."

Profitable stock feeding, H. P. SMITH (*Breeder's Gaz., 45 (1904), No. 20, pp. 945, 946, figs. 5*).—The value on the block of beef carcasses of different types is discussed with special reference to different factors as a means of judging of the quality of the meat.

Experiments with swine, M. CUMMING (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 81–84*).—The value of blood meal and tankage as compared with skim milk was tested with 7 lots of 5 pigs each, those in 5 of the lots averaging 33 lbs. in weight and those in the remaining 2 lots 21 lbs. each. The blood meal and tankage used were obtained in Chicago and were designed especially for use as feeding stuffs. These by-products, with and without skim milk, were added to a basal ration of grain (at first middlings and later barley) and compared with a similar ration of grain and skim milk 1 to 2. The light-weight pigs were fed the packing-house by-products in the proportion of about 1 lb. to 18 lbs. of grain, and the heavy pigs in the proportion of about 1 to 13. When fed with skim milk, the proportion of packing-house by-products was one-half as large as in the case of the light-weight pigs. In the 137 days of the test the total gain of the lot on blood meal and grain was 817 lbs., that of the 2 lots fed tankage and grain 790 and 716 lbs., of the lots fed skim milk and grain 712 and 744 lbs., and of the lots fed blood meal and tankage with skim milk and grain 695 and 800 lbs., respectively. The cost of a pound of gain ranged from 4.08 cts. with one of the lots fed tankage and grain to 5.4 cts. with one of the lots fed skim milk and grain and was in general higher with the lots fed skim milk than with the others. The grain consumed per pound of gain ranged from 3.53 lbs. with the lot fed grain and blood meal to 4.59 lbs. with one of the lots fed skim milk and grain. Among the author's conclusions were the following:

"The pigs, without exception, took to the blood meal and tankage from the very first with great avidity. There is nothing in this experiment to indicate which is the more valuable food, blood meal or tankage. In both cases where light-weight pigs were fed in comparison with heavier pigs, cheaper gains were made by the former.

"Blood meal and tankage have proven themselves fully equal to skim milk for the production of firm bacon, and, so far as this experiment is concerned, have produced cheaper gains.

"This is but a single experiment, and will have to be repeated several times before any reliable results can be announced."

In the above test the author notes that a little green feed was given the pigs each day and "seems to have been most beneficial."

In a second test the attempt was made to feed an ordinary commercial blood meal of Canadian manufacture, not especially prepared as a feeding stuff, 2 lots of 5 pigs each being selected for the purpose. From the first the pigs showed aversion to this food and after 3 weeks it was dropped. When the pigs had recovered their normal condition 9 of them were fed a ration of grain and skim milk 3 times a day to learn something of the comparative merits of frequent feeding.

In 101 days the total gain was 1,224 lbs., the cost of a pound of gain 5.21 cts., and the feed eaten per pound of gain 4.31 lbs. meal and 9.06 lbs. skim milk. These pigs made somewhat greater gains than the lots in the above-mentioned test with which the author considers they are directly comparable, yet, in his opinion, "the extra gain was not sufficient to pay for the extra labor of feeding." . . . From this experiment it is evident that where gains alone, irrespective of cost, are aimed at, as in the case of some "show stock," feeding 3 times a day or possibly more is good practice.

Poultry management, F. B. LINFIELD (*Montana Sta. Bul. 50, pp. 180–190, figs. 3*).—Poultry houses, poultry feeding, and other general topics are discussed with special reference to local conditions.

Killing and plucking poultry (*Mark Lane Express, 90 (1904), No. 3788, pp. 521, 522*).—A summary of data with special reference to the requirements of the English market.

Poultry management at the Maine Agricultural Experiment Station, G. M. GOWELL (*Maine Sta. Bul. 100, pp. 20, pls. 6*).—Data regarding methods of incubation, treatment, and housing of young chicks, and of feeding laying hens are summarized, the discussion being based on the station's experiments with poultry feeding which have extended over a number of years. Descriptions are also included of warmed and curtained-front poultry houses, and the trap nests devised by the station. Although natural incubation is not the preferable method at the station, it is stated that it has been satisfactorily practiced. Nesting boxes, closed with a door of slats and containing a nest with sufficient space in front so that the hen may stand without breaking the eggs, were found satisfactory.

"For the accommodation of the hen with her brood of young chicks, the best arrangement consists of a close coop about 30 in. square, with a hinged roof, and a movable floor in two parts, which can be lifted out each day for cleaning. This little coop has a wire-covered yard attached to it on the south side. The yard is 4 by 5 ft. in size and a foot and a half high."

After a few weeks the chicks need a larger run and the netting can be raised so that they can pass in and out at will.

The use of incubators and brooders has proved very satisfactory. In the case of brooders the greatest difficulty experienced was due to the lamps used as "the tendency is for the oil to become warm and form gases, which causes the flame to stream up." It is suggested that this difficulty may be avoided by using an improved lamp.

When about 100 days old the chickens are moved from the brooders to the fields and the cockrels and pullets are separated and the latter confined in yards in lots of about 100. They are fed twice daily a porridge made of corn meal, middlings, or flour, and fine beef scrap 4:2:1 wet with skim milk or water until the mixture will run but not drop from the end of a wooden spoon. They are fed this mixture in the morning and again toward evening and are given plenty of shade and kept as quiet as possible. Four weeks has been found to be the limit of profitable feeding. Such special feeding is considered profitable as is also the practice of marketing chickens dressed.

"The quality of the well-covered, soft-fleshed chickens, if not too fat, is so much superior to the same birds not specially prepared, that they will be sought for at the higher price. The dairy farmer is particularly well prepared to carry on this work, as he has the skim milk which is of great importance in obtaining yield and quality of flesh."

It is stated that the warmed poultry houses used at the station have given very satisfactory results, as have the poultry houses with a roosting closet closed in front at night with a curtain of oiled cotton and having a scratching room exposed to the sun and air, the floor being covered with clean straw.

On the basis of 21 years' work with the same family of Barred Plymouth Rocks the station has decided upon a method of feeding which is considered satisfactory. Each pen of 22 birds is given a pint of wheat scattered in the litter in the morning and at 9.30 a. m. one-half pint of oats. At 1 p. m. one-half pint of cracked corn is fed in the same way. At 3 p. m. in winter and 4 p. m. in summer they are fed all they will eat in a half hour of a mash made of 2 parts of wheat bran and 1 each of corn meal, wheat middlings, linseed meal, gluten meal, and beef scrap. With this is mixed clover heads and leaves equivalent in bulk to one-fourth of the mash.

"The clover is covered with hot water and allowed to stand for three or four hours. The mash is made quite dry, and rubbed down with the shovel in mixing, so that the pieces of clover are separated and covered with the meal. Cracked bone, oyster shell, clean grit, and water are before them all of the time. Two large mangolds are fed to the birds in each pen daily in winter. They are stuck onto large nails which are partly driven into the wall, a foot and a half above the floor. Very few soft-shelled eggs are laid and, so far as known, not an egg has been eaten by the hens during the last five years."

Report of manager of the poultry department, W. R. GRAHAM (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 152-158*).—The general condition of the poultry department and the success which has attended hatching eggs in different ways are briefly spoken of, and a number of experiments are reported. The fact that Andalusian fowls do not hatch true to color is noted and briefly discussed.

As regards the influence of the position of eggs in incubator trays a trial indicated "that eggs for incubation should lie in the natural way, that is, on their sides. Some incubator operators are not particular about this in the management of their machines, and the result is a considerable number of chickens dead in the shell, which is especially noticeable in eggs placed with the small end up."

The effect of introducing oxygen into the hatching chamber was also studied. In the first test it was observed that on the eighth day of incubation some of the eggs showed what is known as the "blood ring," that is, a ring of blood encircling the embryo. "The oxygen appeared to be too much of a stimulant, causing abnormal growth of the germ, which often resulted in the rupturing of the blood vessels of the germ." From 89 fertile eggs only 27 chicks were hatched, while in an incubator managed in the ordinary way 44 chickens were hatched from 94 fertile eggs. Practically all of these chickens were raised, killed, and sold in the ordinary way, while those hatched in an incubator supplied with oxygen, with one or two exceptions, died, many of them during the first 10 days after hatching, though placed in the same brooder and fed in the same way as the others. Two later trials with smaller amounts of oxygen though not as unsatisfactory as the first trial were "characterized by smaller hatches and poorer chicks than were obtained from machines run in the ordinary way."

The egg production of fowls kept in a cool airy house was tested throughout a period extending from December to October. The house was not warmly built and one of the small windows in the front of it was left partly open and covered with a piece of cotton tacked over it during the winter. The lowest recorded temperature was 9° above zero, which it is stated was exceptional, but 15 to 24° above was very common. In addition to a number of cockerels the flock comprised 18 hens at the beginning and 6 at the end of the test, one having died and a number having been sold. The total number of eggs produced was 1,763. The value of the eggs sold at current prices was $23.33. This sum does not include $3 worth of eggs which were incubated. An account was kept of the feed consumed, and the author calculates

that when all were sold this lot of poultry yielded a profit of $11.88. As regards the effect of this system on different breeds the author states that less satisfactory results were obtained with Leghorns, Minorcas, and similar breeds, than with Wyandottes, Orpingtons, etc., the lighter birds feeling the cold much more than the heavier.

The system of not allowing yearling hens intended for breeders to lay during the winter was tested to some extent, and the results obtained were considered favorable.

Using 16 lots of 12 chickens each, the relative value of skim milk, tankage, blood meal, animal meal, and beef scrap supplementing grain (ground oats, ground buckwheat, and corn meal 2:2:1) was studied and also the value of a ration of potatoes, shorts, and skim milk. In nearly every case the rations were fed to lots in crates and lots in pens to compare the merits of the 2 systems of feeding. On an average the chickens weighed from 3 to 5 lbs. and in the 2 weeks of the trial the gain per lot ranged from 9 lbs. on a ration of potatoes, shorts, and skim milk to 18 lbs. on a ration of grain, skim milk, and animal meal. Considering the test as a whole, the average gain made by the chickens fed skim milk and grain was 14.8 lbs., of those fed packing-house by-products 14.1 lbs., and of those fed a potato ration 9.7 lbs. The cost of feed per pound of gain ranged from 3.4 cts. with one of the lots fed grain and skim milk to 6.2 cts. with one of the lots fed grain and blood meal. This latter lot required the greatest amount of grain per pound of gain, namely, 3.45 lbs. The smallest quantity, 2.2 lbs., was required with one of the lots fed grain and tankage. Of the different substitutes for skim milk tested the author considered digester tankage and animal meal the most satisfactory.

"Blood meal did not give nearly so good returns; and furthermore, these rations were not relished by the chickens. Beef scrap gave very good returns; but at sixty to seventy dollars per ton, it is too expensive. The feeding of both animal meal and skim milk does not appear to have any particular advantage over the feeding of either one singly with the grain ration.

"The potato and shorts [and skim milk] ration is only a fair one, but no doubt would be very convenient for many farmers; and, where the market demands a half-fat chicken, this ration is worthy of consideration.

"The crate-fed birds made a pound of gain cheaper than the birds fed in pens; but if we deduct the second trial in crate feeding, then the cost of a pound of gain is about equal. The chickens fed on the potato ration did better in the pens. . . . [Good chickens], weighing a little more than 3 lbs. each, are more profitable feeders than larger birds."

The relative profits of marketing ducks when first feathered as compared with holding them until later was studied with a flock composed of 51 Pekins, Rouens and Pekin and Indian Runner crosses. When 9 weeks old the ducks weighed on an average 5.1 lbs. They were in good feather and ready for market; however, only 6 were killed. At the end of the next week the 45 ducks remaining had lost 7 lbs. in weight as they were beginning to moult heavily. All but 13 were killed and sold. In dressing they lost 0.75 lb. in weight per pair. "The necks were pulled in the same manner as the chickens are killed. Had the ducks been bled, no doubt there would have been a greater shrinkage." Deducting the price of the feed consumed the author calculates that there was a profit of 34 cts. on each duck, and if they had all been marketed when 9 weeks old the profit would have been 38 cts. The remaining 13 ducks were fed a week longer and gained 2 lbs. in weight, consuming 27 lbs. of grain and a like amount of skim milk.

"There was not much gain made by the ducks until after the new feathers had been fairly well grown. In fact, the cost of the feed eaten each week after the ninth amounted to more than the price of pounds of gain made during the week.

"From this trial it is very evident that when ducks become well feathered, that this is the most profitable time to sell them; and, secondly, that the growth made

after the ninth or tenth week will seldom leave any margin of profit, after deducting the cost of feed."

As regards breeds, the Pekins and Indian Runner Pekins matured the fastest. "They were ready to kill fully one week in advance of the Rouens."

Digestion experiments with poultry, E. W. Brown (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 56, pp. 112, pls. 4, charts 2*).—The digestibility of corn, oats, wheat, and meat was studied with hens, the feces being collected with the aid of a specially constructed aluminium pan attached to the birds by straps. The feces were preserved for analysis by covering them with 95 per cent alcohol slightly acidulated with acetic acid to prevent the loss of ammonia. Full analyses of the feed and feces were made.

In addition to the usual determinations the ammonia, metabolic products, uric acid, pentosans, soluble ash, and silica in the feces were determined. The estimation of the uric acid is of special importance in experiments with poultry, as this represents the bulk of the urine nitrogen. It was determined by a modification of Kionka's method[a] by titration with piperidine, using phenolphthalein as an indicator. Sixteen experiments of from 6 to 13 days' duration are reported, in each of which the feeding stuffs selected were fed alone during the experimental period and during a preliminary period of 5 to 8 days. The following table summarizes the coefficients of digestibility obtained:

Coefficients of digestibility of a number of feeding stuffs—Experiments with hens.

	Organic matter.	Protein.	Ether extract.	Crude fiber.	Nitrogen-free extract.	Pentosans.
Corn, average of 5 tests	86.64	83.95	85.32	[b]14.53	89.25	[c]30.05
Oats, average of 8 tests	64.77	73.38	81.48	[b]8.15	70.77	[d]16.80
Wheat, 1 test	83.94	77.40	58.83	....	86.02	....
Beef, average of 2 tests	87.05	90.20	86.30	....	....	....

[b] Not regarded by author as reliable.
[c] Average of 3 tests.
[d] Average of 7 tests.

On the basis of the amounts of food consumed and digested the following feeding standards were calculated, which the author regards as provisional:

Feeding standards for hens.

[Amounts per day per 100 lbs. live weight.]

	Organic matter.	Protein.	Ether extract.	Nitrogen-free extract.	Fuel value.	Nutritive ratio.
AMOUNTS CONSUMED.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Calories.*	
Hens (3 to 4 pounds), corn	4.83	0.53	0.28	3.89	100,732	1 : 8.6
Hens (3 to 4 pounds), oats	2.84	.37	.15	1.97	54,065	1 : 6.3
Hens (3 to 4 pounds), wheat	3.27	.42	.07	2.72	66,259	1 : 6.9
AMOUNTS ASSIMILATED.						
Hens (3 to 4 pounds), corn	4.19	.45	.24	3.46	88,623	1 : 9.0
Hens (3 to 4 pounds), oats	1.83	.28	.12	1.39	39,438	1 : 6.0
Hens (3 to 4 pounds), wheat	2.70	.32	.04	2.42	56,681	1 : 7.8

[a] Arch. Internat. Pharmacodynamie, 7 (1900), p. 55.

The cost of a pound of nutrients supplied by the different grains is calculated as follows:

Cost of 1 pound of digested nutrients supplied by the different grains.

Kind of grain.	Cost of 1 pound of—			
	Organic matter.	Protein.	Ether extract.	Nitrogen-free extract.
	Cents.	*Cents.*	*Cents.*	*Cents.*
Corn	1.41	1.44	1.46	1.39
Oats	2.32	2.17	1.93	2.25
Wheat	1.78	1.96	2.55	1.76

In connection with the experiments the daily weight of the chickens was recorded, and a number of interesting calculations were made, experimental data and methods in every case being reported and discussed in full, the numerous references to the literature cited constituting an extended bibliography.

The provisional conclusions arrived at were in effect as follows:

Corn, oats, and wheat show marked differences in the digestibility of several of their respective nutrients. The protein and nitrogen-free extract are assimilated in much greater proportion in corn than in oats. The digestion coefficient for the protein of wheat is intermediate in value between the average results for these 2 grains.

The digestibility of the fat of corn is slightly greater than that of oats. The digestibility of the fat of wheat is conspicuously less than that of corn and oats. This fact may at least in part account for the untoward results of a diet of wheat only.

Chickens consume a much greater quantity of corn than oats—an important fact to be kept in mind in a comparison of the digestion coefficients of the 2 grains. The nutritive superiority of corn over oats is indicated by the body weight. An increase is manifested under the use of corn, while a tendency in the opposite direction is seen with oats. The nutrients of corn are fed at a lower cost than those of oats and wheat. The last-named grain is the most costly of the 3 foods. This conclusion is based on the actual digestibility of the various nutrients of the grains.

Regarding the application of these grains in mixed dietaries the following suggestions are offered: Corn may be included for the main nutrients—that is, protein, nitrogen-free extract, and ether extract. Oats may be utilized for the protein and ether extract. Wheat may be employed for the protein and nitrogen-free extract, but adequate provision must be made for the deficient yield of this grain in fat.

The protein and fat of beef show high coefficients of digestibility, the former is considerably higher, the latter but slightly less than the corresponding nutrients in corn.

Composition of by-products of flour, oat, pea, and starch mills, W. P. GAMBLE (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 51–54*).—A brief account of investigations which have been undertaken to learn the composition of by-products used as feeding stuffs.

Annual report for 1903 of the consulting chemist, J. A. VOELCKER (*Jour. Roy. Agr. Soc. England, 64 (1903), pp. 286–295*).—Analyses of a number of feeding stuffs and fertilizers are reported.

DAIRY FARMING—DAIRYING.

Feeding trials with cows, J. L. Hills (*Vermont Sta. Rpt. 1903, pp. 209–264+XXXIV*).—This is a detailed account of feeding experiments conducted during the year along the same general line followed during the previous 5 years. Many of the experiments are repetitions of those reported last year. Tests were made to compare low and medium grain rations; to ascertain the extent of experimental error in feeding trials; and to study the feeding value of distillers' grains, brewers' grains, cotton-seed meal, linseed meal, apple pomace, pumpkins, and a proprietary dairy feed. As in previous years, the detailed data are given in the form of an appendix. The trials included 48 cows and lasted 25 weeks. Each feeding trial lasted 5 weeks, the conclusions in every case being based upon the data obtained during the last 23 days.

Grain rations of 2, 4, and 8 lbs. were compared with 12 cows, the results showing an increase in the yield of milk and fat of 10 per cent when the 2-lb. ration was replaced by the 4-lb. ration, and of 18 per cent when replaced by the 8-lb. ration. It is estimated that when 2 lbs. of grain was fed instead of 4, the saving in cost of feed was $3.32 and the loss in butter not made was $3.74; and that when 2 lbs. of grain was fed instead of 8, the saving in cost of feed was $8.40 and the loss in butter not made was $6.42. The 4-lb. ration was considered more satisfactory in every way than the 2-lb. ration. While the yield of butter from the 8-lb. ration did not pay the extra cost of grain as compared with the 4-lb. ration, yet the heavier ration was considered the more satisfactory when the skim milk and manure are taken into account.

Four cows were used in a test to determine the value of feeding dried distillers' grains alone, as compared with a mixture of these grains and bran. The mixture of distillers' grains and bran produced 3 per cent more milk than the undiluted grains, no change being observed in the quality of the milk. More milk and butter per unit of dry matter, however, was produced when the grains were fed alone. From a financial standpoint the mixed ration resulted in a gain of three-quarters of a cent daily per cow.

As compared with dried brewers' grains in a test with 6 cows, dried distillers' grains produced 5 per cent more milk and 8 per cent more butter, but owing to their high cost proved less economical.

As compared with a mixture of wheat bran, cotton-seed meal, and linseed meal (2:1:1), dried distillers' grains and bran (2:1) produced, in a test with 6 cows, 1 per cent more solids and 3 per cent more fat, although the total yield of milk was not increased. Owing to the extra cost of the distillers' grains the profit was no greater.

In a test with 5 cows a comparison was made of dried brewers' grains with a mixture of cotton-seed meal, linseed meal, and bran. The 2 rations proved equally efficient, but owing to the lower price of the brewers' grains this material was fed more economically.

Apple pomace was compared with pumpkins in a test with 4 cows. The pumpkins increased the yield of milk 6 per cent. The quality of the milk was uniform on both rations. Neither the health of the cows nor the quality of the butter were injured by feeding pumpkins.

Nutrene dairy feed, a proprietary feeding stuff said to be a sugar-house by-product combined with wheat, corn, and oat products, was not readily eaten, and in the opinion of the author does not seem to be a desirable addition to the list of dairy feeds.

Dried distillers' rye grains produced less milk and butter than other distillers' grains in a test with 1 cow.

Apple pomace silage fed in amounts of 24 to 35 lbs. produced 3 per cent more milk and 5 per cent more butter than did immature corn silage fed in the same

amounts. There was no essential difference in the quality of the milk made on the 2 rations. The yield of milk per unit of dry matter was also practically the same.

Additional data concerning the experimental error involved in feeding trials indicated that under favorable conditions the error by the alternation system is slight.

A comparison of feeding-trial methods, J. L. Hills (*Vermont Sta. Rpt. 1903, pp. 264–274*).—The results of the third test of the 2 methods of feeding designated the alternation system and the combined continuous and alternation system, confirm the conclusions reached in the previous report (E. S. R., 14, p. 1112), that the alternation method is the better of the two. The work is to be continued for several years, although it is not expected that material change in the position taken will be necessary.

On the value of sugar beets as a food for dairy cows, G. W. Berglund (*Nord. Mejeri Tidn., 19 (1904), No. 7, pp. 84, 85*).—Sixty-four cows were fed for 92 days during November, December, and January 200 kilos sugar beets, or about 3 kilos per head daily, in addition to straw, ground barley, and peanut cake. The fat content of the milk was maintained during the beet feeding, while the total production of fat was considerably higher during the months when beets were fed than before or after. The author concludes that, under conditions such as prevailed in this experiment, sugar beets are an excellent feed for milk production, and that they pay much better when used for this purpose than when sent to a sugar factory.—F. W. WOLL.

Effect of feed on the composition of milk, butter fat, and on the consistency or body of butter, J. B. Lindsey et al. (*Proc. Soc. Prom. Agr. Sci., 1904, pp. 113–131*).—This is the third experiment of this character conducted at the Massachusetts Station (E. S. R., 13, p. 385; 14, p. 183). The present experiments were made with 2 lots of 5 cows each and covered 4 periods, varying in length from 3 to 7 weeks each. One lot was fed a standard grain mixture consisting of wheat bran, ground oats, cotton-seed meal, and gluten meal during the entire experiment; while the other lot was fed the standard grain mixture during the first period and the same ration replaced in part by gluten meal, gluten meal and corn oil, and corn meal, respectively, during the 3 remaining periods. Detailed data are reported.

The addition of 0.6 lb. of corn oil increased the fat content of the milk 0.23 per cent, the effect of the corn oil disappearing by the end of the second week. The removal of the corn oil from the ration decreased the fat content of the milk 0.54 per cent, the percentage becoming normal after the first week. Corn oil also appeared to decrease the nitrogen content of the milk. It is not believed to be practicable to feed large amounts of oil to cows, owing to the tendency of this material to derange the digestive organs. The composition of the milk of the lot fed the standard grain mixture for the entire experiment remained practically uniform.

The addition of corn oil decreased the saponification number 10 points and the Reichert-Meissl number 3½ points, and increased the iodin number 9 points. The melting point of the fat remained unchanged. It is believed from the results of the present and earlier experiments that neither the proteids nor carbohydrates, when fed in normal amounts, exert any noticeable influence on the composition of milk nor on the chemical character of the butter fat. The changes that do occur are attributed to the presence of oil in the feeding stuffs. The corn and gluten meal tended to produce a soft butter, and this tendency was noticeably increased by the addition of corn oil to the ration.

Report of the professor of dairy husbandry, H. H. Dean (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 60–76*).—Several lines of experiments are reported upon. Some of these are in continuation of work reported last year (E. S. R., 15, p. 74).

Comparative tests were made of different methods of handling milk for household purposes. The methods included clarifying at 90, 140, and 160° F. by running through a cream separator, pasteurizing at 140, 160, and 180°, and filtering through

cotton batting. Samples of each were then placed in cold storage for 24 hours and scored according to the following scale: Smell 20, taste 25, acidity 35, cream 15, appearance 5. The samples were then either returned to cold storage or kept at room temperatures for another 24 hours and again examined. Averaging all the results, milk pasteurized at 140° scored highest at the end of 24 hours, and milk pasteurized at 180° highest at the end of 48 hours. Pasteurized samples scored higher than clarified samples in every instance. Filtering as well as clarifying appeared to be of doubtful value except for the purpose of removing dirt. Where milk is produced under strictly sanitary conditions heating is considered unnecessary. Under ordinary conditions, however, it is deemed best to heat milk to 140 to 180° and cool promptly to 40 to 50°.

In 6 experiments comparisons were made of the oil test and the Babcock test for cream. The conclusion is drawn that "the oil test is not a very reliable test for dividing proceeds of sales of butter among patrons who deliver cream, and should be superseded by the Babcock test as soon as the change can be conveniently made."

In experiments in butter making comparisons were made of a lactic-acid starter prepared at the college and a culture containing lactic acid and *Oïdium lactis* obtained from a German source. On the whole it was concluded that better results were obtained by using the ordinary lactic-acid culture in pasteurized cream.

The relative advantages of keeping butter in ice cold storage and mechanical cold storage (ammonia system) were studied in 5 experiments. The butter was placed in cold storage as soon as made and scored after about 1 week, 1 month, and 3 months. There was very little difference in the quality of the samples at the first scoring, but at the second and third scorings there was a difference of about 1 point in favor of mechanical cold storage. A comparison was also made of keeping butter in mechanical cold storage at 38 to 40° for 1 week and then removing to mechanical cold storage at 28 to 30° as compared with keeping at the lower temperature for the entire period. The butter placed directly in cold storage at the lower temperature scored higher at the end of 1 and 3 months than similar lots moved from a moderate to a low temperature at the end of 1 week. "While the mechanical cold storage has given the best results as compared with ice for holding butter, the expense and difficulty of operating these machines, as at present constructed, make their use too expensive for the average creamery."

In experiments in cheese making, comparative tests were made of ripening in the ordinary curing room, ice cold storage, and mechanical cold storage. The results of the 2 series of experiments showed that cheese ripened in ice cold storage at 40° was superior in quality to cheese ripened in the ordinary curing room at 61°. The flavor of cheese ripened in mechanical cold storage at 40° was slightly better than that of cheese ripened in ice cold storage at the same temperature. Curing at 40° gave better results than curing at 50°. Cheese ripened for 1 week in an ordinary curing room and then removed to ice cold storage scored slightly lower than cheese ripened entirely in cold storage; while cheese moved at the end of 1 week to mechanical cold storage scored slightly higher than that ripened for the entire period in mechanical cold storage, from which it is concluded that there is little or no risk of injuring the quality of cheese by curing in an ordinary room for 1 week before placing in cold storage. Shrinkage in the ordinary curing room was about 4 per cent for one month, in ice cold storage about 1.9 per cent, in mechanical cold storage at 40° 2.6 per cent and at 50° 3.25 per cent. Cheese moved to ice cold storage at the end of 1 week lost 2.9 per cent, and moved to mechanical cold storage, 3 per cent. On the whole it is concluded that a temperature of 40° gave the best results, and that while the quality of cheese was slightly better in mechanical cold storage, the shrinkage was greater than in ice cold storage. Leaving for 1 week in an ordinary curing room increased the loss in shrinkage, but did not affect the quality to any marked extent.

Determinations were made of the moisture in curd at the time of dipping and milling and in green and ripe cheese. "Normal curds contain about 50 per cent moisture at dipping, 40 per cent at milling, 34 per cent when taken from the hoops, and when ripened in cold storage at a temperature of 38 to 40° the cheese at the end of 1 month will have lost very little moisture." In one series in which an excess of about 2 per cent of moisture was incorporated the quality of the cheese was slightly lower.

In 15 experiments comparisons were made of the use of 2, 3½, and 6 oz. of rennet per 1,000 lbs. of milk, the cheese being ripened in one series in mechanical cold storage at 40° and in another series in ice cold storage at the same temperature. The results showed very little difference in the loss of weight in ripening or in the quality of the cheese. Where it is desirable to hasten the process of ripening it is considered safe to use from 4 to 6 oz. of rennet per 1,000 lbs. of milk without danger of injuring the quality of the cheese, provided the cheese is placed in cold storage soon after being made.

Cheese was ripened in either ice or mechanical cold storage at temperatures ranging from 29 to 53°, the best results being obtained by ripening at a temperature of 40°. While no bad results followed ripening at 29°, there was apparently no advantage in ripening at that temperature.

Cheese was ripened for periods of 1, 2, and 3 months in ice cold storage and then moved to the ordinary curing room and compared with cheese ripened for the entire period in cold storage and in the ordinary curing room. The total score for the different lots was as follows: Cold storage for the entire period 93.8, cold storage for 3 months 92.9, cold storage for 2 months 89.9, cold storage for 1 month 89.3, and in the ordinary curing room 88.1, showing the superiority of cold storage. It is concluded that no rapid deterioration in the quality of cheese which has been kept for 2 or 3 months in cold storage need be expected, provided the cheese was of good quality when made.

Placing cheese on shelves and boxing directly from the press were compared in 8 experiments, from the results of which the following conclusions were drawn:

"Cheese may be placed directly from the press in clean, dry boxes, if kept in either ice or mechanical cold storage, without any danger of injuring the quality of the cheese. The only drawback is the mold on the cheese, especially in an ice storage.

"The boxing of cheese when green and leaving them in an ordinary ripening room is not to be recommended, owing to the 'huffing' of the cheese and the large amount of mold which collects. Spraying with formalin tends to check the latter, while turning the boxes tends to prevent the 'huffing.'

"The cheese put directly into boxes lost considerably less in weight than did those on the shelves, hence the plan of boxing is an advantage in this respect, as it saves shrinkage.

"In this series, as in several of the others, the loss in weight during 1 month was greater in the mechanical storage, but the quality of the cheese was slightly better than were those in the ice cold storage. Both lots were better in quality, and the shrinkage was less than in those ripened in the ordinary room."

Tests were made of different temperatures for cooking curds:

"Heating the curds to temperatures of 102 to 110° tended to reduce the percentage of acid in the curds at all the important stages of the process of cheese making. In the case of curds which tend to 'work too fast,' it would seem advisable to heat them to a higher temperature than usual in order to check the development of lactic acid. It is possible that normal curds may be advantageously heated to a higher temperature than is now considered necessary.

"Heating curds to the higher temperatures appears to reduce the yield of cheese obtained from milk. In our experiments the loss was about 4 lbs. of ripe cheese on 3,900 lbs. milk testing 3.7 per cent fat.

"The average quality of the cheese was improved by cooking the curds at the higher temperature."

Further experiments along this line are considered necessary.

The substitution of sugar-beet pulp for mangel-wurzels was tested with 15 cows during about 3 months. The pulp, which was eaten readily, produced less milk than mangel-wurzels in one period and more milk in another period. When fed with corn silage it is considered advisable to feed no more than 20 to 30 lbs. per cow daily, but when fed with dry feed larger quantities may be given with safety. Pulp is believed to be more valuable in a dry ration than in one containing silage.

The average yearly production of the 20 cows in the dairy herd was 6,711 lbs. of milk and 276 lbs. of butter. The largest yield, 10,214 lbs. of milk and 418 lbs. of butter, was made by a grade Holstein cow.

Record of the station herd for 1902-3, J. L. Hills (*Vermont Sta. Rpt. 1903, pp. 274-283*).—This record is similar in character to those of previous years (E. S. R., 14, p. 1112). The average results for the year were as follows: Number of cows 48, yield of milk 4,910 lbs., yield of butter 294 lbs., cost of food $51, and proceeds from sale of butter $88.15. Records for 9 years have now been obtained. It is hoped that another year some general deductions may be made from the data as a whole.

A preliminary note on the associative action of bacteria in the souring of milk and in other milk fermentations, C. E. Marshall (*Michigan Sta. Spec. Bul. 23, pp. 8*).—Two species of bacteria were isolated from milk, one belonging to the lactic-acid group and one to the peptonizing group, the latter eventually producing slimy milk. These species were grown alone and in combination in a number of experiments, the results obtained being noted briefly in this bulletin.

In the first experiment milk inoculated with the 2 species began to curdle 72 hours before milk inoculated with the lactic-acid bacteria alone. In the second experiment the difference in the time of curdling was 48 hours. These results were found constant in 12 or more trials. The lactic-acid bacteria increased much more rapidly when grown in combination with the peptonizing species than when grown alone. The peptonizing bacteria, on the contrary, decreased gradually and disappeared entirely before the fiftieth hour. It is noted that 2 other micro-organisms have been met with which have the same action as the peptonizing bacteria when associated with the lactic-acid bacteria. Two species have also been found which retard the development of the lactic-acid bacteria. It is announced that detailed studies will follow later.

A preliminary note on the associative action of bacteria in the souring of milk, C. E. Marshall (*Centbl. Bakt. u. Par., 2. Abt., 11 (1904), No. 24-25, pp. 739-744*).—This is noted above from another source.

On the bacteriology of so-called "sterilized milk," W. Robertson and W. Mair (*British Med. Jour., 1904, No. 2283, pp. 1122-1125, dgm. 1*).—Bacteriological examinations were made of 90 samples of so-called sterilized milk supplied by the Leith Corporation for the feeding of infants. Of this number only 14 samples were found sterile. Based upon the results obtained, the authors discuss in a general way the preparation and care of milk for infants.

The formation of film on heated milk, L. F. Rettger (*Studies Rockefeller Inst. Med. Research, 1 (1904), Art. 5, pp. 325-330; reprinted from Amer. Jour. Physiol., 7 (1902), No. 4*).—It is concluded from the experiments reported that the formation of film on heated milk is dependent upon caseinogen, and that the presence of fat and surface evaporation facilitate film formation but are not essential.

Cream testing, C. H. Jones (*Vermont Sta. Rpt. 1903, pp. 191-196*).—Comparative tests were made of measuring and weighing cream containing different percentages of fat. With cream testing less than 40 per cent of fat the use of a correction factor for determinations made with measured cream gave satisfactory results in about 80 per cent of the tests. With cream testing over 40 per cent of fat, 60 per cent of the

tests showed wide divergences. A correction factor is believed to be better than none at all, but if accurate results are desired it is considered necessary to weigh 18 gm. of cream into the test bottle. The data for the tests are reported. A brief summary of the results was given in a previous publication of the station (E. S. R., 15, p. 397).

How long may a finished Babcock test be preserved unimpaired? J. L. Hills (*Vermont Sta. Rpt. 1903, pp. 287, 288*).—Four Babcock tests of fresh unpreserved milk were made by the author in September, 1900. The bottles with their contents, subjected to wide ranges of temperatures, were kept in the dark for 3 years and examined annually. The readings were not impaired at the end of 1 year nor materially affected at the end of 2 years, but were obscured at the end of the third year.

"These results are of interest as indicating the possibilities of preserving the actual analyzed material for future use in cases of dispute. It seems likely that a capped and sealed test bottle, kept in the dark in a cool place, ought to present readable contents for a year or, indeed, 2 years after the tests were made unless perchance the preservative, if such were used, should have some ill effect."

The moisture content of butter and methods of controlling it, G. L. McKay and C. Larsen (*Iowa Sta. Bul. 76, pp. 135–166, figs. 5*).—The authors discuss overrun in butter making and leaky and dry butter and report experiments conducted for the purpose of determining the influence of different factors upon the moisture content of butter.

Directions are given for the calculation of overrun. This, it is stated, should always be made from the fat in the milk or cream delivered by the patron, and not from the composition of the butter. American butter is considered low in water content, about 12 per cent being given as the average. As 16 per cent has been quite extensively accepted as a maximum standard, it is argued that as a matter of business the producer should come as near as possible to this standard without injuring the commercial quality of the butter.

Butter may appear leaky or dull and dry, depending upon the way in which the water is incorporated. The chief factors causing the leaky condition are stated to be churning to small granules, washing very little in cold water, salting heavily while the granules are still small and firm, and working very little in the presence of moisture or brine. The dry appearance may be due to an excess of moisture incorporated by prolonged churning in the buttermilk or wash water, or by churning at a very high temperature. It may also be brought about by overworking, in which case the moisture content as a rule is low. It is stated to be very difficult to differentiate between butter containing much and little moisture. When the moisture has been properly incorporated butter may contain much more than 16 per cent without the fact being recognized except by special methods.

Three experiments were conducted to determine the effect of temperature of cream and wash water on the moisture content of the butter. In each experiment one lot was churned at a temperature of 60 to 64° and one at a temperature of 48 to 54°, all the other conditions being as nearly identical as possible. The average water content of the butter churned at the higher temperatures was 13.83 per cent, and of the butter churned at the lower temperatures 13.24 per cent, indicating no great difference in the moisture content due to temperature alone.

In 6 experiments the influence of the amount of churning was studied. Samples of butter were taken from the same churning at different stages, and in every instance the moisture content was found to increase with the amount of churning, the greatest increase noted being from 13.25 to 22.99 per cent. It is stated that the samples containing a high moisture content appeared a trifle dull in color and very dry, but did not show the moisture in any way. Churning is considered the most effective means of controlling the moisture content of butter.

The effect of overchurning in wash water was studied in 16 experiments. Samples were taken at different stages of churning, as in the previous series. Conditions, such as the temperature of the cream and wash water and the fat content of the cream, varied considerably in the different experiments. Churning at a high temperature and washing with cold water, and also churning at a low temperature and washing with warm water, favored the absorption and holding of considerable moisture. The temperature of the wash water, which it is stated must be left to the judgment of the operator, should be regulated according to the hardness of the butter and in some cases according to room temperature. It is believed that best results can be obtained by using as little wash water as will secure efficient washing. Over 40 per cent of moisture was incorporated in some instances by excessive churning.

"In order to retain the moisture in butter and to incorporate it properly, it is necessary that the butter is not in the hard, round, granular shape when the salt is added. The butter granules must not be churned together to such an extent as to cause butter lumps to appear massive throughout before the salt is added, but the small, somewhat irregular butter granules should be united into larger lumps, so that when the mass of butter is opened with a ladle the small granules can still be distinguished as individuals. At this stage it is in proper condition for salting. By working the butter immediately after the salt has been added, the salt will be dissolved quickly and retained by the butter. Salt has the property of attracting moisture. When added to the butter while in the above-described condition the salt does not seem to have so great a tendency to dislocate and run together the minute drops of water into larger drops. This minute state of division of moisture in butter is seemingly brought about by an increase in churning, a building-up process of moisture and fat globules which can not be accomplished, so far as known, in any other way than by churning it."

In each of 8 experiments all of the conditions were practically alike except the fat content of the cream. The results showed that the richer the cream the higher the water content of the butter. This is attributed to unavoidable overchurning.

In 3 experiments the average moisture content of the butter made from pasteurized cream was 15.06 per cent, and from unpasteurized cream 16.74 per cent, the conditions in each experiment being alike except as regards pasteurization. The buttermilk from the pasteurized cream contained more fat in every instance than the buttermilk from the unpasteurized cream.

The effect of fullness of churn on the moisture content of butter was studied in 5 experiments, the results showing no great difference due to this factor. The average moisture content of butter from small churnings was 16.17 per cent and from large churnings 15.55 per cent. The average moisture content of butter made from sweet cream was 12.09 per cent and from ripened cream 12.62 per cent, indicating that the degree of ripeness had practically no influence upon the moisture content of butter.

The method of incorporating moisture in butter by working in the presence of moisture is condemned. No series of experiments along this line are reported. It is noted that previous experiments have shown that the softer the butter is the easier it will absorb and hold moisture.

In summarizing the work as a whole the conclusion is drawn that temperature, degree of churning, and thickness of cream are the only conditions which materially influence the moisture content of butter; and that if the churning is carried to an excess all the other factors have little or no influence, and also, that temperature is the chief factor affecting the incorporation of moisture on excessive churning. The authors believe that "when temperature of cream and wash water is normal, the per cent of moisture can be easily controlled by different amounts of churning." Increasing the water content of butter by churning in the wash water is considered better than by overchurning in the buttermilk, as the latter method incorporates too much curd and milk sugar.

Experiments on the regulation of the water content of export butter, E. WALLER (*Nord. Mejeri Tidn., 19 (1904), No. 4, pp. 43–45*).—Churning experiments were made under the auspices of Södermanland County Creamery Association, with a view to studying the factors influencing the water content of Swedish export butter. Complete data for the churnings made during the months of March, April, and October, 1903, with the percentages of water contained in the different lots of butter, are given in the paper.

The water content ranged from 11.80 to 16.33 per cent, one of the churnings containing over 14.50 per cent of water, and two less than 12 per cent. The deductions drawn by the author from the results obtained are as follows: A high water content is obtained by continuing the churning as far as can be done without danger of overchurning, so that large butter granules are formed, but not lumps. The butter is furthermore not worked at too low a temperature and not cooled too long or too low between salting and working; if possible, it is cooled at 8 to 9° C., and it is also preferably worked at this temperature, at which there is no special danger of overworking.—F. W. WOLL.

Studies upon the keeping quality of butter. I.—Canned butter, L. A. ROGERS (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 57, pp. 24*).—This bulletin deals with the changes occuring in canned butter, the intention being to submit a second paper treating of packed butter. The decomposition of sugar, casein, albumin, and fat is discussed briefly, reference being made to the literature of the subject.

An examination was made of a number of samples of canned butter collected in China, the Philippine Islands, Cuba, and Porto Rico and kept in Washington for about one year. All of the samples showed more or less decomposition. Bacteriological examinations gave negative results in most instances. The few micro-organisms found belonged to the resistant spore-forming group. The increase in the amount of free acid liberated by the breaking up of glycerids was comparatively small. Sterile butter sealed in small tubes and kept at 23° C. for 100 days showed no increase in acidity, indicating that the decomposition of butter under anaerobic conditions is not due to physical agents such as heat and moisture.

Two lots of freshly canned butter were kept at room temperatures and examined at frequent intervals as regards condition, acid number, and bacterial content. In from 250 to 300 days the samples showed a disagreeable fishy flavor and a strong penetrating odor. An increase in the acid number accompanied the progressive change in flavor. The bacteria found were mostly of the lactic-acid type, although small numbers of yeasts and a few liquefying bacteria were present. The lactic-acid bacteria, constituting in some cases over 99 per cent of the total number, and the yeasts decreased rapidly, being practically absent at the end of 100 days. The changes in acidity and flavor progressed steadily after the disappearance of the micro-organisms, showing that the changes were not due to the direct action of the living cells.

Butter treated with thymol to prevent bacterial growth showed a progressive increase in acidity, while butter from the same lot subjected to heat and also treated with thymol remained practically unchanged as regards acid content: from which the conclusion is drawn that the decomposition is due to an enzym unaffected by the antiseptic but destroyed by the heat. The sources of this enzym, namely, secretion with the milk in the udder and production in the milk or butter by micro-organisms, are discussed. Experiments showed that a species of Torula isolated from butter possessed distinct lipolytic action. The presence of a fat-splitting enzym inherent in milk was shown in an experiment in which butter made from fresh unheated cream and treated with formaldehyde to prevent the growth of micro-organisms showed an increase in acid content, while a control sample made under the same conditions but subjected to heat to prevent the action of enzyms showed no change in the acid content.

"It appears from this record of investigation that the only rational conclusion is that the changes which ordinarily occur, or which first occur in canned butter, destroying its fine, fresh flavor and producing other flavors more or less disagreeable, are due to the liberation of free acid, caused mainly, if not wholly, by the action of an enzym, which, produced in the milk or secreted with the milk in the udder of the cow, is carried over into the butter, or are, in some cases at least, produced in the butter itself through the activity of certain micro-organisms. It seems reasonable to presume that the same agents, the enzyms of the milk acting alone or in conjunction with the yeasts and their resulting enzyms, are responsible for the so-called 'fishy' flavor in butter packed in large but unsealed vessels."

On the keeping quality of sour cream butter and sweet cream radiator butter, A. Voss-Schrader (*Landtmannen, 14 (1903), No. 42, pp. 663, 664; Tidn. Mjölkhushall., 12 (1903), No. 40, p. 158*).—Two series of experiments were made in 5 different Finnish creameries, in which the keeping qualities of butter manufactured from ripened separator cream and of radiator butter were ascertained by two careful scorings, 4 and 26 days apart. The water contents of the different lots of butter were also determined.

The sweet-cream butter scored 0.6 of a point less on the second scoring, on the average, than on the first one (average score 36), while the second score of the sour-cream butter was 3.2 points lower than the first score (average score 35). The average score of the radiator butter was 2.4 points higher than that of the separator butter. The average water contents of the butter manufactured by the two methods were 16.43 and 13.86 per cent for radiator and separator butter, respectively.—F. W. WOLL.

On the keeping quality of butter, S. C. Buhl (*Mälkeritid., 16 (1903), No. 40, pp. 709, 710*).—The author draws the conclusion from the examination of 191 tubs of Danish butter scored when 10 days and 21 days old, that high-grade butter will also prove of superior keeping quality unless there is some specific cause why it will not keep well.—F. W. WOLL.

A study of the chemical changes which take place in cheese during the ripening process, W. P. Gamble (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 54, 55*).—This is a brief summary of the results of the investigations which have been conducted at the Ontario Agricultural College during a number of years.

The chemistry of cottage cheese, F. H. Hall, L. L. Van Slyke, and E. B. Hart (*New York State Sta. Bul. 245, popular ed., pp. 10, fig. 1*).—A popular summary of the bulletin previously noted (E. S. R., 15, p. 1004).

Report of the professor of bacteriology, F. C. Harrison (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 96–112*).—The results of bacteriological work during the year are briefly summarized, and investigations on the duration of the life of the tubercle bacillus in cheese, previously abstracted from other sources (E. S. R., 12, p. 985; 14, p. 292), are reported.

International Congress of Dairying, L. Gedoelst and M. Henseval (*Rev. Gén. Lait, 3 (1904), Nos. 7, pp. 156–163; 8, pp. 181–188; 9, pp. 203–210; 10, pp. 228–233; 11, pp. 253–257*).—A summary of the proceedings of this congress held at Brussels, September, 1903. The addresses and discussions related mainly to the repression of frauds, milk hygiene, and the formation of an international dairy association.

Statistics of the dairy, H. E. Alvord (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 55, pp. 88, maps 4, dgms. 5*).—This is a compilation from the United States Census for 1900, and from other sources, of the principal statistics relating to the dairy industry in the United States, with some similar data for foreign countries, and with explanatory notes.

VETERINARY SCIENCE AND PRACTICE.

A study of natural immunity, R. Turró (*Centbl. Bakt. u. Par., 1. Abt., Orig., 36 (1904), No. 1, pp. 103–111*).—The literature of this subject is briefly discussed. The author's experiments were largely confined to a study of oviserum obtained from a solution of the yolk of hen's eggs in albumen. After a period of 20 to 30 days this mixture developed such a pronounced bacteriolytic power as to destroy ¼ of its weight of an anthrax culture without losing any of its strength. Repeated injections of oviserum followed by inoculation with anthrax bacilli were found to hasten the death of rabbits. A single injection of 5 gm. oviserum per 1 kg. of live weight of the animal was found to prolong the course of the disease.

A report on infection, natural and artificial immunity, toxins, immune sera, etc. (*Jahresber. Thier-Chem., 32 (1903), pp. 889–986*).—An elaborate bibliography is presented of literature relating to this subject and published during the year 1902. The more important articles are reviewed at considerable length.

Immune sera, A. Wassermann, trans. by C. Bolduan (*New York: John Wiley & Sons, 1904, pp. IX+77, figs. 4*).—In this volume a general account is given of the nature, chemical affinities and action of hemolysins, cytotoxins, and precipitins. The relation of these bodies is discussed with special reference to the various theories of immunity and susceptibility to bacterial diseases.

The coagulating power of serum, J. Bordet and O. Gengou (*Ann. Inst. Pasteur, 18 (1904), No. 2, pp. 98–115*).—This article contains the results of the continuation of the authors' studies regarding the coagulation of the blood and the factors which are concerned in this process. It was found during these investigations that the serum possessed not only the power of coagulating fibrinogen, but also of increasing considerably the production of fibrin ferment at the expense of the ferment which was peculiar to the blood plasma. The power of transforming fibrinogen into fibrin was exercised even in the absence of lime, while the increase in the production of ferment requires the presence of calcium salts for its operation.

Experiments relating to the phenomenon of agglutination, C. Nicolle (*Ann. Inst. Pasteur, 18 (1904), No. 4, pp. 209–240, figs. 7*).—Attention is called to the necessity of adopting a uniform technique in arriving at satisfactory results from experiments in different phases of agglutination. The author's experiments involved the use of a number of bacterial organisms, especially the typhoid bacillus, and the experimental animals were chiefly rabbits. While it is possible to produce a specific and quite powerful agglutinin in bacterial cultures, this agglutinin is considered as distinct from the agglutinin produced in a living animal body by the use of cultures of the same bacillus. The agglutinin is apparently, in the case of some species of bacteria, produced by the flagella of the bacteria.

Contributions to the study of hemagglutinins and hemolysins, W. W. Ford and J. T. Halsey (*Jour. Med. Research, 11 (1904), No. 2, pp. 403–425*).—As a result of the comparative study of the various chemical bodies in the blood of mammals and birds the authors conclude that the use of the constituents of the blood corpuscles, laked blood, or stroma of one species of animal results in the production of specific bodies—lysins and agglutinins. In a serum which is strongly hemolytic, a rapid solution of the blood corpuscles conceals the appearance of agglutination. In an immune serum the solution of the blood corpuscles in high dilutions may not take place, although agglutination occurs promptly. It is concluded that the phenomena of agglutination and lysis can not be made to occur independently by the injection of different constituents of the blood corpuscles. These phenomena are held to be inseparably connected.

Blood immunity and blood relationship, a demonstration of certain blood relationships amongst animals by means of precipitin tests for blood, G. H. F. Nuttall (*Cambridge: Univ. Press, 1904, pp. XII+444, pls. 2, figs. 4*).—The

purpose of this volume is to discuss the results of an extensive series of experiments conducted by the author in determining the relationship of animals to one another by means of blood tests.

A general account is given regarding the nature of toxins, ferments, agglutinins, and precipitins of various sorts with especial reference to the action of these bodies in the production of immunity. The volume also contains an account of quantitative tests with precipitins for the blood of mammals and birds and a discussion of the blood relationship between the lower vertebrates and arthropods, as shown by 2,500 tests with precipitating antisera. In carrying out these last-named experiments, the author was assisted by T. S. P. Strangeways and G. S. Graham-Smith. The literature relating to serum constituents and immunity is critically discussed in connection with an extensive bibliography.

As a result of the author's experiments, it appears that there are many points of resemblance between different antibodies. It is suggested that much improvement may be made in the methods of obtaining antisera for use in precipitin tests. The precipitins and precipitable substances combine in a quantitative manner. The rate of interaction between these two substances is greatly influenced by the temperature being retarded by cold and hastened by heat. Apparently the precipitin content of serum in the body undergoes considerable fluctuation during the process of immunization. As a rule, precipitins and antisera are strictly specific in action when used in high dilutions. The more powerful the antisera is, however, the greater is its action upon blood of different species of animals.

Atlas and outlines of bacteriology, a text-book of special bacteriological diagnosis, K. B. Lehmann and R. O. Neumann (*Atlas und Grundriss der Bakteriologie und Lehrbuch der Speziellen Bakteriologischen Diagnostik. Munich: J. F. Lehmann, 1904, 3. ed., vol. 1, pp. 94, pls. 76; vol. 2, pp. XVI+623, figs. 38*).—In this volume the authors present a general account of bacteriology including the classification, biology, and morphology of bacterial organisms and pathogenic microbes. The functions and physiological action of bacteria are considered in detail and special accounts are presented on the biological relations and pathological effects of various bacteria which cause diseases of animals and plants.

Bacteriological diagnosis for veterinarians and students of veterinary science, J. Bongert (*Bakteriologische Diagnostik für Tierärzte und Studierende. Weisbaden: Otto Nemnich, 1904, pp. VI+276, pls. 20, figs. 7*).—This volume contains an account of the use of the microscope in the diagnosis of animal diseases, methods of microscopic and bacteriological examination, the morphology and biology of bacteria, and a detailed account of biological and morphological characters of the various bacterial organisms which are pathogenic for animals.

Staining certain bacteria (glanders bacillus, typhoid bacillus, etc.) in sections of the skin and other organs, K. Zieler (*Centbl. Allg. Path. u. Path. Anat., 14 (1903), No. 14, pp. 561–565*).—The author's method consists in the use of any desired fixing and hardening solution and in embedding in paraffin. Sections are then stained for 8 to 24 hours in a solution of orcein, after which they are washed in alcohol and water, stained in polychromic methylene blue, and differentiation of internal structures is brought about by treatment with a mixture of glycerin and ether.

A simple method of demonstrating the presence of bacteria in the mesentery of normal animals, A. G. Nicholls (*Jour. Med. Research, 11 (1904), No. 2, pp. 455–468, pl. 1*).—During the author's experiments on the lower animals it was found that bacteria could be demonstrated in the mesenteries and in various internal organs of normal animals. It is concluded, therefore, that the old doctrine of the sterility of normal organs is a false conception. The author believes that normal organs are not actually sterile but only potentially so. Bacteria may be readily carried into them and, in health, undergo quite rapid destruction.

32846—No. 11—04——7

A study of chronic infection and subinfection by the colon bacillus, G. A. Charlton (*Jour. Med. Research, 11 (1904), No. 2, pp. 507–519*).—The inoculation experiments reported in this paper were made in rabbits. It was found that as a result of infection with the coli bacillus a pronounced anemia was produced, somewhat resembling pernicious anemia in man, and accompanied with a great diminution in the number of red blood corpuscles. The disease differs from pernicious anemia, however, in producing a decrease of hemoglobin parallel with the decrease of the red blood corpuscles. In advanced stages of infection a diffuse degeneration of the spinal cord was brought about affecting chiefly the posterior and lateral columns of the cord.

The action of artificial oxydases on the toxin of tetanus, A. Lumière et al. (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 10, pp. 652–654*).—Experiments were carried out during which artificial oxydases composed largely of mineral substances, such as salts of manganese, iron, and cerium were used in testing their effects upon tetanus toxin. The samples of the toxin thus treated were later tested by the inoculation of guinea pigs. It was found that these artificial oxydases, whether of an alkaline or acid reaction, exercise considerable effect upon the toxin of tetanus. The salts of cerium, cobalt, and nickel, as well as those of iron and manganese, attenuate or entirely destroy tetanus toxin.

Proceedings of the American Veterinary Medical Association for 1903 (*St. Paul: Pioneer Press Co., pp. 346, pl. 1, figs. 60*).—The fortieth annual meeting of the association was held in the City Hall, Ottawa, Canada, September 1–4, 1903. The papers which were read at these meetings have been previously noted (E. S. R., 15, pp. 112–119). The present published form of the proceedings contains four other papers which were read by title only, together with a list of the members and an account of the business of the sessions.

Tumors in domesticated animals, J. Desmond (pp. 204–212).—In this paper submitted by the government veterinarian of South Australia, an account is given of various tumors of horny and other nature as observed in domesticated animals. Horns on the skin of animals are classified in 4 varieties, viz, sebaceous, wart horns, hoof horns, and cicatricial horns. Notes are also given on tumor-like growths in various organs, especially a case of true endothelioma, which is reported as the first case of this sort observed in animals.

An outbreak of epizootic encephalitis of the horse in South Carolina, G. E. Nesom (pp. 213–215).—This disease is said to have prevailed in the South for more than 50 years, being especially severe in the southern Atlantic States. It has been known by a number of common names and has been referred to a number of causes. The author believes, however, that all well-investigated cases are due to eating damaged corn or hay, or sometimes both of these feeds, in a moldy or spoiled condition.

A question relating to the serum-therapy of the aphtha epizootica—its actual state, E. Perroncito (pp. 283–291).—The literature relating to this subject is critically reviewed by the author. The results obtained thus far are encouraging but are not quite satisfactory. It is urged that further study should be made of this problem in order to devise means for the preparation of a more efficient serum in the treatment of foot-and-mouth disease.

A preliminary report on the sheep disease, ictero-hæmaturia, in Western Montana, H. P. Johnson (pp. 301–313).—This disease was observed in Montana in 1890. It is largely confined to Deer Lodge and Silver Bow valleys. The disease is considered as identical with carceag of Europe, and is due to the action of the blood parasite *Piroplasma ovis*. The means of transmission of the disease are not understood. It is suggested that this occurs through the agency of some biting insect, perhaps the sheep tick. Experiments with this insect, however, gave negative results. No success was had in reproducing the disease by means of inoculation with virulent blood. It is suggested, therefore, that infection with this disease requires a peculiar susceptibility derived by digestive organs.

Report of the live stock sanitary board of Wisconsin for 1901-2, G. McKerrow, E. D. Roberts, and H. L. Russell (*Wisconsin State Live Stock Sanit. Bd. Rpt. 1901-2, pp. 71, pls. 2*).—During the 2 years under report a study was made of tuberculosis in cattle. Numerous tuberculin tests were made and the data obtained from these tests are presented in a tabular form. Notes are given on the geographical distribution of the disease in the State of Wisconsin.

Statistics were collected regarding the comparative susceptibility of different breeds of cattle to tuberculosis. From the data thus obtained it is impossible to conclude that 1 breed is more susceptible than another. The most important means of spreading the disease from place to place is believed to be through the medium of animals which are bought and sold. A copy is given of regulations of the live-stock sanitary board regarding methods of disposal of the carcasses of tuberculous animals, isolation and quarantine of tuberculous animals, and shipment of such animals for immediate slaughter. The authors discuss briefly the subject of disinfection of premises after the prevalence of contagious diseases. Recommendations are made of various chemicals for use in such work.

Glanders is said to be a very serious disease in the State. A large proportion of cases appear to originate from range horses imported from western States. A copy is given of a regulation regarding the quarantine and inspection of such horses. Notes are also given on anthrax. This disease in 1 outbreak was shown to be carried for considerable distance in water which percolated through the soil. The prevalence of rabies, hemorrhagic septicemia, and blackleg are also discussed.

Report for the years 1902-3 of the principal of the Royal Veterinary College, J. McFadyean (*Jour. Roy. Agr. Soc. England, 64 (1903), pp. 262-285*).—Anthrax is said to be on the increase throughout Great Britain. This spread of the disease is not believed to be due to local conditions, but to fresh importation of the pathogenic micro-organisms from outside sources. The suggestion is made that infection in many instances may be due to the importation of infected feeding stuffs. Hog cholera appears to be on the decline. Statistics show that the number of cases in 1903 was considerably fewer than in the previous two years. It is not believed possible, however, to eradicate this disease for some time to come.

Glanders is more prevalent than heretofore. Numerous experiments were made in the application of the mallein test and the question of infection from reactors and ceased reactors was tested. It was found that horses which merely react to glanders are capable of transmitting the disease, but that such transmission does not occur as a rule. During the author's experiments eleven ceased reactors were placed in contact with healthy horses without any case of transmission of the disease having been observed as a result.

Notes are given on the status of the problem of tuberculosis. The author believes that the evidence points to the identity of the human and bovine forms of this disease. A contagious disease of the udder in cows was observed, and experiments in combating this trouble indicate that the general cleansing and disinfection of the premises repeated three times is sufficient to check the disease in a decided manner.

Brief notes are also given on stomach worms in ruminants, on a form of vaginitis in breeding ewes, and on the introduction of epizootic lymphangitis among the horses of Great Britain. The occurrence of this disease in Great Britain is believed to be due to importations which occurred during the progress of the South African war.

Report of the division of veterinary science, J. A. Gilruth (*New Zealand Dept. Agr. Rpt. 1903, pp. 190-336, pls. 23, figs. 2*).—A brief statement is given of the staff of veterinarians and inspectors in the veterinary service of New Zealand, together with notes on laboratory work, registration of veterinary surgeons, veterinary lectures to farmers, unsoundness in horses, quarantine regulation, strangles, dairy inspection, management of dairy herds, and inspection in abattoirs. On account of the increasing importance of strangles the author recommends that immediate steps be taken

to control this disease. Statistics are presented showing the number of carcasses condemned in the prosecution of meat inspection, and the causes for which condemnation was made. Certain desirable changes are suggested in the inspection law of the colony.

The work on tuberculosis during the year was largely of a routine nature. A general discussion of the relationship of bovine and human tuberculosis is presented, in which the position is taken that these two forms of the disease are due to the same organism and are intertransmissible.

An elaborate study was made of hepatic cirrhosis in horses and cattle. This is a continuation of studies which have been in progress for a number of years and the author was able to demonstrate clearly that the cause of this disease is *Senecio jacobaea*. This plant is described and notes are given on its distribution in New Zealand and elsewhere. The disease has existed in New Zealand for the past 20 years and has seriously affected both horses and cattle. The symptoms during the whole course of the disease in horses and cattle are described in detail, and notes are given on the pathological changes in the liver. The most characteristic lesions occur in this organ in the form of extravasations of blood, distension of the intralobular veins, coalescence and formation of hepatic giant cells, deposition of brownish-yellow pigment in the liver cells, and the accumulation of an interlobular fibrillar tissue which causes the characteristic cirrhotic appearance.

Numerous experiments were made in feeding this plant in various conditions to horses and cattle. During these experiments it was shown that the disease could readily be produced by feeding the plant in a cut and dried condition or in a green condition. Where the plant was allowed to stand on the ground until entirely dead and dry, however, the poisonous principle seemed to have been lost. The characteristic symptoms with fatal outcome were brought about by allowing horses and cattle to feed upon the plant in bloom in an inclosed field. Sheep withstand the effects of the plant for long periods and apparently relish the weed. Under certain circumstances however, especially after long-continued grazing upon the plant, cirrhotic conditions are produced in sheep.

In treating the disease no satisfactory results can be expected after pronounced lesions have developed in the liver. In the early stages of poisoning, however, apparent recovery was brought about by the administration of Barbados aloes in 7 dr. doses followed by strychnin in doses of $\frac{3}{4}$ gr. for 1 month or longer. In some cases of apparent recovery, however, the disease subsequently recurred with fatal results. In cattle treatment with strychnin and sodium sulphate gave the best results. The disease is believed to be identical with Pictou disease of Canada and with 1 form of stomach staggers reported from Great Britain.

Notes are also given on contagious mammitis in cows, anthrax, contagious abortion in cattle, hog cholera, blackleg, verminous pneumonia, various tumors in domestic animals, etc. The cause of 1 outbreak of contagious mammitis was found to be a streptococcus which produced no serious results in guinea pigs, rabbits, and cattle when inoculated subcutaneously or intravenously, but produced mammitis in cattle when injected into the udder. It was shown that the disease was transmitted from 1 animal to another on the hands of the milker. Anthrax spores were demonstrated in bone fertilizer, and the importance of this fact is emphasized by the author. The careful application of antiseptic measures were successful in eradicating contagious abortion from a number of herds. Attention is called to the importance of a serum test in the diagnosis of doubtful outbreaks resembling hog cholera. It was found that a red coloration observed in certain samples of butter was due to the growth of *Aspergillus nidulans*.

Report of chief veterinary inspector, J. G. RUTHERFORD (*Rpt. Min. Agr. Canada, 1903, pp. 69-151*). The author calls attention to the organization of the veterinary-inspection service of the Dominion of Canada, with special reference to

the work of the various inspectors in different parts of Canada and of the biological laboratory. Notes are given on hog cholera, tuberculosis, glanders, Pictou cattle disease, sheep scab, cattle mange, blackleg, foot-and-mouth disease, and various other diseases of domesticated animals.

The spread of hog cholera is said to be partly due to difficulty in obtaining strict observance of quarantine regulations by railroad employees and to the tendency of farmers to conceal cases of the disease. Glanders has prevailed to a serious extent. During the season 313 horses were destroyed after a positive reaction from the mallein test. The author outlines his method of quarantining incipient cases of glanders, some of which recover.

Notes are also given on the quarantine stations, car inspection, and stock yards.

The pathologist, C. H. Higgins, presents a report on the operations of the biological laboratory (pp. 93–107). This work involved a study of anthrax, tuberculosis, glanders, hog cholera, hemorrhagic septicemia, actinobacillosis, and Pictou cattle disease. Reports are also presented by various other inspectors concerning the prevalence of animal diseases in various parts of Canada.

In a study of Pictou cattle disease some corroboration was obtained for the belief that this disease is due to the *Senecio jacobœa*. The evidence obtained in Canada, however, is not considered conclusive, and arrangements have been made for an extensive experiment for determining this point on a farm of 200 acres rented for the purpose.

Report of the chief inspector of stock, J. R. WEIR (*Jour. Dept. Agr. Victoria, 2 (1903), No. 3, pp. 242–244*).—The recent prolonged droughts caused an unusual number of deaths among the stock on account of the scarcity of suitable forage upon the range. Notes are given on the prevalence of tuberculosis, actinomycosis, and swine diseases.

Diseases of stock, W. E. DAVIDSON (*Pretoria: Government Office, 1903, pp. 12.*)—Copies are given of the regulations made by the Lieutenant-Governor of the Transvaal regarding the importation and quarantine requirements for domestic animals. Specific statements are made concerning rinderpest, pleuro-pneumonia, tuberculosis, foot-and-mouth disease, glanders, anthrax, sheep scab, and hog cholera.

Quarantine rules and regulations (*Gen. Circ. West. Trunk Lines, No. 72, pp. 80*).—Copies are presented of quarantine rules and regulations of the United States Department of Agriculture and of the various States and Territories, Mexico, and Canada, in so far as these rules apply to State and interstate traffic. The circular is revised up to February 22, 1904.

Canadian regulations relating to animals' quarantine (*Ottawa: Government Printing Office, 1904, pp. 15*).—Copies are given of quarantine regulations issued by the Canadian Government regarding the importation of cattle, sheep, hogs, horses, mules, and other animals for the purpose of controlling the distribution of infectious diseases.

Lessons in disinfection and sterilization, F. W. ANDREWS (*London: J. & A. Churchill, 1903, pp. 222; rev. in Public Health* [*London*], *16 (1904), No. 6, p. 374*).—As explained by the subtitle, this volume, which is an expansion of a series of lectures delivered to hospital nurses, presents an elementary course of bacteriology, together with a scheme of practical experiments illustrating the subject-matter.

Experiments in burning animal bodies in the open air, G. I. SVYETLOV *Arch. Vet. Nauk, St. Petersburg, 34 (1904), No. 3, pp. 235–253*).—A commission was appointed from the Russian veterinary service for the purpose of investigating the feasibility of burning bodies of animals dead of contagious diseases and the best methods for accomplishing this. Notes are given on the time required for complete incineration of such carcasses under different conditions.

The disposal of animal carcasses by incineration, LOTHES and O. PROFÉ (*Fortschr. Vet. Hyg., 1 (1904), No. 12, pp. 325–328*).—Data are presented showing

the amount of wood or other fuel necessary for incinerating given weights of animal bodies. The cost of destroying the carcasses by this method may be readily estimated from such data. While it is recognized that this method involves the destruction of much valuable material, it is considered necessary for the present to incinerate carcasses of animals dead of highly infectious diseases.

Abridged bibliography of infectious diseases, D. MONFALLET (*Bibliographie Abrégée des Infections. Paris and Santiago: C. Goffi, 1903, pp. 65*).—In this bibliography the author's purpose was to present for the practical investigator and student a list of the most important publications relating to the various infectious diseases of animals and man. The number of diseases on which bibliographies are presented is about 90.

The principles and conditions of combating epizootic diseases, V. NAGORSKI (*Arch. Vet. Nauk, St. Petersburg, 34 (1904), No. 1, pp. 1–26, figs. 7*).—A general discussion of the principles involved in eradicating infectious diseases, including an account of quarantine measures, medicinal treatment, disinfection, and preventive vaccination.

The relations of human and bovine tuberculosis, V. A. MOORE (*Cornell Countryman, 1 (1904), No. 5, pp. 137, 138*).—The author outlines in a brief manner the history of the controversy regarding the identity of these 2 forms of tuberculosis. The opinion is maintained that results of investigations indicate conclusively that human and bovine tuberculosis are essentially identical.

Human and bovine tuberculosis, A. D'ESPINE (*Rev. Sci. [Paris], 4. ser., 20 (1903), No. 19, pp. 593–596*).—The author reviews briefly the literature bearing on the relationship between these 2 forms of tuberculosis, and concludes that the evidence is very strong in favor of their identity.

Tuberculosis of cattle as related to that of man, E. PERRONCITO (*Extract from Gaz. Med. Ital., 54 (1903), No. 22, pp. 4*).—As a result of the author's experiments and studies of this disease together with a review of the literature of the subject, it is concluded that the human and bovine forms of tuberculosis are essentially the same and are intertransmissible.

An inquiry into the primary seat of infection in 500 cases of tuberculosis, J. O. SYMES and T. FISHER (*British Med. Jour., 1904, No. 2259, pp. 884, 885*).—On account of the importance of determining the extent of infection of man from eating the milk and meat of tuberculous animals, statistics were compiled by the authors relating to 500 fatal cases of tuberculosis in man. From these statistics it appears that, if the local foci of disease are considered as evidence of the primary seat of infection, the percentage of infection during the first 12 years of life is 4 times as great in the air passages as in the alimentary tract.

The reaction of tuberculous animals to subcutaneous infection with the tubercle bacilli, F. A. DELLA CELLA (*Centbl. Bakt. u. Par., 1. Abt., Orig., 36 (1904), No. 1, pp. 12, 13*).—Experiments were carried out for the purpose of determining what local alterations are caused as a result of subcutaneous inoculation with tubercle bacilli. For this purpose cultures were used which, in moderate doses, caused the death of guinea pigs within a period of 2 weeks. It was found that by greatly reducing the size of the dose the course of infection was much slower.

In 1 experiment 10 guinea pigs were inoculated and 20 days after infection were again inoculated subcutaneously with a minute dose of virulent tubercle bacilli. In nontuberculous animals similarly inoculated no local reaction took place until after 12 days, while in the tuberculous animals a pronounced local lesion was observed on the day following the inoculation. Similar results obtained in other experiments convinced the author that there existed a sort of local immunity in the subcutaneous connective tissue against tubercle bacilli. This immunity is brought about by previous inoculation and is indicated by the almost uniform absence of tubercle bacilli at the point of inoculation in tuberculous animals and the presence of the bacilli in control animals.

The morbid anatomy and etiology of avian tuberculosis, V. A. Moore (*Jour. Med. Research, 11 (1904), No. 2, pp. 521–536, pl. 1*).—The literature of this subject is critically reviewed in connection with numerous bibliographical references. Notes are given on the symptoms of tuberculosis in fowls and on the pathological lesions. A number of experiments were carried on for the purpose of determining the method of natural infection. Negative results were obtained from feeding fowls on the sputum of tuberculous patients, but it appears probable that infection of fowls naturally takes place through the alimentary tract, and that the disease is spread largely through the excreta.

The tuberculosis (animal) compensation bill, A. J. Laird (*Public Health [London], 16 (1904), No. 7, pp. 418–421*).—The author states that considerable support has been promised in Parliament to a proposed bill granting indemnity for slaughtered tuberculous animals. Attention is called to the various opportunities which will be furnished for frustrating the legitimate purposes of this bill and for the practice of fraud in obtaining indemnities.

On anthrax, J. Dunstan (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 16 (1904), pp. 75–91*).—This disease is reported as being on the increase in Great Britain, despite the efforts which have been made to control it. The number of animals which die annually of the disease is, however, rather small as compared with the losses from other causes. Detailed notes are given on the symptoms, methods of diagnosis, and the control of the disease.

The morphology and biology of anthrax bacillus, H. Preisz (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1904), Nos. 3, pp. 280–293; 4, pp. 416–434; 5, pp. 537–545; 6, pp. 657–665, pls. 2*).—An elaborate study was made of the various forms under which the anthrax bacillus occurs on different nutrient media with special reference to the formation of spores. The literature relating to this subject is reviewed in connection with a bibliography.

Preparations of anthrax bacillus were stained in different ways, and a study was made of the various structures which could be identified in the body of the bacillus after treatment with different stains. As a result of the author's study of this organism, it is concluded that the formation of spores always takes place in the end of the cell and that the peripheral layer of the cell body is especially concerned in this process. The author believes that the cell nucleus is not related to the spore. It was found in studying the various cultures of the anthrax bacillus that a certain percentage of them could not be induced to form spores.

Investigation of natural and artificial immunity to anthrax, A. Pettersson (*Centbl. Bakt. u. Par., 1. Abt., Orig., 36 (1904), No. 1, pp. 71–83*).—This article is occupied with a discussion of artificial immunity to anthrax in dogs. During these studies the author carried out numerous inoculation experiments and examined various tissues from pathological and chemical standpoints. It was found that infection of anthrax produces considerable increase in the bactericidal power of the blood. The serum in itself appears to be quite inactive both before and after infection. During the process of immunization of the dog toward the anthrax, no formation of new immune bodies takes place, but the production of complement is considerably increased. There is also a marked increase in the number of leucocytes, which probably assist in distributing the complement to points where it may be most effective.

The immunizing action of the nucleoproteid extracted from anthrax bacilli, N. Tiberti (*Centbl. Bakt. u. Par., 1. Abt., Orig., 36 (1904), No. 1, pp. 62–71*).—The author describes in detail his method of obtaining a nucleoproteid from anthrax bacilli. The experimental animals used by the author were rabbits and guinea pigs. In 1 series of experiments, 12 rabbits were treated with varying doses of nucleoproteid and inoculated gradually with virulent cultures of anthrax at different periods of time, and of this number 8 survived while 4 became infected with anthrax.

In a second experiment, 9 out of 12 rabbits resisted infection. The author concludes, therefore, that it is possible to produce an active immunity in a majority of cases by inoculation with the nucleoproteid contained in anthrax bacilli.

The bactericidal power of plasma-free blood, plasma, and serum of normal pigeons and those which have been immunized against anthrax, S. SPANGARO (*Centbl. Bakt. u. Par., 1. Abt., Orig., 36 (1904), No. 1, pp. 83–91*).—The author describes his method for obtaining what he denominates pure blood, or blood free from plasma. Such material and also the plasma and serum were tested for the purpose of determining their bactericidal action. The plasma and serum were found to possess no demonstrable bactericidal power, while this power in pure blood was very conspicuous. The difference between the blood of the normal and immunized pigeons consists simply in the intensity of the bactericidal power, being much greater in the latter. A large quantity of bacilli in pure or plasma-free blood may be completely destroyed within a period of 2 or 3 hours.

Transmission of African coast fever, C. P. LOUNSBURY (*Agr. Jour. Cape Good Hope, 24 (1904), No. 4, pp. 428–432, pls. 3*).—According to the investigations thus far made on the etiology of African coast fever it appears that the brown tick (*Rhipicephalus appendiculatus*) is the chief and perhaps the only natural means of transmitting this disease to cattle.

The brown tick is widely distributed in South Africa. Notes are given on the habits and life history of the tick with especial reference to the relationship between its habits and the transmission of the disease. The brown tick is found chiefly on cattle, but may also infest horses, asses, mules, sheep, goats, dogs, and cats. It was first shown in November, 1902, that this tick was concerned in the transmission of African coast fever, and subsequent experiments have confirmed the results obtained at that time.

The most effectual means of controlling the brown tick has been found in repeated dipping in arsenical dips. This process may take place every 2 weeks during the warm season, and is effective in destroying other species of ticks as well as the one under consideration.

Rhodesian redwater or African coast fever, R. KOCH (*Agr. Jour. Cape Good Hope, 24 (1904), No. 5, pp. 549–560*).—This constitutes the author's fourth report on the subject of African coast fever. Many of the experiments reported in previous articles have been repeated and results obtained which are believed to be reliable.

The general results of the author's investigations indicate that African coast fever is a cattle disease due to a specific blood parasite distinct from that of Texas fever. The 2 diseases, however, may exist simultaneously in the same animal and, under such circumstances, hemoglobinuria is observed. The disease did not originate in Rhodesia, but was introduced from the eastern coast. It is not transmissible directly, but only through the agency of ticks. The mortality is very high, usually about 90 per cent. Recovered animals are immune to subsequent attacks, but retain small numbers of the parasites in their blood. Such animals are therefore capable of transmitting the disease to other animals through the agency of ticks.

The disease can not be reproduced by means of single injections of virulent blood. Repeated injections, however, at intervals of 2 weeks produce a mild infection, which after a period of 4 or 5 months results in a permanent immunity. In obtaining blood for inoculation purposes care should be exercised that it does not contain organisms of other diseases. Notes are also given on other means of prevention, especially dipping for the destruction of ticks.

Heart-water inoculation experiments, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 24 (1904), No. 4, pp. 433–442*).—Experiments had already indicated the possibility of immunizing goats to heart-water by means of intravenous injections of the blood of recovered animals. The animals which had just been immunized were exposed to natural infection with virulent heart-water, and were also inoculated

intravenously with virulent blood. The results obtained from this experiment were highly satisfactory. It appeared that the 3 sheep used in the experiment successfully withstood the inoculation with large doses of virulent blood, while 1 of the 2 goats resisted inoculation and the other died.

The organism of toxemic hemoglobinemia in cattle in Kuban, Russia, E. Djatschenko (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1904), No. 6, pp. 727–729*).—In studying cases of this disease the author found a spirillum which grew rapidly on agar at a temperature of 27 to 30° C. Inoculation experiments were made on rabbits, white rats, and mice with negative results in every case. The author believes, however, that the organism which he discovered may prove to be the cause of the disease and proposes for it the name *Spirillum tschichir.*

An epizootic outbreak of rinderpest and preventive vaccination in various parts of Samarkand, L. Motzarski (*Arch. Vet. Nauk, St. Petersburg, 34 (1904), No. 2, pp. 144–173, fig. 1*).—An account is given of the serious outbreak of rinderpest which occurred in the Province of Samarkand in June, 1903. In combating this outbreak the author carried on a number of experiments in the application of preventive vaccination.

As a result of these experiments it was found that the development of the disease in isolated localities could be quickly and decisively checked by the thorough application of preventive vaccination to all of the cattle. The effect of vaccination on healthy animals was not serious; the curative action of the vaccine gave little encouragement to the use of vaccination for this purpose. The immunity, however, as produced in healthy animals was effective and lasting.

Notes on the different degrees of susceptibility to rinderpest exhibited by the various pure and mixed breeds of bovines and buffaloes submitted to serum test during the years 1899–1903, A. Lingard (*Muktesar, India, 1903, pp. 12*).—During the author's extended investigations of this disease it was found that the breed is a very important factor in determining the dose of serum necessary for producing immunity. It was found that the half-bred hill and plains animals require from 15 to 18 times the quantity of serum which is necessary for producing immunity in plains animals. The cattle and buffaloes from the high regions of the Himalayas are far more susceptible to rinderpest than any of the animals found in the plains regions. The same is true of goats and sheep from the Himalayas region. Half-bred animals exhibit generally the relative insusceptibility of the plains cattle.

The preparation of dry, anti-rinderpest serum, E. Dschunkowsky and J. Kupzis (*Centbl. Bakt. u. Par., 1. Abt., Orig., 36 (1904), No. 1, pp. 91–94*).—During the experiments reported in this paper it was found possible to obtain a dry antirinderpest serum in a readily transportable form by a desiccation of fluid serum in thin layers upon glass plates after the addition of $\frac{1}{5}$ per cent sodium hydrate. The quantity of dry serum averaged about 10 per cent as great as the fluid serum. The dry serum was readily soluble in water and so far as experiments have been conducted is as effective as the fluid serum.

Infectious abortion among cattle, J. W. Connaway (*Mo. Bul. Missouri State Bd. Agr., 3 (1904), No. 12, pp. 8*).—The cause of this disease and the means of distribution are briefly discussed by the author. Attention is called to the fact that some breeders conceal the presence of outbreaks of the disease and thus contribute to its more extensive distribution. The symptoms of the disease are described and the usual preventive and curative measures are recommended.

Contagious abortion in Montana, H. C. Gardiner (*Montana Sta. Bul. 49, pp. 167–176*).—From circular letters sent to various parts of the State it was found that this disease prevails to an unusual extent among dairy cows of the State. Notes are given on the symptoms of the disease and the methods of transmission and treatment. The author recommends the thorough use of disinfectants in controlling the disease.

The new treatment of milk fever in cows, J. LAW (*Cornell Countryman, 1 (1904), No. 2, pp. 43–48*).—A historical statement is given concerning the various treatments which have been applied in attempts to control this disease. Notes are also given on the nature and symptoms of milk fever. Particular attention is devoted to the treatment of the disease by means of injection of oxygen and air. The details of this treatment are outlined and notes are given on the author's experiments in its application. It is recommended as a highly effective treatment for milk fever.

Suppuration of the milk ducts in cows, E. THIERRY (*Jour. Agr. Prat., n. ser., 7 (1904), No. 10, p. 312*).—When inflammatory processes result in the establishment of suppuration in the teats of cows the author recommends frequent milking and injections of antiseptics, such as borate or fluorid of soda.

Permanent infection of the mammary gland, H. D'ANCHALD (*Jour. Agr. Prat., n. ser., 7 (1904), No. 12, p. 400*).—Attention was called to the importance of mammary affections in dairy cows and to the means by which such troubles can be controlled.

Sterility in cattle, E. THIERRY (*Jour. Agr. Prat., n. ser., 7 (1904), No. 16, pp. 521–523*).—The various causes of sterility or barrenness in cattle are briefly outlined with especial reference to the dietetic, medicinal, and surgical treatments which have been found successful in controlling this trouble.

Actinomycotic orchitis in bulls, I. M. COVALEVSKI (*Arch. Vet. Nauk, St. Petersburg, 34 (1904), No. 3, pp. 254–257*).—Notes are given on the symptoms and pathogenic anatomy of actinomycosis in the testis.

Papillomatosis in cattle, A. ZIMMERMANN (*Fortschr. Vet. Hyg., 2 (1904), No. 1, pp. 18–22, fig. 1*).—The appearance and pathological anatomy of wart-like outgrowths upon the skin of cattle are discussed with especial reference to a generalized case with fatal outcome which came under the author's observation.

Ergotism in cattle, N. S. MAYO (*Industrialist, 30 (1904), No. 25, pp. 399–401*).—During the season of 1902 an unusual amount of ergot was observed on wild rye and wild barley. Brief notes are given on outbreaks of ergotism which occurred during 1903.

Dipping tanks (*Jour. Jamaica Agr. Soc., 8 (1904), No. 3, pp. 93–96*).—Formulas are presented for the preparation of cattle dips containing soda, soap, Stockholm tar, and arsenic. Dips may be used for both horses and cattle, and both kinds of animals may be driven into the same dipping tanks. Brief notes are given on the general physiological effects of dipping upon animals.

Departmental dipping experiments (*Natal Agr. Jour. and Min. Rec., 7 (1904), No. 3, pp. 315–317*).—A proprietary dip paste for the destruction of ticks on cattle was given a thorough test. It was found that when used in too strong a solution it destroyed the ticks within 3 days, but affected the appetite of the animals unfavorably and also caused considerable injury to the skin. These unfavorable effects were avoided when the dip was diluted to such an extent that 5 days were required for the destruction of the ticks.

Calcium sulphid as a remedy for mange (*Rev. Asoc. Rural, Uruguay, 32 (1903), No. 20, pp. 490–494*).—The use of lime-sulphur dips is recommended for the control of sheep scab and mange of other domestic animals. Formulas are given for the preparation of these dips, together with notes on the effectiveness of calcium sulphid.

The sheep maggot-fly, R. S. MACDOUGALL (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 16 (1904), pp. 128–143*).—In Scotland a number of flies occasionally lay their eggs in the wool of sheep, but the two species of greatest importance are *Lucilia sericata* and *L. cæsar*. The percentage of infestation from these flies in different flocks of sheep varies from 2 to 50 and depends upon various external conditions as well as upon the cleanliness of the wool. Notes are given on the effect of infestation by these maggots and on the conditions which determine their relative abundance as suggested by various sheep raisers.

Circular letters of inquiry sent to sheep men elicited replies which indicate that sheep are quite regularly dipped for destroying these pests, but not always at the proper season of the year. A complaint has been made that the numbers of sheep maggot-flies are somewhat increased as a result of the practice of hanging decaying meat in forest areas as a breeding place for the maggots which are eaten by grouse. In controlling this pest the author recommends cleanliness, dipping, and hand treatment with kerosene or substances with offensive odor.

Prophylaxis of foot-and-mouth disease, P. LABULLY (*Ann. Soc. Agr., Loire, 2. ser., 23 (1903), No. 2, pp. 125, 126*).—Brief notes are given on the production of immunity toward foot-and-mouth disease by means of serum inoculations. Such immunity, however, has been found to be merely temporary.

Acute ulcerative inflammation of the cornea or eye-ball, in cattle, sheep, and goats, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 24 (1904), No. 5, pp. 621–624*).—The symptoms and pathological anatomy of this disease are briefly described. In controlling the disease it is recommended that affected animals be isolated and that the eyes be treated with a weak antiseptic solution, such as corrosive sublimate.

Joint ill (*Jour. Bd. Agr. [London], 11 (1904), No. 2, pp. 110–114*).—This disease affects lambs, calves, and colts. The source of infection is through the umbilical cord at the time of birth. Detailed directions are given regarding the control of the disease in lambs by means of proper disinfectant measures.

Loco, N. S. MAYO (*Industrialist, 30 (1904), No. 30, pp. 473–475*).—The symptoms of loco disease attributed to eating *Astragalus mollissimus* are described. As a result of observations and experiments on this disease the author believes that the disease is a result of malnutrition or starvation, exaggerated perhaps by some injurious substance in the loco weed.

The composition of Zygadenus venenosus and the pharmacological action of its active principle, N. VEJUX-TYRODE (*Jour. Med. Research, 11 (1904), No. 2, pp. 399–402*).—In a study of the bulbs of this plant obtained from Montana the author found a wax-like body, a crystalline neutral substance, an oil, a gum, and two resins. All of these substances are inactive except the resins. From one of the resins a basic body and an acid called zygadinic acid were isolated. The basic body is denominated zygadinein and was found in animal experiments to be the active principle. In minute doses in experimental animals, including guinea pigs, rabbits, and dogs, it produced marked salivation, staggering, and respiratory paralysis followed by death, in some cases within a few minutes, but usually within a few hours.

Osteomalacia and paralysis, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 24 (1904), No. 4, pp. 479–487*).—This disease is believed to be of dietetic origin. It occurs over a large area of Cape Colony, but is most prevalent on the eastern coast. It affects cattle, sheep, goats, and horses, but rarely assumes the paralytic form in horses. Animals affected with the disease manifest intense desire for bones and all kinds of animal-food materials. Notes are given on the pathological anatomy of the disease. In controlling this disease the obvious suggestion is made of adding a daily allowance of bone meal, bone ash, or similar material to the ration.

Observations on epizootic outbreaks of tapeworms in sheep in the Government of Moscow, M. L. BLUMENFELD (*Arch. Vet. Nauk, St. Petersburg, 34 (1904), No. 1, pp. 29–38*).—An account is presented of the extent of infestation of sheep in the Government of Moscow by *Tænia expansa*. The percentage of infestation in different parts of the government is shown in a tabular form. The author concludes that considerable pathogenic action is exercised by the presence of tapeworms in sheep and that these pests cause a great loss to the sheep industry.

The development of Herpetomonas, S. PROWAZEK (*Arb. K. Gesundheitsamte, 20 (1904), No. 3, pp. 440–452, figs. 7*).—The literature of this subject is critically discussed in connection with bibliographical references. Particular attention is given to details in the life history and development of *Herpetomonas muscæ-domesticæ*. The different

forms under which this blood parasite occurs are described, and notes are given on the interrelationships of the different stages of development. Experiments were made in infecting flies with *H. sarcophagæ* which is described as a new species. In one series of experiments 8 out of 100 flies became infected when fed on blood containing this parasite.

The polycephalic bladder worms, especially Cœnurus cerebralis and C. serialis, F. KUNSEMÜLLER (*Zool. Jahrb., Abt. Anat. u. Ontog. Thiere, 18 (1904), No. 4, pp. 507–538, pls. 4, figs. 3*).—Detailed notes are given on the anatomy and developmental stages of these parasites, and the literature of the subject is critically discussed in connection with a bibliography.

Intestinal parasites in hogs, K. W. STOUDER (*Iowa Agr., 4 (1904), No. 4, pp. 167–169*).—Brief notes are given on *Balantidium coli, Echinorhynchus gigas, Ascaris suilla, Trichocephalus crenatus,* and trichina.

Sarcosporidia and their enzyms, H. RIEVEL and M. BEHRENS (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1903), No. 3, pp. 341–352, figs. 4*).—Large numbers of Sarcosporidia were found by the authors in the musculature of a llama. The morphology of these organisms is discussed in detail. A number of inoculation experiments were made with rabbits. It is believed that the organism is different from any species of Sarcosporidia hitherto described. It develops a very virulent poisonous principle which paralyzes the central nervous system, and which appears to resemble an enzym rather than a toxin. It was found possible to immunize rabbits against this organism.

Swine fever, J. D. STEWART (*Jour. Dept. Agr. West Australia, 8 (1903), No. 5, pp. 418–433, figs. 8*).—Notes on the nature, cause, symptoms, and treatment of hog cholera. The author outlines briefly the pathological lesions found in cases of this disease and makes general recommendations regarding the disinfection of premises after outbreaks of the disease and sanitary measures to be adopted in preventing further spread of hog cholera.

The production of a serum for use in the prevention of swine plague and hog cholera, M. PRETTNER (*Centbl. Bakt. u. Par., 1. Abt., Orig., 36 (1904), No. 1, pp. 94–103*).—In these experiments dogs were used as the source of serum and this serum was tested on white mice. The results of the experiments are set forth in a tabular form. It was found during the author's study of this problem that the serum of dogs immunized toward swine plague possessed protective properties against the bacilli of swine plague and hog cholera. The serum of dogs immunized against hog cholera was likewise active against both diseases. The highest protective property, however, was obtained when the dogs were treated with both species of bacilli.

Diseases which resemble hog cholera, O. MALM (*Norsk Vet. Tidsskr., 16 (1904), No. 2, pp. 25–38*).—The symptoms and pathological lesions of hog cholera, swine plague, and swine erysipelas are described for the purpose of calling attention to the various points of similarity of these diseases and to the means of differentiating them. Notes are also given on the prevalence of these diseases in Norway and on the results obtained by different methods which have been adopted for checking the diseases.

Rachitis in pigs, E. THIERRY (*Jour. Agr. Prat., n. ser., 7 (1904), No. 9, p. 291*).—The cause of this trouble in young pigs is said to be found in an improper dietary containing but little phosphate of lime or other lime salts. In order to prevent the development of a weakness of the bones in young pigs it is recommended that ground bone be added to the usual ration.

The danger of introducing glanders from foreign countries, ARNDT (*Ztschr. Vet. Hyg., 2 (1904), No. 1, pp. 1–5*).—Statistics are presented showing the relative extent of importation of horses from foreign countries into Germany. The bearing of these statistics upon the prevalence of glanders is discussed in a critical manner. In the author's opinion a general scheme for controlling this disease must include supervision of the books of horse dealers, quarantine upon international boundar

lines, and thorough inspection of all imported horses. Special mention is made of the danger of introducing glanders from Russia, and it is suggested that it would be desirable to prohibit the importation of Russian horses if it were not for the fact that so many of these horses are needed.

Horse sickness and its prevention, R. Koch (*Agr. Jour. Cape Good Hope, 24 (1904), No. 4, pp. 505–508*).—This is of the nature of a progress report of the author concerning his investigations of horse sickness in South Africa. Numerous observations have been made on the symptoms and distribution of the disease, together with careful post-mortem examinations. It has been found that animals which recover from the disease are highly immune. Serum obtained from such animals when inoculated into susceptible animals renders the latter immune to natural infection.

Horse sickness, H. Watkins-Pitchford (*Natal Agr. Jour. and Min. Rec., 7 (1904), No. 2, pp. 190–197*).—The author continued his investigations regarding the production of immunity in horses toward this disease. It was found necessary to induce a reactionary fever by means of the virus of the disease. A definite thermal reaction in experimental animals was brought about, whether the virus was introduced hypodermically or into the stomach, and a latent infection or reaction persisted in most cases for many weeks. The degree of immunity brought about by this treatment appears to be rather striking, but has not been tested by exposure of the treated animals to natural infection. During the process of immunization a negative phase is passed through, or a period in which an increased susceptibility to the disease is manifested.

An African trypanosoma pathogenic for horses, A. Laveran and F. Mesnil (*Compt. Rend. Acad. Sci. Paris, 138 (1904), No. 12, pp. 732–735, fig. 1*).—The morphological characteristics of *Trypanosoma dimorphon* are carefully described. The organism is pathogenic for horses, rats, rabbits, guinea pigs, dogs, goats, etc. The species upon which the authors experimented is considered distinct from *T. gambiense*, and notes are given on the characters by which the two species may be differentiated.

Alternation of generation and host in a case of Trypanosoma and Spirochæte, F. Schaudinn (*Arb. K. Gesundheitsamte, 20 (1904), No. 3, pp. 387–439, figs. 20*).—The anatomical and biological characteristics of these two genera are given in detail with especial reference to their easy diagnosis. Particular attention is given to the life history of *Trypanosoma noctuæ*. This organism occurs in the blood of owls and is apparently carried by *Culex pipiens*. The anatomy of these mosquitoes is described with especial reference to their agency in transmitting the blood parasite. Notes are also given on the habits of mosquitoes. The life history of *Spirochæte ziemanni* is described by way of comparison with that of *T. noctuæ*.

Treatment of mal de caderas, M. S. Bertoni (*Rev. Agron., Paraguay, 3 (1903), No. 7–8, pp. 238–240*).—The author discusses briefly the use of arsenate of soda, arsenious acid, potassium permanganate, corrosive sublimate, quinin, and other treatments. The transmission of the disease is believed to be accomplished through the agency of *Stomoxys calcitrans*.

Trypanosoma and trypanosomiasis, with special reference to surra in the Philippine Islands, W. E. Musgrave and M. T. Clegg (*Philippine Dept. Int., Bureau Govt. Lab., 1903, No. 5, pp. 248, figs. 155*).—This report contains a general discussion of animal diseases due to infestation with species of Trypanosoma. The species of this genus which infest oysters, fish, birds, mammals, and man are described and classified in a systematic manner.

The authors discuss also the various modes of transmission and infection by these parasites, the symptoms of different forms of trypanosomiasis in various animals and man, the duration, complications, and diagnosis of these diseases, as well as the pathological anatomy, treatment, and serum therapy. In all cases of trypanosomiasis in which *Trypanosoma evansii* is shown to be the parasite, it is recommended that surra be employed as the proper name of the disease. The life cycle of this parasite

is not completely known at present, but many additional observations upon the subject are made by the authors.

The prevalence of the disease appears to depend largely upon the agency of biting insects, and the authors believe that this is by far the most important mode of transmission, or perhaps the only mode which requires consideration. The question of identity or nonidentity of surra, nagana, dourine, and mal de caderas is considered in detail and the authors incline toward the opinion that these diseases are all one and the same and should be referred to by the term surra.

The micro-organisms of pleuro-pneumonia and influenza in horses and the treatment of these diseases, Z. F. Eleneveski (*Arch. Vet. Nauk, St. Petersburg, 34 (1904), Nos. 2, pp. 93–125; 3, pp. 205–235, pls. 2*).—An elaborate study was made of the symptoms and etiology of these diseases with especial reference to the pathogenic micro-organisms. The latter were cultivated on various nutrient media and notes are given on their biological and morphological characters.

The value of serum therapy was tested by means of numerous experiments. From this study the author concludes that horses may be inoculated with the organisms of contagious pleuro-pneumonia and influenza for the purpose of obtaining a preventive and curative serum. The serum obtained from animals thus treated exercises a preventive action in comparatively small doses and possesses pronounced curative properties. The curative action of this serum is considerably greater than that of the ordinary pharmaceutical preparations which are recommended for treating these diseases in ordinary practice. The application of serum therapy in these diseases brings about great improvement during the early stages.

Bots in horses, S. S. Cameron (*Jour. Agr. and Ind. South Australia, 7 (1904), No. 9, pp. 496–498*).—Brief descriptive, biological, and economic notes on this pest. No satisfactory results are obtained from the administration of ordinary drugs for expelling this parasite. The use of capsules of carbon bisulphid is recommended as somewhat efficacious.

Thymol, H. H. Cousins (*Bul. Dept. Agr. Jamaica, 2 (1904), No. 3, pp. 57, 58*).—Thymol is recommended as the most satisfactory remedy for botflies in horses. It may be dissolved in alcohol containing ten times its quantity of sugar. The mixture is then heated so as to cause the alcohol to evaporate, thus leaving a uniform mixture of thymol and sugar. This remedy may then be administered by mixing it with the grain feed in doses of 15 grains twice per day for 2 days.

Centrifugalization and disintegration in relation to the virus of rabies, J. O. W. Barratt (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1904), Nos. 5, pp. 633–640; 6, pp. 769–775, fig. 1*).—The author made a study of the nature of rabies virus with special reference to the effect of centrifugalization and disintegration upon it. It was found that when the brain of a rabbit was disintegrated by the use of sand and physiological salt solution the disintegrated material retained its virulence, as shown by the inoculation of healthy rabbits.

In another series of experiments a much more complete trituration was brought about at the temperature of liquid air without the use of sand or salt solution. No purely toxic effect was produced by the injection of an emulsion of centrifugalized brain. When the disintegrated brain substance, however, was used for inoculation the toxic effects appeared at first, but were not noticeable during the second week.

Note on the disintegration of rabid brain substance, J. O. W. Barratt (*Proc. Roy. Soc. [London], 72 (1903), No. 483, pp. 353, 354*).—The author undertook experiments for the purpose of determining whether the virus of rabies contains organized bodies. To this end the brain of a rabbit which had died of rabies was disintegrated with sand at the temperature of liquid carbon dioxid and the disintegrated material was tested by the inoculation of healthy rabbits.

As a result of these experiments it was found that the process of disintegration when carried on for from one-half to one hour is usually sufficient to destroy the

virulence of rabies virus. The disintegration for a period of five minutes was not sufficient to destroy the virulence. Further tests were made during which it was shown that this destruction of the virulence of the rabies virus was not due to the formation of any inorganic substance in disintegrated brain material. The experiments therefore seem to confirm the view that the virus of rabies is of an organized nature.

The passage of rabies virus through filters, P. Remlinger (*Ann. Inst. Pasteur, 18 (1904), No. 3, pp. 150–164*).—A detailed account is presented of experiments carried out by the author in passing rabies virus through filters of various types. The virus was then studied for the purpose of determining the influence of filtration upon its virulence. The evidence obtained by the author in these experiments indicates that rabies should be classified in a special group of diseases quite distinct from those grouped under pathogenic protozoa.

The relation between modifications of the virulence of rabies virus and alterations in Negri's corpuscles, E. Bertarelli (*Centbl. Bakt. u. Par., 1. Abt., Orig., 36 (1904), No. 1, pp. 42–51*).—An attempt was made to determine the relation of Negri's corpuscles to changes in virulence in rabies virus, and to alterations in the central nervous system in infected animals. For this purpose dogs and rabbits were used as experimental animals. The results are set down in detail in a tabular form. It was found that Negri's corpuscles were not much affected by extreme changes in virulence. The corpuscles appeared to possess a greater resisting power to various reagents than the surrounding tissues. The author is in doubt, however, whether these corpuscles should be considered as protozoan organisms or as pathological structures containing such organisms.

Two cases of recovery from experimental rabies, P. Remlinger and M. Effendi (*Ann. Inst. Pasteur, 18 (1904), No. 4, pp. 241–244*).—A detailed account is given of the course and symptoms of two cases of rabies produced by inoculation of dogs. The symptoms in both cases were of a serious nature, and inoculation experiments made subsequently showed that both of the dogs were affected with a virulent form of rabies. The complete recovery which took place in both cases is considered of sufficient rarity to warrant a detailed account.

Experimental rabies in birds, J. von Löte (*Centbl. Bakt. u. Par., 1. Abt., Orig., 35 (1904), No. 6, pp. 741–744*).—Experiments were carried out for the purpose of determining the possibilities of infecting birds with rabies. During these experiments it was found that various birds, including owls and eagles, were susceptible to rabies. Chickens and pigeons are less susceptible to the disease. Only a small percentage of inoculated birds developed the disease, and many of these cases showed a spontaneous recovery.

Fowl cholera and fowl plague, M. Hertel (*Arb. K. Gesundheitsamte, 20 (1904), No. 3, pp. 453–511, pl. 1*).—The results obtained by other investigators in the study of these diseases are briefly pointed out. In the author's experiments the cultures used in the study of fowl cholera were largely obtained from infected geese. Pigeons were found to be the most susceptible of all domestic fowls.

In a series of more than 25 experiments, the organism of fowl cholera was obtained in pure culture from the blood of inoculated pigeons. Since sparrows are almost constantly present in poultry yards and susceptible to fowl cholera, it is suggested that these birds may have some influence in spreading the disease. Rats are comparatively refractory to the disease, while rabbits are very susceptible. The author made a careful study to determine the natural method of infection in fowls. It was found possible to infect fowls readily by feeding the virus along with their food or by bringing the virus in contact with the mucous membranes or feather follicles. The possibility of transmission of the disease through the agency of mites and lice must also be admitted.

Experiments were carried on during which it was found that the fowl cholera bacilli would multiply vigorously when inoculated into fresh eggs. Inoculation experiments showed that the fowl cholera bacilli were capable of retaining their virulence for 48 hours in muck, for 6 days in sand, and for 7 days in sawdust. The donkey was found to produce a very effective serum for fowl cholera. The fowl cholera bacilli were agglutinated by this serum when used in a dilution of 1:1600. Pigeons inoculated with 0.5 cc. of the serum resisted inoculation with virulent cultures of the fowl cholera bacilli. The symptoms, etiology, and distribution of fowl plague are carefully described by way of comparison with fowl cholera. It was found that the virus of fowl plague readily passed through the Berkefeld and Chamberland filters. It is believed to be impossible to differentiate with certainty between fowl cholera and fowl plague by means of any one test.

Spirillosis of fowls, C. LEVADITI (*Ann. Inst. Pasteur, 18 (1904), No. 3, pp. 129–149, pl. 1*).—The literature relating to this subject is briefly reviewed by the author. It was found that when a small quantity of blood containing the virus of the disease was introduced subcutaneously into a fowl, the spirilla could not be found in the general circulation until after a period of 2 days. At the point of inoculation the spirilla were observed in large numbers for about 35 minutes, after which they gradually disappeared.

There seems to be no multiplication of the spirilla at the point of inoculation. The process of multiplication in the general circulation, however, increases until the greatest quantity of spirilla are found at the end of the fifth or sixth day. The serum of fowls which recover possesses quite pronounced agglutinating power. It also brings about at the same time an agglomeration of the white blood corpuscles. The sudden death of a number of fowls which were treated with the serum of recovered birds was attributed to the agglutinating action of this serum. The author suggests that their death was thus caused by embolism as the result of the existence of the agglutinated masses of spirilla and white blood corpuscles.

Minor ailments of poultry, C. E. J. WALKEY (*Jour. Bd. Agr. [London], 10 (1904), No. 4, pp. 476–487*).—Among the more important predisposing causes of diseases in poultry the author mentions damp houses, excessive drafts, filth, and careless breeding. Practical recommendations were made concerning the treatment of apoplexy, bronchitis, bumble-foot, colds, leg weakness, pneumonia, scaly leg, etc. Formulas are given for preparing suitable remedies in treating these various troubles.

Poultry diseases common in Montana, H. C. GARDINER (*Montana Sta. Bul. 50, pp. 191–196*).—Brief notes on the symptoms, etiology, and means of combating roup, catarrh, and gapes, together with a brief account of chicken lice.

AGRICULTURAL ENGINEERING.

Agricultural engineering, S. FRASER (*Cornell Countryman, 1 (1904), No. 6, pp. 170–172, figs. 2*).—A note on the development of instruction and investigation in this line in the United States.

The field for study and development of rural engineering in Nebraska (*Agriculture [Nebraska], 3 (1904), No. 2, pp. 8–13*).—A brief general discussion.

The natural features and economic development of the Sandusky, Maumee, Muskingum, and Miami drainage areas in Ohio, B. H. FLYNN and MARGARET S. FLYNN (*U. S. Geol. Survey, Water Supply and Irrig. Paper No. 91, pp. 130, figs. 11*).—This paper, which treats of the natural features and development of the four principal drainage areas of Ohio, contains valuable data with reference to the flow of the Maumee, Sandusky, Miami, and Muskingum rivers, and the natural advantages they offer with reference to water power and domestic water supply. "Of particular interest is that part of the paper which deals with the early history of the water powers, their general relation to the canal systems of Ohio, and the

decline in value that has taken place since the establishment of modern methods of manufacturing, trade, and transportation.

"The chapter dealing with public water supplies comprises unusually complete information with reference to the sources, equipment, and value of the systems that were installed during the latter part of the last century."

Irrigation in India, H. M. WILSON (*U. S. Geol. Survey, Water Supply and Irrig. Paper No. 87, pp. 238, pls. 27, figs. 66*).—A second edition of this report revised and brought up to date. "The most important feature of the revision is the bringing of all the financial and statistical data concerning the more important works in each province up to 1901, the date of the last official Indian reports.

"At the close of 1901 the area of India, including native States, was 1,559,603 square miles, the total population was 294,266,701, and the total expenditure upon all classes of irrigation works by the government of India had been $337,850,000. In the year 1900–1901 the expenditures on account of irrigation amounted to $11,500,000 and the revenues to $12,075,000, showing a profit of 7.5 per cent on the capital outlay for construction. The total area cultivated in India the same year was 180,151,093 acres, and the total area irrigated was 18,611,106 acres, or, counting areas double cropped or those irrigated more than once in a season, the area irrigated was 33,096,031 acres.

"The estimated value of the irrigated crops in 1900–1901 was $150,000,000, and of these it is interesting to note that the area under cultivation in wheat amounted to over 16 million acres, and in cotton to over 8⅓ million acres, and that the total value of the latter crop alone was $52,773,000."

Notes on irrigation in the valley of the Tumbez (*Données sur les irrigations de la vallée de Tumbes. Lima, Peru: Min. Agr. et des Travaux Publics, 1902, pp. 28, pls. 3, maps 2*).

Address of Hon. Joseph W. Hunter, State Highway Commissioner, delivered at annual meeting of State Board of Agriculture, January 28, 1904 (*Pennsylvania State Dept. Agr. Bul. 121, pp. 15*).—This address discusses the act of the State legislature of April 15, 1903, creating a department of public highways and explains what has already been done under its provisions.

Historic highways of America, A. B. HULBERT (*Cleveland, Ohio: Arthur H. Clark Co., 1904, vol. 8, pp. 237, pls. 2, maps 4; 1903, vol. 9, pp. 220, maps 3; 1904, vol. 10, pp. 207, pls. 3, maps 2; 1904, vol. 11, pp. 201, pls. 7*).—These volumes deal with the military roads of the Mississippi Basin (the conquest of the old Northwest), the waterways of westward expansion (the Ohio River and its tributaries), the Cumberland road, and pioneer roads and experiences of travelers. For a notice of previous volumes of this series see E. S. R., 15, p. 415.

Tenth annual report of the commissioner of public roads for the year ending October 31, 1903, H. I. BUDD (*Somerville, N. J.: The Unionist Gazette Assoc., 1904, pp. 262, pls. 40, map 1*).—The report includes descriptions of the roads built in 1903, with statements of their cost, the text of the public roads act of April 1, 1903, and the standard specifications for different kinds of roads.

The international good roads convention (*Engineer. News, 51 (1904), No. 21, pp. 494–496*).—An account of the convention held at St. Louis May 16–21 under the auspices of the National Good Roads Association.

Oil engines for agricultural purposes, W. W. BEAUMONT (*Jour. Bd. Agr. [London], 10 (1904), No. 4, pp. 435–460, figs. 18*).

Systems and methods of mechanical refrigeration, S. H. BUNNELL (*Engineer. Mag. and Ind. Rev., 27 (1904), No. 3, pp. 397–408*).—A general discussion of the history, advantages, and disadvantages of different methods.

The cold-storage building and experiments, J. B. REYNOLDS (*Ontario Agr. Col. and Expt. Farm Rpt. 1903, pp. 14, 15*).—Brief notes are given on the success in

maintaining uniform temperatures under a variety of conditions in the cold-storage building described in an earlier report (E. S. R., 15, p. 95).

The modern silo, T. CHERRY (*Jour. Dept. Agr. Victoria, 2 (1903), No. 4, pp. 320–331, pls. 3, figs. 4; Dept. Agr., Victoria, Bul. 8, pp. 14, pls. 3, figs. 4*).—A popular discussion of the construction of silos and the preparation and use of silage, with special reference to Australian conditions.

Windmills, R. GAGEY (*Bul. Agr. Algérie et Tunisie, 10 (1904), Nos. 5, pp. 91–104, figs. 34; 6, pp. 111–130, figs. 31*).—This article discusses the construction, operation, and efficiency of a large number of different forms as well as the uses to which they may be put in Tunis, including pumping, grinding, etc.

MISCELLANEOUS.

Sixteenth Annual Report of Alabama College Station, 1903 (*Alabama College Sta. Rpt. 1903, pp. 24*).—This includes the organization list of the station; a financial statement for the fiscal year ended June 30, 1903; and reports of the director and agriculturist, chemists, plant physiologist, veterinarian, and horticulturist on the work of the station during the year.

Thirteenth Annual Report of Kentucky Station, 1900 (*Kentucky Sta. Rpt. 1900, pp. XLII+244*).—The report proper contains the organization list; a financial statement for the fiscal year ended June 30, 1900; and reports of the director and heads of departments, parts of which are noted elsewhere. Reprints of Bulletins 86–90 of the station on the following subjects are appended: Inspection and analyses of foods (E. S. R., 12, p. 586); Kentucky forage plants—the grasses, analyses of some Kentucky grasses (E. S. R., 12, p. 547); analyses of commercial fertilizers (E. S. R., 12, p. 1026); wheat (E. S. R., 12, p. 1035); and commercial fertilizers (E. S. R., 13, p. 124).

Sixteenth Annual Report of Vermont Station, 1903 (*Vermont Sta. Rpt. 1903, pp. 292+XXXIV*).—This contains the organization list of the station; a financial statement for the fiscal year ended June 30, 1903; a report of the director reviewing the work of the station during the year and giving abstracts of Bulletins 96–99 of the station; and reports of the heads of departments, containing a number of articles abstracted elsewhere in this issue.

Abstract of Sixteenth Annual Report, 1903 (*Vermont Sta. Bul. 106, pp. 225–272*).—This is a popular résumé of the annual report of the station noted above, and is intended for general distribution in place of the report, which is printed in only a limited edition.

Experiment Station Work, XXV (*U. S. Dept. Agr., Farmers' Bul. 193, pp. 32, figs. 9*).—This number contains articles on the following subjects: Watermelons in the North, watermelon culture in Georgia, muskmelon culture in the North, Rockyford muskmelons, cold storage of fruits, selection of seed corn, bread and toast, cooking meat, and bitter milk.

Crop Reporter (*U. S. Dept. Agr., Bureau of Statistics Crop Reporter, vol. 5, Nos. 10, pp. 77–84; 11, pp. 85–92; 12, pp. 93–100*).—These numbers for February, March, and April, 1904, contain the usual statistical reports on the crops in the United States and foreign countries.

An outline of cooperative demonstrations and tests for 1904 (*New York Cornell Sta. Bul. 216, pp. 118–122*).—This is a list of the demonstrations or experiments in agronomy, plant selection and breeding, horticulture, entomology, animal husbandry, poultry husbandry, and dairy industry which it is proposed to conduct during the season of 1904, in cooperation with farmers throughout the State.

NOTES.

Colorado Station.—J. E. Payne, field agent, has resigned.

Hawaiian Sugar Planters' Station.—E. G. Clarke has been appointed agriculturist.

Purdue University and Station.—At a meeting of the board of trustees of the university, held June 7, 1904, resolutions involving a change in the organization of the experiment station were adopted. The work, equipment, staff, income, and expenses of the State chemist were placed under the control of the experiment station and become a part of its organization. The farm, except such areas as are now or may hereafter be set aside for permanent experimental purposes, is to be under the care of the university to maintain and administer. The permanent experimental fields and buildings are to be occupied and used by the station without rent, and the proceeds of the same will be appropriated to the use of the station. The station is to bear all costs of labor and materials used in experimental work, and it is understood that in its work the station is to receive the aid and cooperation of the university in every possible way.

Maine University.—J. E. Burbank, instructor in physics, has resigned to accept a position in the Magnetic Survey, at Washington. L. E. Woodman, formerly assistant in physics at Dartmouth, has been elected to fill the vacancy.

Maryland College and Station.—C. F. Austin, associate horticulturist in the college and station for the past two years, resigned to accept the position of horticulturist at the Central Cuba Station.

Massachusetts College.—The recent legislature increased the permanent appropriation of the college by $10,000 annually. The provision for a horticultural building was withdrawn.

Minnesota Station.—L. B. Bassett has been appointed farm foreman.

Montana College and Station.—John Maxey, of Bozeman, has been appointed a member of the governing board, vice John M. Robinson, whose term expired. The latter succeeds Joseph Kountz, whose term expired. S. Fortier, professor of civil engineering in the college, and director and irrigation engineer of the station, who for the past year has been absent on leave and in charge of work under the irrigation division of the Office of Experiment Stations in California, has resigned to continue work with the Department and the University of California. F. B. Linfield, agriculturist and for the past year acting director, has been made director of the station. J. S. Baker, a graduate of the Utah Agricultural College, for the past year professor of civil engineering in the Montana College, has been elected to the position of irrigation engineer of the station, vice S. Fortier. Alfred Atkinson, a graduate of the Iowa Agricultural College, has been elected to the position of assistant in agronomy. Herbert Reese, a graduate of the Montana Agricultural College, has been made assistant chemist.

Oklahoma College and Station.—F. O. Foster, assistant in dairying at the college and in agriculture at the station, has resigned to engage in commercial dairying in Baltimore. A dairy building to cost $4,000 and a greenhouse to cost $3,000 are now under construction.

Rhode Island College and Station.—A. E. Stene, assistant horticulturist at the college and station, has been transferred to the demonstration and extension department of the college. He will be succeeded in the regular college and station work by Maurice Blake, a graduate of the Massachusetts Agricultural College.

Utah College.—J. A. Bexell, head of the commerce department, has been made secretary of the governing board, vice P. W. Maughan, resigned.

Virginia College and Station.—A. M. Soule, formerly director of the Tennessee Station, has been elected dean of the department of agriculture of the college and director of the station, to take effect September 1.

Wisconsin Station.—W. B. Richards, assistant in animal husbandry at the station, has been elected to a similar position in North Dakota. He will be succeeded at Wisconsin by J. G. Fuller, a graduate of the Wisconsin Agricultural College.

Wyoming University.—President Lewis of the university died, after a brief illness, June 19.

First Convention of the American Civic Association.—The American Civic Association is the name of a new organization formed by the consolidation of the American Park and Outdoor Art Association and the American League of Civic Improvement. These are strong national organizations, which for a number of years have been working along the same lines, each duplicating to a certain extent the work of the other. Committees have been working on the plan for two years, and the union of the two organizations was finally brought about at their recent joint convention at St. Louis, June 9 to 11. The active propaganda of the association will be conducted largely through departments under the leadership of departmental vice-presidents and secretaries.

The officers elected were as follows: President, J. Horace McFarland, Harrisburg; first vice-president, Clinton Rogers Woodruff, Philadelphia; general vice-presidents, George Foster Peabody, New York, Franklin MacVeagh, Chicago; secretary, Charles Mulford Robinson, Rochester; treasurer, William B. Howland, New York. Woman's Outdoor Art League: President, Mrs. Charles F. Millspaugh, Chicago; first vice-president, Mrs. Sylvester Baxter, Boston; second vice-president, Mrs. Basil Duke, Louisville, Ky.; recording secretary, Mrs. George T. Banzet, Chicago; corresponding secretary, Mrs. Francis Copley Seavey, Chicago; treasurer, Mrs. William H. Crosby, Racine, Wis.; directors, Mrs. W. J. Washburn, Los Angeles, Cal.; Mrs. H. B. Stearns, New Orleans; Mrs. A. W. Sanborn, Ashland, Wis.; Miss Elizabeth Bullard, Bridgeport, Conn.

The departments of work of the American Civic Association and their respective vice-presidents are as follows: Public recreation, Joseph Lee, Boston; arts and crafts, Mrs. M. F. Johnston, Richmond, Ind.; city making, F. S. Lamb, New York; outdoor art, Warren H. Manning, Boston; factory betterment, Edwin L. Shuey, Dayton, Ohio; children's gardens, Dick J. Crosby, Washington, D. C.; libraries, H. Putnam, Library of Congress, Washington, D. C.; parks and public reservations, G. A. Parker, Hartford, Conn.; rural improvements, O. C. Simonds, Chicago; school extension, Charles Zueblin, Chicago; social settlements, Frank Chapin Bray, Chicago; press, Mrs. Condé Hamlin, St. Paul.

Agricultural Education.—The Travelers' Protective Association at its annual convention in Springfield, Ill., June 8, adopted resolutions favoring radical changes in our educational system. The resolutions demand among other things that "our entire educational system should be so remodeled as to teach every child to be a lover of nature and the country, and to train them toward the land as a source of livelihood rather than away from it, and thus counteract the drift of population to the cities and turn it back to the land;" that farm training schools should be established by county, municipal, State, and the National governments; that what remains of our public domain "should be sacredly reserved for actual home builders," and "that a permanent committee on education, irrigation, forestry, and lands should be appointed by this association," and that this committee should formulate without delay a plan for actively enlisting the personal cooperation of all members of this association in the movement for thus modifying our educational system.

Agricultural Education in England.—At the conclusion of an address upon this subject by J. C. Medd, the following suggestions were made for placing the rural and agricultural education upon a more satisfactory basis: "1. Close small village schools and convey their children daily to some central school. This would insure better buildings and equipment, more regular attendance, and a more efficient staff. This has been already done in parts of the United States and Canada. 2. Develop a few favorably situated schools upon the model of the Écoles primaires supérieures. The full course at these schools extends over three years, and for the first year the instruction is general. Afterwards the pupils enter one or other of the following sections: (a) Commercial, (b) industrial, (c) agricultural. The schools founded by Lady Warwick at Bigods, and by the Duchess of Sutherland at Goldspie, are somewhat analogous to these. 3. Organize a continuation school in every village with such a curriculum as that previously described. 4. Establish winter schools of agriculture and horticulture in selected districts according to the particular requirements and characteristics of each county, and make the services of their directors available for all farmers and gardeners during the summer. 5. Put demonstration plats in the charge of men who combine scientific accuracy with some actual knowledge of practical farming, and are in touch with the farmers of the district. 6. Provide liberal scholarships to pass capable children by successive stages from the elementary school to the collegiate center, to which each county should be affiliated."

As evidence of the increasing appreciation of the facilities offered by institutions of varying grades, the following statistics were appended: "Fifty-four pupils passed through the Basing School Farm (which can only accommodate 16 pupils at a time) last year, of whom 90 per cent were the sons and daughters of farmers. The number of boarders at the Dauntsey Agricultural School, which is too isolated for many day pupils, has risen from 11 in 1900 to 38 in 1904; of these, almost all follow the agricultural course. At the Harper Adams Agricultural College the number of students is 45, about 70 per cent of whom are the sons of landowners, land agents, or farmers. Within the past two years the number at Wye Agricultural College has increased from 49 to 72, about half of whom are by birth associated with the land."

Victoria School of Horticulture.—In a recent report of the principal of this school, the following summary is given regarding the value of horticultural instruction for women as observed at the school: "Of about 140 women students attending, about 10 per cent may be said to have thoroughly mastered some branch of profitable horticulture. Another 20 per cent gained as much experience and habit of work as to make them capable helpers or directors of their own properties. The remainder of the students gave no definite proof of what they may be able to do in the future. A few students are earning a livelihood wholly, or in part, through their experience gained here. Two are engaged in designing and maintaining gardens. One is managing a small mixed estate. One is a writer on horticulture, one or two take pruning contracts, and one has laid out and managed a young orchard of considerable extent in such a business-like manner as to warrant the assertion that of its age and character there is no property to equal it for general excellence in the State of Victoria."

The New Building of the Seed Control Station of Vienna.—A recent number of *Zeitschrift für das Landwirtschaftliche Versuchswesen in Oesterreich* gives an illustrated account of the new building and grounds of this station and briefly reviews the history of the institution since its establishment in 1881. The plat on which the building stands has a total area of a little less than an acre, of which the building covers 552 square meters (5,941.67 square feet), and test plats occupy 400 square meters (4,305.55 square feet). The building is of artificial stone, with tile roof, and was constructed at a cost of $36,236.73, exclusive of internal equipment. It contains 35 rooms, of which 5 are used for offices and library, 18 for laboratories, 5 for mailing

and storage purposes, and 8 are available for miscellaneous purposes. The building is provided with the best modern arrangements for heating, lighting, ventilation, and sanitation. Laboratories fully equipped with the most approved appliances and machines, many of which are of special design, are provided for botanical, microscopic-physiological and plant-breeding investigations, analytical work, germination tests, baking experiments, and studies of Alpine plants. The test plats furnish a means for studies in breeding of cereals and for growth of typical varieties of cereals, leguminous plants, grasses, and other useful plants, as well as weeds, etc. The station is especially well equipped for studies in breeding of cereals (including baking tests), and this is to be a prominent feature of its work.

Miscellaneous.—There has been recently established by the National Society of Agriculture of France, a committee for the purpose of securing and erecting a monument to the memory of the late Louis de Vilmorin. The personnel of this committee is given in *Journal d'Agriculture Pratique*, n. ser., 7 (1904), No. 18, pp. 374, 375. The list embraces the names of many individuals who are prominent in agriculture and allied subjects in France and elsewhere. The American membership consists of Prof. C. S. Sargent, director of the Arnold Arboretum, Boston, Mass.; Dr. William MacMurtrie, president of the Chemical Society of New York; and D. M. Ferry, seed dealer, Detroit, Mich. Subscriptions to the fund for the erection of this monument may be addressed to the treasurer of the committee, Léon Bourguignon, 26 Rue Jacob, Paris.

Jean Dufour, professor of plant pathology and director of the viticultural station connected with the agricultural experiment station of the Agricultural Institute, Lausanne, Switzerland, died late in 1903, in his forty-fourth year. An account of his life and work is given by two of his colleagues in *Chronique agricole du Canton de Vaud*, 17 (1904), Nos. 5, pp. 165–171; 7, pp. 235–242, of which journal Dufour was one of the founders and editors.

Dr. H. C. Müller, vice-director of the experiment station and farm at Halle, has been appointed director of the chemical control station at the same place, to succeed Dr. L. Bühring, deceased. Dr. W. Krüger, at the head of the bacteriological division of the Halle Station, has succeeded Dr. Müller as vice-director.
